Definition 9.63 (Physical cohomological EOM and retarded kernels)**.** On the BRST–physical Hilbert space $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10), the cohomology–restricted equations of motion (EOM) are

$$\mathcal{E}^{\mathrm{coh}}_{\mathbf{\Phi}}(\bar{\Sigma}) = 0, \qquad \mathcal{E}^{\mathrm{coh}}_{\mathbf{\Theta}}(\bar{\Sigma}) = 0, \tag{9.28}$$

defined modulo ζ–exact terms and evaluated with $\bar{\Sigma}$ from Definition 9.60 (cf. the cohomological EOM framework and Ward/Slavnov identities in Section 7.5). The corresponding *physical* retarded kernels,

$$G^{\mathrm{R}}_{\Phi\Phi;\mathrm{phys}}(x, x'), \qquad G^{\mathrm{R}}_{\Theta\Theta;\mathrm{phys}}(x, x'), \tag{9.29}$$

are the Σ–causal Green functions associated to the quadratic operators obtained by linearizing (9.28) about the realized background, as specified in Definition 9.62. They inherit gauge–parameter independence on certified plateaus from Proposition 9.61 and are compatible with graded transport/Hermiticity (cf. Definition 9.7 and Proposition 9.6).

Definition 9.64 (Nielsen insertion functional)**.** Let $\theta \in \{\xi, \alpha_{\mathrm{gf}}, \dots\}$ be a gauge–fixing parameter and ζ the gauge–fixing fermion (cf. Section 7.5). Define the band–local, graded–linear map of ghost number -1,

$$\mathcal{W}_\theta : \ \mathfrak{O} \ \longmapsto \ \mathcal{W}_\theta(\mathfrak{O}), \qquad \mathcal{W}_\theta(\mathfrak{O}) \ \simeq \ \int_{\mathcal{X}_q} (\partial_\theta \zeta) \triangleright \mathfrak{O} \, \mathrm{d}\mu,$$

such that for any gauge–covariant, ghost–number–0 observable $\mathfrak{O}$,

$$\partial_\theta \mathfrak{O} \ = \ [\, \hat{Q}_{\mathrm{BRST}}, \, \mathcal{W}_\theta(\mathfrak{O}) \,]_\pm. \tag{9.30}$$

Band–locality and covariance follow from Definitions 6.280, 9.7 and 9.10; BRST hygiene of the tag gives $\mathfrak{B}_{\lambda,\ell}\big([\, \hat{Q}_{\mathrm{BRST}}, \mathcal{W}_\theta(\mathfrak{O}) \,]_\pm\big) = [\, \hat{Q}_{\mathrm{BRST}}, \, \mathfrak{B}_{\lambda,\ell}[\mathcal{W}_\theta(\mathfrak{O})] \,]_\pm$ (cf. Lemma 9.59).

Lemma 9.65 (Ward/Slavnov identities in Σ–form)**.** *The BRST current improved by* $\bar{\Sigma}$ *satisfies* $\nabla^{(\mathrm{rel})}_\mu J^\mu_{\mathrm{BRST}} = 0$ *in* H^0*. Any residual breaking is ζ–exact and cannot move physical poles/residues of* (9.29)*.*

Proof. (1) Setup: realized background and cohomological EOM. Work on a certified plateau $\mathfrak{P}$ and let $\bar{\Sigma}_{\mu\nu}$ be the realized chronogeometry from the Σ–realization map (cf. Definitions 9.58 and 9.60 and eq. (9.27)). The physical (cohomology–restricted) equations of motion are imposed modulo ζ–exact terms on $\mathcal{H}_{\rm phys} := H^0(\hat{Q}_{\rm BRST})$ (cf. Definition 9.63 and Section 6.10). Denote by $\nabla^{(\rm rel)}$ the torsion–free, $\bar{\Sigma}$–compatible connection (Relational Levi–Civita; cf. Definition 9.62).

(2) BRST current and $\bar{\Sigma}$–improvement. Let $J^{\mu}_{\rm BRST}$ be the Noether current associated with BRST symmetry in the gauge–fixed (but BRST–invariant) formulation (cf. Section 7.5). To maintain covariance on the realized background, add the standard improvement term fixed by $\nabla^{(\rm rel)}$ (Belinfante–type completion in the $\bar{\Sigma}$ geometry), yielding the $\bar{\Sigma}$–improved current—denoted again $J^{\mu}_{\rm BRST}$—which transforms covariantly under graded transport (cf. Definition 9.7 and Proposition 9.6).

(3) Slavnov–Taylor identity and ζ–exact divergence. BRST invariance of the gauge–fixed generator implies the Ward/Slavnov identity: the divergence of the BRST current equals a BRST–exact insertion controlled by the gauge–fixing fermion ζ (cf. Section 7.5). Equivalently, using the Nielsen insertion functional $\mathcal{W}_\theta(\cdot)$ of Definition 9.64 and writing it schematically as $\mathcal{W}(\zeta;\bar{\Sigma})$ on the realized background, one has

$$\nabla^{(\rm rel)}_{\mu} J^{\mu}_{\rm BRST} = [\,\hat{Q}_{\rm BRST},\, \mathcal{W}(\zeta;\bar{\Sigma})\,]_{\pm},$$

where the use of $\nabla^{(\rm rel)}$ ensures background–covariance (cf. Definition 9.62).

(4) Projection to H^0 and conservation. Since $\mathsf{P}_{\rm phys}$ projects onto $H^0(\hat{Q}_{\rm BRST})$ and annihilates BRST–exact operators, $\mathsf{P}_{\rm phys}\,[\hat{Q}_{\rm BRST},\cdot]_{\pm}\,\mathsf{P}_{\rm phys} = 0$ (cf. Section 6.10 and Lemma 9.59). Therefore, in H^0,

$$\nabla^{(\rm rel)}_{\mu} J^{\mu}_{\rm BRST} = 0,$$

which is the desired Ward/Slavnov identity in Σ–form.

(5) Consequence for poles/residues of the physical retarded kernels. Residual breakings are ζ–exact by Step (3). Insertions of BRST–exact operators cannot alter physical matrix elements on H^0 and, in particular, cannot shift the locations or residues of poles of the Σ–causal retarded kernels $G^{\rm R}_{\Phi\Phi;\rm phys}$, $G^{\rm R}_{\Theta\Theta;\rm phys}$ (cf. eq. (9.29) and Definition 9.62). Moreover, on a certified plateau the Σ–Nielsen identity guarantees gauge–parameter independence of $\bar{\Sigma}$ (and hence of any $\bar{\Sigma}$–dependent kernel) (cf. Proposition 9.61), so neither gauge scans nor ζ–exact redefinitions can move physical poles/residues. This establishes both claims. □

Definition 9.66 (Σ–projected two–point functions of band modes)**.** Let $\hat{A}^{\dagger}_a, \hat{K}^{\dagger}_b$ denote the pre–physical Apeiron/Kymon creation operators obtained from the Σ–weighted principal modes and block factorizations (cf. Proposition 9.36 and eqs. (9.15) to (9.17); see also Remark 9.41 and Corollary 9.40). Define their Σ–projected *physical* two–point functions by

$$\Pi^{(\Phi)}_{ab}(p) \;:=\; \Big\langle \mathcal{U}_\Sigma[\hat{A}_a]\,\mathcal{U}_\Sigma[\hat{A}^{\dagger}_b] \Big\rangle(p), \qquad \Pi^{(\Theta)}_{cd}(p) \;:=\; \Big\langle \mathcal{U}_\Sigma[\hat{K}_c]\,\mathcal{U}_\Sigma[\hat{K}^{\dagger}_d] \Big\rangle(p), \tag{9.31}$$

where $\mathcal{U}_\Sigma[\cdot]$ is the Σ–realization map (cf. Definition 9.60) evaluated on a certified plateau $\mathfrak{P}$ (cf. Definition 9.58), and the expectation $\langle\cdot\rangle$ is the physical Born/GNS pairing on $\mathcal{H}_{\rm phys} := H^0(\hat{Q}_{\rm BRST})$ (cf. Section 6.10 and Definitions 1.18 and 1.34). The momentum

argument p is defined via the $\bar{\Sigma}$–compatible (Relational Levi–Civita) structure used for Fourier/Green analysis (cf. Definition 9.62). Well–posedness and gauge–parameter independence on $\mathfrak{P}$ follow from BRST hygiene of the band map and the Σ–Nielsen identity (cf. Lemma 9.59 and Proposition 9.61), and covariance from the graded transport and Fourfold Hermiticity/covariance (cf. Definition 9.7 and Proposition 9.6).

Theorem 9.67 (Realization criterion and spectrum extraction)**.** *A pre–physical mode operator* $\hat{M}^\dagger \in \{\hat{A}_a^\dagger, \hat{K}_b^\dagger\}$ *realizes as a physical particle iff:*

R1 $\Pi(p)$ *from Definition 9.66 contributes a* Σ–causal retarded pole *to the corresponding kernel in* (9.29) *at* $p = p_\star$*, and* $\partial_{\xi,\alpha_{\rm gf}} p_\star = 0$ *(Nielsen–flatness on certified plateaus; cf. Definition 9.58 and Proposition 9.61);*

R2 *the residue at* $p_\star$ *is positive in* $H^0(\hat{Q}_{\rm BRST})$ *(Kugo–Ojima unitarity; cf. Section 6.10), and the mode's propagation respects the* $\bar{\Sigma}$*–cones (hyperbolicity; cf. Definition 9.62).*

When R1 and R2 hold:

(i) Geometry block

Σ*–null (pure phase–flow) directions in* $\mathcal{N}_\Phi^{\rm pre}$ *yield a* massless spin–2 graviton*;* Σ*–radial (amplitude) directions yield* massive Gaiaton (Apeiron) *modes (cf. Proposition 9.36 and Lemma 9.38).*

(ii) Matter block

Σ*–principal modes in* $\mathcal{N}_\Theta^{\rm pre}$ *realize as the* Kymon *spectrum; isolating the torsional temporal sub–block gives the* Chrono–Kymon *(cf. Propositions 9.36 and 9.39 and Remark 9.41).*

Proof. (1) From pre–physical modes to realized two–point functions and kernels. Pre–physical principal modes are obtained by the Σ–weighted eigenproblems and block factorizations (cf. Proposition 9.36 and eqs. (9.15) to (9.17)). Their physical images are defined via the Σ–realization map $\mathcal{U}_\Sigma[\cdot]$ on certified plateaus (cf. Definitions 9.58 and 9.60). The Σ–projected two–point functions $\Pi_{ab}^{(\Phi)}, \Pi_{cd}^{(\Theta)}$ are given in Definition 9.66; the physical retarded kernels $G^{\rm R}_{\Phi\Phi;{\rm phys}}, G^{\rm R}_{\Theta\Theta;{\rm phys}}$ are the Σ–causal Green functions associated with the cohomology–restricted EOM (cf. Definitions 9.62 and 9.63). Standard linear–response/spectral relations on the realized background (Källén–Lehmann–type correspondence in the Σ–geometry) imply that isolated singularities (poles) of Π contribute the same mass–shell singularities to the corresponding retarded kernel (compatibly with graded transport/Hermiticity; cf. Proposition 9.6).

(2) Nielsen–flatness and gauge–parameter independence. On a certified plateau, the Σ–Nielsen identity ensures $\partial_{\xi,\alpha_{\rm gf}} \bar{\Sigma} = 0$ (cf. Proposition 9.61). Since the Σ–causal operators and dispersion relations depend on the gauge parameters only through $\bar{\Sigma}$ (cf. Definition 9.62), the location $p_\star$ of any pole inherited from Π is gauge–parameter independent: $\partial_{\xi,\alpha_{\rm gf}} p_\star = 0$. Ward/Slavnov identities in Σ–form further ensure that any residual breaking is ζ–exact and cannot shift physical poles/residues in H^0 (cf. Lemma 9.65).

(3) Positivity and hyperbolicity. The residue at $p_\star$ equals the norm (matrix element) of the one–particle state created by the realized operator $\mathcal{U}_\Sigma[\hat{M}^\dagger]$ in the physical Hilbert space; positivity of this residue is precisely the Kugo–Ojima unitarity condition in $H^0(\hat{Q}_{\rm BRST})$

(cf. Section 6.10). By construction of $\nabla^{(\mathrm{rel})}$ and Σ–causal Green functions, propagation is supported inside the $\bar{\Sigma}$–future cone (hyperbolicity; cf. Definition 9.62); thus the realized excitation respects the realized chronogeometric cones.

(4) $\Rightarrow$ If R1 and R2 hold, $\hat{M}^\dagger$ realizes as a particle. Assume an isolated Σ–causal retarded pole at $p_\star$ with gauge–independent location and positive residue in H^0. Then the LSZ–type argument adapted to the realized background identifies a stable (or metastable) one–particle contribution in $G^{\mathrm{R}}_{\bullet\bullet;\mathrm{phys}}$ with causal propagation; acting with $\mathcal{U}_\Sigma[\hat{M}^\dagger]$ on the physical vacuum creates a non–null physical state with that mass–shell. Hence the mode realizes as a physical particle.

(5) $\Leftarrow$ If a mode realizes as a particle, then R1 and R2 hold. Conversely, a realized particle contributes an isolated mass–shell pole to the corresponding retarded kernel with non–negative residue. Gauge–parameter independence of $p_\star$ follows from Proposition 9.61; positivity of the residue follows from Kugo–Ojima positivity on H^0; and hyperbolicity follows from the Σ–causal construction in Definition 9.62. Therefore both (R1) and (R2) are necessary.

(6) Blockwise identification of species. In the geometry block, the Σ–weighted principal directions decompose into *phase–flow* (Σ–null) and *amplitude* (Σ–radial) modes (cf. Lemma 9.38). When (R1)–(R2) hold, the former realize as a massless spin–2 graviton, while the latter produce massive Gaiaton (Apeiron) excitations. In the matter block, Σ–principal modes realize as Kymons, and the torsional temporal sub–block isolates the Chrono–Kymon channels, with inter–modal mixing governed by $\hat{G}_{\Theta\Theta}$ and weighted correctly by $\hat{t}_{\mu\nu}$ (cf. Proposition 9.39 and Remark 9.41). Stability of the extracted spectra under small band deformations follows from Lemma 9.42.

Combining (1)–(6) establishes the stated iff criterion and the blockwise spectrum identification. □

Corollary 9.68 (Cross–block consistency)**.** *On certified plateaus $\mathfrak{P}$, off–diagonal Σ–couplings $\hat{\Sigma}_{\Phi\Theta}$ either vanish in H^0 or generate BRST–admissible mixing angles; in either case, realized masses/dispersion relations are gauge–parameter independent.*

Proof. (1) Setting and notation. Work on a certified plateau and let $\bar{\Sigma}$ be the realized chronogeometry (cf. Definitions 9.58 and 9.60 and eq. (9.27)). Consider the cohomology–restricted quadratic operator for the combined geometry–matter sector, written in block form relative to $(\Phi \oplus \Theta)$,

$$\mathcal{K}_\Psi(\bar{\Sigma}) \;=\; \begin{pmatrix} \mathcal{K}_{\Phi\Phi}(\bar{\Sigma}) & \mathcal{K}_{\Phi\Theta}(\bar{\Sigma}) \\ \mathcal{K}_{\Theta\Phi}(\bar{\Sigma}) & \mathcal{K}_{\Theta\Theta}(\bar{\Sigma}) \end{pmatrix},$$

whose Σ–causal retarded Green operator yields $G^{\mathrm{R}}_{\Phi\Phi;\mathrm{phys}}$ and $G^{\mathrm{R}}_{\Theta\Theta;\mathrm{phys}}$ after projection (cf. Definitions 9.62 and 9.63). The pre–physical principal modes and their Σ–weighted factorizations provide the band modes $\hat{A}^\dagger_a, \hat{K}^\dagger_b$ and the Σ–projected two–point functions $\Pi^{(\Phi)}_{ab}, \Pi^{(\Theta)}_{cd}$ (cf. Proposition 9.36, eqs. (9.16) and (9.17), and Definition 9.66); inter–modal mixing is treated by the generalized eigenproblem (cf. Proposition 9.39).

(2) BRST screening of cohomologically trivial off–diagonal pieces. If the off–diagonal coupling $\hat{\Sigma}_{\Phi\Theta}$ (or the corresponding entry $\mathcal{K}_{\Phi\Theta}$) is BRST–exact on the band, then by BRST hygiene of the tag and projection (cf. Lemma 9.59 and Section 6.10) its physical matrix

elements vanish:

$$\mathsf{P}_{\mathrm{phys}}\,\mathfrak{B}_{\lambda,\ell}\Big([\,\hat{Q}_{\mathrm{BRST}},Y]_{\pm}\Big)\,\mathsf{P}_{\mathrm{phys}}=0.$$

Hence the off–diagonal block decouples in H^0, and the realized dispersion relations are determined by the diagonal blocks alone.

(3) BRST–admissible mixing when the off–diagonal is BRST–closed. If $\hat{\Sigma}_{\Phi\Theta}$ is BRST–closed (ghost number 0) but not exact, then it survives projection and induces a physical mixing. On $\mathcal{H}_{\mathrm{phys}}$, diagonalize the realized quadratic form with respect to the Σ–inner product defined by $\bar{\Sigma}$ (cf. Definition 9.62 and Proposition 9.61). By Proposition 9.39, the generalized eigenproblem absorbs cross–terms and yields a Σ–orthonormal transformation U on H^0 (block–unitary with respect to the Σ–metric) that brings $\mathcal{K}_\Psi(\bar{\Sigma})$ to block–diagonal form. The (physical) *mixing angles* are those parameterizing U inside the relevant two–mode subspaces; being constructed from BRST–closed, gauge–covariant data and evaluated on H^0, these angles are *BRST–admissible*.

(4) Gauge–parameter independence of realized spectra. On a certified plateau, $\partial_\theta\bar{\Sigma}=0$ for every gauge–fixing parameter $\theta\in\{\xi,\alpha_{\mathrm{gf}}\}$ by the Σ–Nielsen identity (cf. Proposition 9.61). Therefore $\partial_\theta\mathcal{K}_\Psi(\bar{\Sigma})=0$, and the spectral projectors/eigenvalues of the realized operator are θ–independent. Equivalently, Ward/Slavnov identities in Σ–form imply that any θ–variation is BRST–exact and thus annihilated between $\mathsf{P}_{\mathrm{phys}}$ insertions (cf. Lemma 9.65 and Section 7.5). Consequently, the pole locations and residues extracted from the physical retarded kernels (9.29) are gauge–parameter independent, whether or not a BRST–admissible mixing is present.

Combining (2)–(4): either the off–diagonal couplings vanish in cohomology (decoupling) or they generate BRST–admissible, Σ–orthonormal mixings; in both cases, the realized masses/dispersion relations are gauge–parameter independent on $\mathfrak{P}$. This proves the corollary. □

Proposition 9.69 (Quadrant mapping under realization)**.** *Let* $(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}},\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}})$ *be the pre–physical order parameters of Definition 9.47, with classification by Definition 9.49. On certified plateaus (cf. Definition 9.58):*

(i) QI→QI
Σ–contrasts stay $\mathcal{O}(\varepsilon)$; only BRST–closed modes can realize.

(ii) QII→QII/QI
Law symmetry persists; state asymmetry survives iff not ζ–exact; realized NG/pNG structure is gauge–independent.

(iii) QIII/QIV
Any BRST–forbidden law asymmetry is annihilated by $\mathsf{P}_{\mathrm{phys}}$; otherwise it persists as explicit breaking visible in Σ–Ward identities (Lemma 9.65).

Proof. (1) Band stability and BRST hygiene. On a certified plateau $\mathfrak{P}$, band–local quantities vary by at most $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ (grid diagnostics and acceptance; cf. Definition 9.58, eqs. (7.394) to (7.396), and Proposition 7.203), and the pre–physical Σ–contrasts are finite/continuous in probes and band knobs (cf. Lemmas 9.27 and 9.46). The band tag $\mathfrak{B}_{\lambda,\ell}$ is a BRST chain map and commutes with projection to cohomology (cf. Lemma 9.59 and Section 6.10); hence BRST–exact contributions are removed by $\mathsf{P}_{\mathrm{phys}}$ in the realization map $\mathcal{U}_\Sigma$ (cf. Definition 9.60).

(2) Law channel under realization. The law–channel visibility is Nielsen–flat on plateaus (cf. Corollary 9.56), and $\bar{\Sigma}$ is gauge–parameter independent (cf. Proposition 9.61). Therefore $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}} = \mathcal{O}(\varepsilon)$ remains $\mathcal{O}(\varepsilon)$ after realization, and the realized retarded kernels depend on gauge parameters only through $\bar{\Sigma}$, hence are gauge–parameter independent (cf. Definitions 9.62 and 9.63).

(3) State channel under realization. State–channel asymmetries that are BRST–exact are annihilated by $\mathsf{P}_{\mathrm{phys}}$ (cf. Lemma 9.59); BRST–closed asymmetries survive. In particular, phase–flow (Goldstone–like) vs. amplitude (Higgs/Gaiaton–like) content diagnosed pre–physically by Σ persists through realization (cf. Lemma 9.38 and Theorem 9.67), with gauge independence ensured by Proposition 9.61.

(4) Case analysis of the quadrant map.

QI (law & state symmetric).
Pre–physical $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}, \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}} < \varepsilon$ remain within $\mathcal{O}(\varepsilon)$ under plateau–controlled realization by (1)–(3). Only BRST–closed mode content can survive; any BRST–exact remnants are removed by $\mathsf{P}_{\mathrm{phys}}$ (cf. Lemma 9.59). Hence QI maps to QI.

QII (law symmetric, state asymmetric).
Law symmetry persists by (2). If the state asymmetry is BRST–exact, projection removes it, yielding QI; if it is BRST–closed, it survives as QII. The realized NG/pNG structure (phase–flow vs. amplitude and possible small explicit breakings) is determined by Lemma 9.38 and Proposition 9.39 and realized as physical poles/residues by Theorem 9.67, with gauge–parameter independence from Proposition 9.61.

QIII/QIV (law asymmetric).
If the law asymmetry is BRST–forbidden (cohomologically trivial), it is annihilated by projection (cf. Lemma 9.59), so the realized law channel reverts to symmetry and the classification follows the surviving state channel. If it is BRST–admissible (BRST–closed), it persists as explicit breaking and appears as a non–vanishing divergence/source in the Σ–Ward/Slavnov identities (cf. Lemma 9.65); nevertheless, realized pole locations/residues remain gauge–parameter independent by Proposition 9.61.

(5) Consistency with spectra and mixing. Any realized particle must satisfy the iff criterion of Theorem 9.67; cross–block effects are either removed in cohomology or produce BRST–admissible Σ–orthonormal mixings without gauge drift (cf. Corollary 9.68). Thus the quadrant mapping is consistent with spectrum extraction.

Combining (1)–(5) yields the stated mapping and properties. □

Lemma 9.70 (Health checklist (Σ–centric))**.** *On any certified plateau $\mathfrak{P}$, realized data satisfy: (i) $\det \bar{g}^{\mathrm{Lor}} < 0$ and a fixed time orientation (Lorentzianity); (ii) Σ–causality/hyperbolicity for the physical retarded kernels (9.29); (iii) Nielsen–flatness of poles/residues; (iv) spectral finiteness on the band (no UV–induced pole drift on $\mathfrak{P}$); (v) unitarity (positive residues in H^0).*

Proof. (i) Lorentzianity. By the definition of a certified plateau, $\bar{\Sigma}$ admits a Lorentzian projection and defines causal cones (cf. Definition 9.58). The Relational Levi–Civita construction fixes $\bar{g}^{\mathrm{Lor}}$ and its time orientation consistently with $\bar{\Sigma}$ (cf. Definition 9.62); hence $\det \bar{g}^{\mathrm{Lor}} < 0$ and the time orientation is globally fixed on $\mathfrak{P}$.

Algorithm 2 Σ-aware upgrade and spectrum readout

1. **Preconditions:** verify $\mathfrak{P}$ (Definition 9.58), BRST hygiene (Lemma 9.59), Σ-regularity.
2. **Realize Σ:** compute $\bar{\Sigma}$ via (9.27); build $\nabla^{(\mathrm{rel})}$ and $\bar{g}^{\mathrm{Lor}}$ (Definition 9.62).
3. **Physical EOM:** form $\mathcal{E}^{\mathrm{coh}}_{\boldsymbol{\Phi}/\boldsymbol{\Theta}}(\bar{\Sigma})$ and $\mathcal{K}_{\Psi}(\bar{\Sigma})$ (Definition 9.63); construct $G^{\mathrm{R}}_{\bullet;\mathrm{phys}}$ with Σ-causal support.
4. **Modes → particles:** evaluate $\Pi^{(\Phi/\Theta)}(p)$ from (9.31); locate Σ-retarded poles and residues; test **(R1)**–**(R2)** of Theorem 9.67.
5. **Health checks:** apply Lemma 9.70; report the graviton/Gaiaton/Kymon ledger with mixing constraints (Corollary 9.68).

(ii) Σ–causality/hyperbolicity of $G^{\mathrm{R}}_{\bullet\bullet;\mathrm{phys}}$. By Definition 9.62, the physical retarded kernels (9.29) are the unique Σ–causal Green functions supported in the $\bar{\Sigma}$–future cone and defined with boundary conditions from $\nabla^{(\mathrm{rel})}$. Therefore they satisfy hyperbolicity and causal support on the realized background.

(iii) Nielsen–flatness. On $\mathfrak{P}$, the Σ–Nielsen identity gives $\partial_{\xi,\alpha_{\mathrm{gf}}}\bar{\Sigma} = 0$ (cf. Proposition 9.61). Since the kernels and dispersion data depend on gauge parameters only through $\bar{\Sigma}$ (cf. Definitions 9.62 and 9.63), their pole locations and residues are gauge–parameter independent. Ward/Slavnov identities in Σ–form ensure that any residual breaking is ζ–exact and thus invisible in H^0 (cf. Lemma 9.65).

(iv) Spectral finiteness and no UV–induced drift on $\mathfrak{P}$. Spectral Smoothness and the Principle of Finite Entanglement Capacity imply endogenous regularization: triads and the derived operators $\hat{g}_{\mu\nu}, \hat{t}_{\mu\nu}, \hat{\Sigma}_{\mu\nu}$ are finite on the band (cf. Propositions 9.13 and 9.14 and Remark 9.21). Continuity under band deformations yields $\mathcal{O}(\varepsilon)$ control for observables and mode spectra (cf. Lemmas 9.27 and 9.42); the plateau acceptance rule maintains these bounds uniformly across $\mathfrak{P}$ (cf. Definition 9.58 and Proposition 7.203). Hence there is no UV–induced pole drift within $\mathfrak{P}$.

(v) Unitarity (positive residues in H^0). Realized particles satisfy the iff criterion of Theorem 9.67: their poles are Σ–causal and the residues are positive on the BRST–physical Hilbert space $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Kugo–Ojima positivity; cf. Section 6.10 and Theorem 9.67). Therefore unitarity holds for the realized spectrum.

All items (i)–(v) are thus guaranteed on any certified plateau $\mathfrak{P}$, completing the proof. □

Summary of Section 9.5. The realization stage is completed in a Σ–centric and BRST–clean manner as follows. (i) The *unified* chronogeometry $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$, defined band–locally by SOT–C^2 Hessians, is promoted to its realized tensor $\bar{\Sigma}_{\mu\nu}$ via the Σ–realization map $\mathcal{U}_{\Sigma}$ on certified plateaus $\mathfrak{P}$ (cf. Definitions 9.20, 9.58 and 9.60 and eq. (9.4)), with BRST hygiene of the tag guaranteeing cohomological well–posedness (cf. Lemma 9.59). (ii) Physical dynamics are posed as cohomology–restricted EOM together with Σ–*causal* retarded kernels supported

within the $\bar{\Sigma}$–cones (cf. Definitions 9.62 and 9.63 and eq. (9.29)). Ward/Slavnov identities in Σ–form ensure that any residual breaking is ζ–exact and therefore invisible on $\mathcal{H}_{\text{phys}}$ (cf. Lemma 9.65). (iii) Spectrum extraction proceeds from Σ–projected two–point functions of band modes to Σ–causal retarded poles with gauge–independent locations and residues: gauge–parameter independence follows from the Σ–Nielsen identity (cf. Definition 9.66 and Proposition 9.61), while positivity of residues is the Kugo–Ojima unitarity condition on $H^0(\hat{Q}_{\text{BRST}})$ (cf. Section 6.10 and Theorem 9.67). Cross–block effects are either removed in cohomology or appear as BRST–admissible mixing angles that do not induce gauge drift (cf. Corollary 9.68).

Within this framework, Σ–weighted principal modes characterize the *provisional* particle assignments, subject to all health checks (cf. Proposition 9.36 and Lemma 9.70). Tangential (Σ–null, pure phase–flow) directions in the geometry block provisionally correspond to a *massless spin–2 graviton*; radial (Σ–amplitude) directions yield *massive Gaiaton (Apeiron)* modes (cf. Lemma 9.38 and Theorem 9.67). In the matter block, Σ–principal modes provisionally realize as the *Kymon* spectrum, with a torsional temporal sub–block isolating the *Chrono–Kymon*, and inter–modal mixing handled coherently by the generalized eigenproblem (cf. Proposition 9.39 and Remark 9.41). All identifications are *plateau–qualified*: Lorentzianity and causal support are enforced by the Relational Levi–Civita structure (cf. Definition 9.62); poles/residues are Nielsen–flat on $\mathfrak{P}$ (cf. Proposition 9.61 and Corollary 9.56); spectral finiteness and stability under band deformations are controlled by endogenous regularization and plateau diagnostics (cf. Proposition 9.13, Lemmas 9.27 and 9.42, and Definition 9.58); and unitarity is certified in H^0 by residue positivity (cf. Theorem 9.67). Consequently, the realized sector inherits the quadrant–level logic consistently with pre–physical diagnostics (cf. Proposition 9.69), while keeping all particle–level assignments explicitly *provisional* pending verification across certified plateaus.

9.6 Minimal "How-to" Pipeline

Definition 9.71 (Inputs and knobs)**.** The pipeline takes as input the Fourfold inter-modal correlator $\hat{\mathbf{G}}_\Lambda$ and gauge-covariant transport $\mathcal{U}$ (Definitions 9.5 and 9.7), the graded modal structure (Definition 9.8), the band tag $\mathfrak{B}_{\lambda_{\text{UV}},\ell}$ (Definition 9.10), and, if used, an admissible spectral operator $\hat{D}$ satisfying the spectral discipline (Proposition 9.13).

Definition 9.72 (Band choice and Σ-regularity check)**.** Choose $(\lambda_{\text{UV}}, \ell)$ with Spectral Smoothness and Finite Entanglement Capacity (Proposition 9.13). On the band, form $\hat{\mathbf{G}}_\Lambda^{(\lambda,\ell)} := \mathfrak{B}_{\lambda,\ell}[\hat{\mathbf{G}}_\Lambda]$ and verify that the strong-operator Hessians at coincidence exist for D^2, T^2, hence $\hat{g}_{\mu\nu}, \hat{t}_{\mu\nu}$ and

$$\hat{\Sigma}_{\mu\nu} := \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}, \qquad \hat{\Sigma}^{(\Phi)} := \Pi_{\Phi\Phi}^\dagger \hat{\Sigma}\, \Pi_{\Phi\Phi}, \quad \hat{\Sigma}^{(\Theta)} := \Pi_{\Theta\Theta}^\dagger \hat{\Sigma}\, \Pi_{\Theta\Theta} \tag{9.32}$$

(Definition 9.20).

Definition 9.73 (Σ-order parameters and quadrant classification)**.** Fix probe directions $\{v_k\} \subset T_x\mathcal{X}_q$ and a band-local, gauge-invariant functional $\mathcal{I}$. With $\hat{Q}_x[v] := v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$

(Definition 9.22), define

$$\begin{aligned}\Delta^{\Sigma}_{\mathrm{law}}(g;x;v_k) &:= \Big(\mathcal{I}[\hat{Q}_x[v_k] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v_k]]\Big)^{1/2},\\ \Delta^{\Sigma}_{\mathrm{state}}(g;x;v_k) &:= \Big|\mathcal{I}_{\Psi}[\hat{Q}_x[v_k]] - \mathcal{I}_{g\cdot\Psi}[\hat{Q}_x[v_k]]\Big|^{1/2}.\end{aligned} \tag{9.33}$$

and aggregate as in Definition 9.47:

$$\Delta^{\Sigma}_{\mathrm{law}}(g;x) := \Big(\sum_k [\Delta^{\Sigma}_{\mathrm{law}}(g;x;v_k)]^2\Big)^{1/2}, \quad \Delta^{\Sigma}_{\mathrm{state}}(g;x) := \Big(\sum_k [\Delta^{\Sigma}_{\mathrm{state}}(g;x;v_k)]^2\Big)^{1/2}. \tag{9.34}$$

Classify QI–QIV with tolerance ε as in Definition 9.49.

Definition 9.74 (Σ-weighted broken-sector mode extraction)**.** For broken generators X determined by Definition 9.73, compute the graded tangents on blocks (Definition 9.32), $\delta_X\hat{G}_{\Phi\Phi}$, $\delta_X\hat{G}_{\Theta\Theta}$, form the Gram operators (eq. (9.15))

$$C_\Phi = (\delta_X\hat{G}_{\Phi\Phi})^\dagger\hat{\Sigma}^{(\Phi)}\delta_X\hat{G}_{\Phi\Phi}, \qquad C_\Theta = (\delta_X\hat{G}_{\Theta\Theta})^\dagger\hat{\Sigma}^{(\Theta)}\delta_X\hat{G}_{\Theta\Theta},$$

and solve the generalized eigenproblems (eq. (9.16))

$$C_\Phi u_a = \lambda_a\hat{\Sigma}^{(\Phi)}u_a, \qquad C_\Theta v_b = \mu_b\hat{\Sigma}^{(\Theta)}v_b.$$

Define $\hat{A}^\dagger_a, \hat{K}^\dagger_b$ as in Definition 9.37, with Σ-orthonormality (9.18).

Lemma 9.75 (Σ-centric pre-physical health checks)**.** *If $\hat{\Sigma}$ passes the band regularity of Definition 9.72, then: (i) Σ-cones are well-defined and respected by the principal directions (Lemma 9.38); (ii) Δ^Σ in (9.34) varies continuously under small band deformations (Lemma 9.27); (iii) principal spectra $\{\lambda_a, \mu_b\}$ are stable (Lemma 9.42).*

Definition 9.76 (Certified plateau and Σ-realization)**.** Identify a certified plateau $\mathfrak{P}$ (Definition 9.58). Define the Σ-realization map $\mathcal{U}_\Sigma$ by (9.26). Obtain the physical chronogeometry $\bar{\Sigma}_{\mu\nu} = \langle\mathcal{U}_\Sigma[\hat{\Sigma}_{\mu\nu}]\rangle$ (Definition 9.60) and build the Σ-causal retarded kernels $G^{\mathrm{R}}_{\Phi\Phi;\mathrm{phys}}, G^{\mathrm{R}}_{\Theta\Theta;\mathrm{phys}}$ (Definitions 9.62 and 9.63).

Theorem 9.77 (Pipeline soundness)**.** *Assume $\mathfrak{P}$ satisfies Definition 9.58 and the BRST hygiene of the band map (Lemma 9.59). Then the outputs of Definition 9.76 are: (a) gauge-parameter independent (Proposition 9.61); (b) Σ-causal and hyperbolic (Definition 9.62); (c) unitary in $H^0(\hat{Q}_{\mathrm{BRST}})$ with positive residues at realized poles (Theorem 9.67).*

Corollary 9.78 (Spectrum readout rule)**.** *Let $\hat{M}^\dagger \in \{\hat{A}^\dagger_a, \hat{K}^\dagger_b\}$. If $\Pi(p) = \langle\mathcal{U}_\Sigma[\hat{M}]\mathcal{U}_\Sigma[\hat{M}^\dagger]\rangle$ (cf. Definition 9.66) produces a Nielsen-flat Σ-retarded pole with positive residue, then $\hat{M}^\dagger$ realizes as: (i) massless spin-2 (graviton) for Σ-null geometry directions; (ii) massive Gaiaton for Σ-radial geometry directions; (iii) Kymon (incl. Chrono–Kymon) for matter-block principal modes, with BRST-admissible mixings (Theorem 9.67 and Corollary 9.68).*

Remark 9.79 (Triadic attribution and block sensitivity)**.** For interpretability, decompose $\bar{\Sigma} = \bar{\Sigma}^{\mathrm{corr}} + \bar{\Sigma}^{\mathrm{vac}} + \bar{\Sigma}^{\mathrm{spec}}$ and attribute quadrant decisions and realized poles to channels (Proposition 9.48). Block-resolved diagnostics remain available via $\hat{\Sigma}^{(\Phi)}, \hat{\Sigma}^{(\Theta)}$ (Definition 9.33).

Algorithm 3 Σ-aware minimal pipeline

1. **Band & regularity** (Definition 9.72): pick $(\lambda_{\mathrm{UV}}, \ell)$, build $\hat{\mathbf{G}}_{\Lambda}^{(\lambda,\ell)}$; certify SOT–Hessians for $\hat{g}, \hat{t}$.
2. **Build** Σ (Definition 9.72): form $\hat{\Sigma}$ and its block restrictions (9.32).
3. **Order parameters** (Definition 9.73): compute $\Delta^{\Sigma}_{\mathrm{law}}$, $\Delta^{\Sigma}_{\mathrm{state}}$ and classify QI–QIV.
4. **Modes** (Definition 9.74): solve the Σ-weighted eigenproblems; construct $\hat{A}^{\dagger}_{a}$, $\hat{K}^{\dagger}_{b}$.
5. **Pre-physical health** (Lemma 9.75): check Σ-cone compatibility, Σ-weight positivity, stability under band deformations.
6. **Plateau** (Definition 9.76): certify $\mathfrak{P}$ (BRST viability, Nielsen-flatness, Σ-causality).
7. **Σ-realization** (Definition 9.76): apply $\mathcal{U}_{\Sigma}$ to $\hat{\Sigma}$, $\hat{A}^{\dagger}_{a}$, $\hat{K}^{\dagger}_{b}$; obtain $G^{\mathrm{R}}_{\bullet;\mathrm{phys}}$.
8. **Spectrum** (Corollary 9.78): locate Σ-retarded poles/residues; enforce Ward/Slavnov and Kugo–Ojima conditions.

What this achieves (summary). The pipeline implements a *quadrant-aware PSR calculus* using Σ-based order parameters (Definition 9.73), a *graded-consistent, Σ-weighted* construction of Apeiron/Kymon band operators (Definition 9.74), and a *Σ-aware realization* (Definition 9.76) that produces a gauge-clean, causal, unitary spectrum in $H^0(\hat{Q}_{\mathrm{BRST}})$ (Theorem 9.77 and Corollary 9.78).

9.7 Invariance of Chronogeometric Formalisms

Definition 9.80 (The Σ–realization)**.** Define the physical chronogeometry by the Σ–realization map of Definition 9.60:

$$\boxed{\bar{\Sigma}_{\mu\nu}(x) := \Big\langle \mathsf{P}_{\mathrm{phys}} \lim_{(\lambda,\ell)\in\mathfrak{P}} \mathfrak{B}_{\lambda,\ell}\big[\hat{\Sigma}_{\mu\nu}(x)\big]\, \mathsf{P}_{\mathrm{phys}} \Big\rangle} \tag{9.35}$$

All subsequent constructions in Chapters 7–8 (cohomological EOM, linear response, visibilities, Ward/Slavnov identities) are to be understood as functions of $\bar{\Sigma}$. This statement references Definitions 9.10, 9.20, 9.58 and 9.60.

Remark 9.81 (Upstream formalisms are unchanged)**.** Let Q_{BRST} be the BRST charge of Chapter 7 and $H^0(Q_{\mathrm{BRST}})$ the physical sector. Then:

1. **BRST sector:** $Q^2_{\mathrm{BRST}} = 0$, $\mathcal{H}_{\mathrm{phys}} = H^0(Q_{\mathrm{BRST}})$; gauge fixing is ζ-exact; physical observables are defined modulo ζ-exact terms.

2. **Field/bundle scaffolding:** The generalized field operator $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^{\mathsf{T}}$, the Fourfold correlator $\hat{\mathbf{G}}_{\Lambda}$, the operator-bundle connection/curvature, and the graded modal algebra of Definitions 9.5, 9.7 and 9.8 persist verbatim.
3. **Relational geometry (physical side):** The Relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$ and Lorentzian projection of $\bar{g}$ (implicit in $\bar{\Sigma}$) continue to govern linear response/propagators and Ward/Slavnov identities, with Kugo–Ojima unitarity checks unchanged; see Definitions 9.62 and 9.63.

Remark 9.82 (Σ–Nielsen identities: same proofs, stronger statement)**.** On certified plateaus $\mathfrak{P}$ (Definition 9.58), $\bar{\Sigma}$ is gauge–parameter independent by Proposition 9.61. Therefore any quantity in Chapters 7–8 that was previously shown gauge–parameter independent (Nielsen-safe) remains so when rewritten as a functional of $\bar{\Sigma}$; only the *wording* changes (from "triads" to "$\bar{\Sigma}$").

Remark 9.83 (Σ–causal linear response (statement only))**.** Replace the background "metric+temporal data" by $\bar{\Sigma}$ from (9.35). Then the quadratic operators $\mathcal{K}_{\Psi}(\bar{\Sigma})$ and the physical retarded kernels $G^{\mathrm{R}}_{\bullet;\mathrm{phys}}$ defined in Definitions 9.62 and 9.63 are *Σ–causal*: their support respects the cones of $\bar{\Sigma}$. No cohomological overlay or Ward/Slavnov step is altered.

Remark 9.84 (Mode normalization: Σ–inner product vs. triad metrics)**.** When realized quanta (graviton/Gaiaton/Kymons) are discussed in H^0, normalization by the Σ–inner products of Definition 9.33 is equivalent—up to a positive, blockwise bounded reweighting—to any triad-by-triad metric used earlier. Hence particle *criteria* (poles, residues, positivity, gauge-independence) remain identical; see Theorem 9.67.

Remark 9.85 (Quadrant diagnostics (unchanged logic, Σ–inputs))**.** In Chapter 8's PSR stage, compute law/state order parameters with the Σ–based scalars of Definition 9.47 instead of distances-only, and classify QI–QIV via Definition 9.49. The realization mapping then uses $\mathcal{U}_{\Sigma}$ (Definition 9.60) but lands in the same $H^0(Q_{\mathrm{BRST}})$ with the same viability/uniqueness tests; see Proposition 9.69.

Remark 9.86 (What definitively does not change)**.** None of the following are modified: ghost sector and the BRST charge; cohomology definitions; proof strategies for gauge–parameter independence and anomaly exclusions; the operator–bundle/gauge–group filtration recovering the SM sector (Ch. 11 excerpt).

Bottom line. Pre-physical chronogeometry only *feeds* Chapters 7–8: $\hat{\Sigma} \xrightarrow{\mathcal{U}_{\Sigma}} \bar{\Sigma}$. All downstream axioms, definitions, and proofs remain intact. In practice you gain cleaner causality (Σ–cones), unified normalization (Σ–inner products), and simpler, globally gauge–independent statements—while the BRST–physical sector and its machinery are unchanged.

9.8 Parasymmetric Type – Location – Onset on the Σ Pre-Physical Layer

Scope and substrate (with cross-references). This section establishes a fully pre-physical, expectation-free pipeline on the emergent Hilbert layer $\mathcal{H}_{\mathrm{em}}$ (Definition 1.34), beginning at

Algorithm 4 Minimal editorial patch for Chapters 7–8

1. Insert the bridge (9.35) at the start of Chapter 7 (just after introducing the physical arena).
2. Replace every "triadic background" dependency in the statements of cohomological EOM, linear response, visibilities, Ward/Slavnov identities $\rightsquigarrow$ the single symbol $\bar{\Sigma}$.
3. Leave all lemmas/proofs verbatim; optionally add a parenthetical "(Σ–Nielsen form)" referencing Remark 9.82.

the Primordial Quantum Singularity (PQS) (Definition 1.25) and running strictly below the Planckian regime. All constructions are formulated *exclusively* at operator level, using the operator chronogeometry $\hat{\Sigma}_{\mu\nu}$ (Definition 5.25), the unified inter-modal correlator $\hat{\mathbf{G}}_\Lambda$ (Definition 6.4) built from the ΦΦ (Gaiamiti) and ΘΘ (Tantrakyma) blocks and the fourfold dialectical basis $\{0, 1, p, s\}$ (Section 1.4.2 and Definition 4.9), band instrumentation $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$ (Definitions 7.26 and 9.10 and eq. (7.29)), and the BRST algebra/hygiene that guarantees gauge-parameter independence on the band (Lemma 9.54). Expectation-level objects (bars) never appear; all diagnostics and meters are defined directly on operators supported by the band.

Intent. From the common substrate $(\hat{\Sigma}_{\mu\nu}, \hat{\mathbf{G}}_\Lambda, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell})$ we *derive*—rather than posit—causal structure via the Σ–pre-physical cone $\mathcal{C}_x^{\hat{\Sigma},*}$ and its quadratic probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (Definition 9.22), enforce retardedness and microcausality on band-admissible kernels, and test *typed hyperbolicity*. Within each block ΦΦ (apeiron) and ΘΘ (kymon) (Definition 9.31 and eq. (9.12)) we then *discover* the permitted kinematic content by constructing typed, cone-compatible projectors $\Pi^{[\chi]}$ (spin/helicity/polarization, in the pre-physical sense) and recording a *permit ledger* $\mathcal{C}^{[\cdot]}_{\mathrm{admissible}}$. Using the Σ-probe and BRST-closed band functionals $\mathcal{I}, \mathcal{I}_\Psi$ (Definitions 9.45 and 9.47 and eqs. (9.21) and (9.22)), we define typed Σ–contrasts $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law/state}}$, normalise them to typed Σ–visibilities $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}} \in [0, 1]$, and diagnose *Type* via the quadrant map

$$\mathrm{Quad}^{[\chi]} = \mathrm{Quad}\Big(\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}, \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}\Big) \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\} \quad (\textit{Definitions } 7.685 \textit{and } 9.28).$$

Finally, we port the *Parasymmetric meters* of §8.6 to the band (restricted by $\Pi^{[\chi]}$) to deliver **T–L–O**: the quadrant *Type*, the *Location* (arena/sector/position/cone sheet; cf. Section 8.1), and the scale/time *Onset* $\big(r^\star[\chi], t^\star[\chi]\big)$. The entire stack is BRST/Nielsen-safe at operator level (Lemma 9.54), and regulator-robust under small retunings of $(\lambda_{\mathrm{UV}}, \ell)$ (Definition 9.10).

Meaning. Causality is extracted from $\hat{\Sigma}$ alone: the covector cone $\mathcal{C}_x^{\hat{\Sigma},*}$ is defined operationally by band functionals (cf. Definition 9.20), IR windowing can only *shrink* cones (Definition 9.10), and all kernels are retarded and cone-gated inside $J^+(\mathcal{C}^{\hat{\Sigma},*})$. Typed hyperbolicity is an *admission test*: a label χ is permitted only if the principal quadratic form

of $\hat{Q}_x[k]$ (Definition 9.22) is strictly positive on cone-timelike covectors after restriction by $\Pi^{[\chi]}$, yielding the permit ledgers $\mathcal{C}^{[\mathrm{apeiron}]}_{\mathrm{admissible}}$ and $\mathcal{C}^{[\mathrm{kymon}]}_{\mathrm{admissible}}$. With $\Pi^{[\chi]}$ fixed, the typed contrasts $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law/state}}$ (Definition 9.45) provide retarded, BRST-closed diagnostics of explicit-law versus state-level effects; normalisation gives $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}$ (Definition 9.47 and eq. (9.22)), and the quadrant predicate $\mathrm{Quad}^{[\chi]}$ classifies the mechanism (QI/QII/QIII/QIV) (Definitions 7.685 and 9.28), optionally with corr/vac/spec attribution (Definition 5.54). Parasymmetric meters at local anchors $a \in \{L, S\}$ and on the relational LS pair (Section 8.6),

$$\upsilon^{(a);\,[\chi]}_{\mathrm{Synthesis}}, \qquad \upsilon^{(LS);\,[\chi]}_{\mathrm{Synthesis}},$$

turn these into operational valuations whose scale/time dependence furnishes onset thresholds $\big(r^\star[\chi], t^\star[\chi]\big)$, while the location metadata records $(\mathfrak{P}/\mathfrak{P}_\partial,\ \Phi\Phi/\Theta\Theta,\ P_x,\ \text{cone sheet})$ (Section 8.1).

BRST hygiene at pre-physics. Band taggers and typed projectors commute with the nilpotent charge $\hat{Q}_{\mathrm{BRST}}$ and carry ghost number 0 (Lemma 9.54); the band functionals $\mathcal{I}, \mathcal{I}_\Psi$ annihilate BRST-exact insertions and project to ghost number 0 (Definition 9.45). Consequently, any gauge-parameter variation is cohomologically exact and evaluates to zero under $\mathcal{I}, \mathcal{I}_\Psi$: the pipeline is Nielsen-safe without invoking $\bar{\Sigma}$ or $H^0(\hat{Q}_{\mathrm{BRST}})$ (Lemma 9.54). Scope discipline is strict: only the $\Phi\Phi$ and $\Theta\Theta$ blocks receive kinematic labels in the sub-Planckian regime (Definition 9.31); any mapping of permitted sectors to gravitons/particles is deferred to the expectation-level domain and lies outside the present construction.

Relation to the established framework. The present section inherits the fourfold correlator architecture and operator chronogeometry from Chapters 4–6 (no bars; Definitions 4.9, 5.25 and 5.54), respects the unified block field $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^{\mathsf{T}}$ and its covariant transport from Chapter 7 (Definitions 6.4 and 6.184), adopts band instrumentation and BRST hygiene in the spirit of Chapter 8 (Definitions 7.26 and 9.10 and Lemma 9.54), and instantiates a sector-conditioned witness pair $(\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}, \Lambda^{\Sigma;[\chi]}_{\mathrm{state}})$ that reproduces the canonical quadrant decision of Chapter 9—now *typed* and *cone-gated* (Section 8.1 and Definition 7.685). Parasymmetric meters provide the SynTh dashboard that operationalises T–L–O on the band (Sections 8.2.1 and 8.6).

Design guarantees and practical notes. Causal correctness follows from retarded support and cone gating by $\mathcal{C}^{\hat{\Sigma},*}_x$ with probe $\hat{Q}_x[v]$ (Definition 9.22); gauge cleanliness follows from BRST-closed instrumentation and BRST-invariant band functionals (Lemma 9.54 and Definition 9.45); well-posedness is enforced by typed hyperbolicity; stability and functoriality ensure small retunings of $(\lambda_{\mathrm{UV}}, \ell)$ alter estimates but not quadrant membership (within tolerances) (Definition 9.10). Practically, the probe set $\{v_k\}$ defining $\Lambda^{\Sigma;[\chi]}$ must be band-admissible and cone-separating (Definition 9.47); null-sheet degeneracies should be handled as limits from the timelike interior when computing $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}$ (Definition 9.45); and each χ should ship with a certificate triple (cone compatibility, typed hyperbolicity, band-stability window), with mode extraction aligned to the Σ-weighted principal-mode framework (Proposition 9.36, eq. (9.16), and Corollary 9.40).

We turn $\hat{\Sigma}$ (Definition 5.25), $\hat{\mathbf{G}}_\Lambda$ (Definition 6.4), and $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.10) into a BRST-clean, cone-gated, expectation-free engine that (i) *discovers* which χ are kinematically allowed for apeiron/kymon and then (ii) *diagnoses* their *Type–Location–Onset* via typed Σ–visibilities and Parasymmetric meters (Definition 9.47 and Section 8.6)—strictly pre-physical, from the PQS (Definition 1.25) up to just below Planckian.

Hard Constraints (Formal Specification)

Definition 9.87 (Pre-physical arena and PQS baseline)**.** The *pre-physical arena* is the GNS/emergent Hilbert layer $\mathcal{H}_{\mathrm{em}} \equiv \mathcal{H}_{\overset{\circ}{\Psi}}$ obtained from the Quantum Holo-State $\omega^{\overset{\circ}{\Psi}}$ (Definition 1.34). The locus of analysis is any PQS site $\mathfrak{B}_x$ (Definition 1.25), and all constructions in this section hold *from* PQS up to *just below* the Planckian regime.

Definition 9.88 (Operator substrate and expectation map)**.** Let $\mathfrak{A}_{\mathrm{em}}$ denote the $*$–algebra on $\mathcal{H}_{\mathrm{em}}$ (Definition 9.87) generated by the operator fields and instrumentation

$$\hat{\mathbf{F}}(x) = \big(\hat{\mathbf{\Phi}}(x), \hat{\mathbf{\Theta}}(x)\big)^{\mathsf{T}}, \quad \hat{\Sigma}_{\mu\nu}(x), \quad P_x(\lambda_{\mathrm{UV}}),\ K^{(\ell)}_{\mathrm{IR}},\ \hat{Q}_{\mathrm{BRST}},$$

with graded-gauge transport as in Definition 9.7 and band-closedness as in Definition 9.96. For any (not necessarily used) state ω on $\mathfrak{A}_{\mathrm{em}}$, write $E_\omega : \mathfrak{A}_{\mathrm{em}} \to \mathbb{C},\ A \mapsto \omega(A)$ for the *expectation map*, and denote by $\bar{A}$ any symbol that is either $E_\omega(A)$ or a functional of such expectations (e.g. $\bar{\Sigma}_{\mu\nu}$).[1]

Axiom 9.89 (Expectation-free, operator-only regime (tight form))**.** All statements in this section are made *exclusively* in the operator substrate $\mathfrak{A}_{\mathrm{em}}$ of Definition 9.88; in particular:

(O1) **Bar prohibition.** No barred objects appear. Concretely, $\bar{\Sigma}_{\mu\nu}$, $\bar{g}_{\mu\nu}$, $\bar{t}_{\mu\nu}$ and any $\bar{\cdot}$ obtained from E_ω are *excluded*.

(O2) **Admissible operations.** Allowed constructions use only algebraic operations in $\mathfrak{A}_{\mathrm{em}}$ (sums, products, $*$, graded commutators), BRST action with ghost number 0 instruments (Definition 9.96), graded-gauge conjugations (Definition 9.7), and band restriction.

(O3) **Causality and probes are operator-defined.** Causal support and cones are defined via $\hat{\Sigma}$ and the probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (Definitions 9.95 and 9.104); kernels are retarded, cone-gated (Definition 9.106 and Proposition 9.107).

(O4) **Numerical readouts are band functionals, not expectations.** When numbers are needed, we use the band functionals $\mathcal{I}, \mathcal{I}_\Psi$ (Definitions 9.96 and 9.127), which annihilate BRST-exact insertions (Nielsen safety; Proposition 9.97). No E_ω is invoked.

(O5) **Typed restriction only by projectors in $\mathfrak{A}_{\mathrm{em}}$.** Kinematic typing uses $\Pi^{[\chi]} \in \mathfrak{A}_{\mathrm{em}}$ satisfying Definition 9.116 (block internality, BRST-closedness, cone-compatibility), with admission by typed hyperbolicity Definition 9.111.

Lemma 9.90 (Syntactic/semantic bar-elimination)**.** *Under Axiom 9.89, any occurrence of a barred symbol $\bar{A}$ renders a formula* ill-typed *in this section. Each construct that might otherwise refer to an expectation-level notion has an operator-level counterpart:*

[1] In some sources one also pushes $\mathfrak{A}_{\mathrm{em}}$ to an "expectation layer" algebra $\overline{\mathfrak{A}}$; $\bar{\cdot}$ covers that image as well.

- *chronogeometry $\hat{\Sigma}_{\mu\nu}$ and probe $\hat{Q}_x[v]$ (Definition 9.95);*
- *cones, retardedness, microcausality (Definitions 9.104 and 9.106 and Proposition 9.108);*
- *typed contrasts/visibilities and quadrants (Definitions 9.127, 9.133 and 9.137);*
- *Parasymmetric meters and T–L–O (Definitions 9.141, 9.143 and 9.147).*

Proposition 9.91 (Gauge-parameter independence in the operator-only regime)**.** *With Axiom 9.89 and BRST hygiene (Definition 9.96 and Proposition 9.97), every scalar diagnostic produced in §9.133–§9.147 is invariant under gauge-parameter changes. In particular, for any BRST-exact variation $\delta_\theta \mathcal{O} = [\hat{Q}_{\mathrm{BRST}}, X_\theta]$, $\partial_\theta \mathcal{I}(\mathcal{O}) = \partial_\theta \mathcal{I}_\Psi(\mathcal{O}) = 0$ (Proposition 9.97 and Lemmas 9.128 and 9.145).*

Proof of Proposition 9.91. Fix a one–parameter gauge choice $\theta \mapsto g_\theta$ and write δ_θ for differentiation at θ. By the operator-only axiom (Axiom 9.89) we work entirely in $\mathfrak{A}_{\mathrm{em}}$, and by BRST hygiene (Definition 9.96) the band taggers satisfy $[\,\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})\,] = [\,\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}\,] = 0$ and the band functionals kill BRST-exact insertions ($\mathcal{I}([\,\hat{Q}_{\mathrm{BRST}}, X]) = \mathcal{I}_\Psi([\,\hat{Q}_{\mathrm{BRST}}, X]) = 0$, Proposition 9.97). Typed projectors are BRST-closed as well ($[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$, Definition 9.116).

Step 1: Pointwise typed contrasts are invariant. By definition (Definition 9.127), the basic inputs are

$$\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x) \quad \text{and} \quad \hat{Q}_x[v]\Big|_{\Pi^{[\chi]}} = \Pi^{[\chi]} \hat{Q}_x[v] \Pi^{[\chi]} \quad (\textit{Definitions 9.95 and 9.109}).$$

Any gauge-parameter variation of these inputs is BRST-exact: $\delta_\theta \hat{Q}_x[v] = [\,\hat{Q}_{\mathrm{BRST}}, X_\theta\,]$ for some band-admissible X_θ (graded covariance, Definition 9.7), and the same holds after typed restriction because $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$:

$$\delta_\theta\Big(\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big) = \Pi^{[\chi]}[\,\hat{Q}_{\mathrm{BRST}}, X_\theta\,]\Pi^{[\chi]} = \Big[\,\hat{Q}_{\mathrm{BRST}},\, \Pi^{[\chi]} X_\theta \Pi^{[\chi]}\,\Big].$$

Applying the band functionals that define the law/state contrasts (Definition 9.127) and using Proposition 9.97 yields

$$\partial_\theta \mathcal{I}\Big[\Big(\hat{Q}_x[v] - \mathrm{Ad}_{g_\theta(x)}\, \hat{Q}_x[v]\Big)\Big|_{\Pi^{[\chi]}}\Big] = \partial_\theta \mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big] - \partial_\theta \mathcal{I}_{g_\theta\cdot\Psi}\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big] = 0.$$

Hence $\partial_\theta \Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law/state}}(g_\theta; x; v) = 0$. This recovers Lemma 9.128.

Step 2: Aggregated contrasts and visibilities are invariant. Aggregation is by weighted ℓ^2-combination over a fixed probe family (Definition 9.131), so by the chain rule and Step 1, $\partial_\theta\, \Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(x; \mathcal{V}, w) = 0$. The typed visibilities are obtained by a fixed normalizer Vis applied to these aggregates (Definition 9.133); therefore $\partial_\theta\, \Lambda^{\Sigma;[\chi]}_{\bullet}(x) = 0$, as summarized in item (a) of Proposition 9.134.

Step 3: Quadrant predicate is invariant. The quadrant assignment depends only on the pair $(\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x), \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x))$ (Definition 9.137). Since this pair is gauge-invariant by Step 2, the quadrant $\mathrm{Quad}^{[\chi]}(x)$ is gauge-invariant as well.

Step 4: Parasymmetric meters and T–L–O are invariant. Band-reduced typed meter states and valuations are defined in Definitions 9.141, 9.143 and 9.144. Because the band restriction

and typed projector commute with $\hat{Q}_{\mathrm{BRST}}$ and the meter maps act at ghost number 0, gauge-parameter variations are BRST-exact and are annihilated by the band functionals that feed the meters; thus all valuations are invariant (Lemma 9.145(b)). The T–L–O triple draws *only* on these visibilities and meters (Definition 9.147); hence $\mathrm{TLO}^{[\chi]}(x;r)$ is gauge-parameter independent.

Combining Steps 1–4 shows that every scalar diagnostic in §9.133–§9.147 (typed visibilities, quadrants, meter valuations, and T–L–O outputs) is invariant under gauge changes. The explicit identities $\partial_\theta \mathcal{I}(\mathcal{O}) = \partial_\theta \mathcal{I}_\Psi(\mathcal{O}) = 0$ for any BRST-exact variation $\delta_\theta \mathcal{O} = [\,\hat{Q}_{\mathrm{BRST}}, X_\theta\,]$ are precisely Proposition 9.97, and the pointwise typed consequence is Lemma 9.128; meters obey Lemma 9.145(b). This completes the proof. □

Corollary 9.92 (Deliverables depend only on $\mathfrak{A}_{\mathrm{em}}$)**.** *All deliverables of §9.174 (permit ledgers, typed Σ–maps, Parasymmetric dashboards, quadrant certificates) are computed purely from* $\mathfrak{A}_{\mathrm{em}}$ *and the band tag, with no reference to any expectation map. Hence* $\mathrm{Del}[\bullet](x)$ *is meaningful and verifiable within the scope of Axiom 9.89.*

Remark 9.93 (Compatibility if an expectation layer is introduced later)**.** While barred objects are excluded here, if a later section introduces an expectation layer, then—by Nielsen safety (Proposition 9.97) and typed hyperbolicity (Definition 9.111)—the operator-level numbers coincide with those obtained by replacing $\mathcal{I}, \mathcal{I}_\Psi$ with compatible expectation-valued functionals on BRST cohomology classes. This remark is out of scope for the present axiom but clarifies forward compatibility.

Definition 9.94 (Unified generalized field and correlator (block form, fourfold modes))**.** Let the generalized field be

$$\hat{\mathbf{F}}(x) = \Big(\hat{\mathbf{\Phi}}(x),\, \hat{\mathbf{\Theta}}(x)\Big)^{\mathsf{T}},$$

and the unified inter-modal correlator (Definition 6.4) be written in block form over the geometry/matter split and the fourfold dialectical basis $\{0, 1, p, s\}$ (Section 1.4.2 and Definition 4.9):

$$\hat{\mathbf{G}}_\Lambda(x,x') = \begin{pmatrix} \hat{G}_{\Phi\Phi}(x,x') & \hat{G}_{\Phi\Theta}(x,x') \\ \hat{G}_{\Theta\Phi}(x,x') & \hat{G}_{\Theta\Theta}(x,x') \end{pmatrix}, \qquad \text{cf. eq. (9.12).} \tag{9.36}$$

Parallel transport and grading are those of Definition 9.7.

Definition 9.95 (Operator chronogeometry and Σ-probe)**.** The operator-valued unified chronogeometric tensor is

$$\hat{\Sigma}_{\mu\nu} \;=\; \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu} \qquad \text{(cf. Definition 5.25)}, \tag{9.37}$$

and its band-local quadratic probe is

$$\hat{Q}_x[v] \;:=\; v^\mu v^\nu\, \hat{\Sigma}_{\mu\nu}(x), \qquad \text{cf. Definition 9.22.} \tag{9.38}$$

Definition 9.96 (Band instrumentation and BRST-closed taggers)**.** The band tag is

$$\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = \Big(P_x(\lambda_{\mathrm{UV}}),\, K^{(\ell)}_{\mathrm{IR}}\Big),$$

where $P_x(\lambda_{\mathrm{UV}})$ is the UV projector (Definition 7.26 and eq. (7.29)) and $K_{\mathrm{IR}}^{(\ell)}$ is the IR kernel/window (Definition 9.10). Both are ghost number 0 and commute with the BRST charge:

$$[\,\hat{Q}_{\mathrm{BRST}},\, P_x(\lambda_{\mathrm{UV}})\,] = [\,\hat{Q}_{\mathrm{BRST}},\, K_{\mathrm{IR}}^{(\ell)}\,] = 0 \qquad \text{(cf. Lemma 9.54).} \tag{9.39}$$

Band functionals $\mathcal{I}, \mathcal{I}_\Psi$ are assumed admissible as in Definitions 9.45 and 9.47.

Proposition 9.97 (Nielsen safety on the band)**.** *If $\mathcal{I}, \mathcal{I}_\Psi$ satisfy the BRST-annihilation property of Definition 9.45, then for any band-supported operator $\mathcal{O}$ whose gauge-parameter variation is BRST-exact, $\delta_\theta \mathcal{O} = [\,\hat{Q}_{\mathrm{BRST}}, X_\theta]$, one has*

$$\partial_\theta\, \mathcal{I}(\mathcal{O}) = \mathcal{I}([\,\hat{Q}_{\mathrm{BRST}}, X_\theta]) = 0, \qquad \partial_\theta\, \mathcal{I}_\Psi(\mathcal{O}) = \mathcal{I}_\Psi([\,\hat{Q}_{\mathrm{BRST}}, X_\theta]) = 0.$$

Hence all band readouts used in this section are gauge-parameter independent without invoking expectation values (cf. Lemma 9.54).

Proof of Proposition 9.97. Let $\theta \mapsto \mathcal{O}(\theta)$ be a band-supported operator family with gauge-parameter variation $\delta_\theta \mathcal{O} = [\,\hat{Q}_{\mathrm{BRST}}, X_\theta]$, where X_θ is band-admissible. By construction of the band functionals (Definitions 9.45 and 9.96), $\mathcal{I}$ and $\mathcal{I}_\Psi$ are linear and continuous on the band algebra (ghost number 0 output). Hence differentiation passes under the functionals:

$$\partial_\theta\, \mathcal{I}(\mathcal{O}) = \mathcal{I}(\partial_\theta \mathcal{O}), \qquad \partial_\theta\, \mathcal{I}_\Psi(\mathcal{O}) = \mathcal{I}_\Psi(\partial_\theta \mathcal{O}). \tag{9.40}$$

Inserting $\partial_\theta \mathcal{O} = [\,\hat{Q}_{\mathrm{BRST}}, X_\theta]$ and using the *BRST-annihilation* property of the band functionals

$$\mathcal{I}([\,\hat{Q}_{\mathrm{BRST}}, Y]) = \mathcal{I}_\Psi([\,\hat{Q}_{\mathrm{BRST}}, Y]) = 0 \quad \text{for all band-admissible } Y \qquad \text{(Definition 9.45)},$$

we obtain

$$\partial_\theta\, \mathcal{I}(\mathcal{O}) = \mathcal{I}([\,\hat{Q}_{\mathrm{BRST}}, X_\theta]) = 0, \qquad \partial_\theta\, \mathcal{I}_\Psi(\mathcal{O}) = \mathcal{I}_\Psi([\,\hat{Q}_{\mathrm{BRST}}, X_\theta]) = 0,$$

which is the desired Nielsen (gauge-parameter) independence on the band.

Typed/restricted observables. If $\mathcal{O}$ enters through a typed restriction $\mathcal{O}\big|_{\Pi^{[\chi]}} = \Pi^{[\chi]} \mathcal{O}\, \Pi^{[\chi]}$ (as in Definitions 9.109 and 9.127), then by BRST-closedness of the projector $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116) we have

$$\delta_\theta\Big(\mathcal{O}\big|_{\Pi^{[\chi]}}\Big) = \Pi^{[\chi]}[\,\hat{Q}_{\mathrm{BRST}}, X_\theta]\Pi^{[\chi]} = \Big[\,\hat{Q}_{\mathrm{BRST}},\, \Pi^{[\chi]} X_\theta \Pi^{[\chi]}\,\Big],$$

so the same annihilation argument applies and the conclusion holds verbatim for all typed band readouts (contrasts/visibilities Definition 9.133, meter valuations Definitions 9.143 and 9.144, and T–L–O outputs Definition 9.147).

This establishes the proposition; see also its use in Lemmas 9.128 and 9.145 and Proposition 9.91. □

Definition 9.98 (Σ–pre-physical covector cone)**.** Define the covector cone at x by

$$\mathcal{C}_x^{\hat{\Sigma},*} := \Big\{ k \in T_x^* \setminus \{0\} : \sup_{\Psi \in \mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x)\Big] \le 0 \Big\}, \tag{9.41}$$

with null boundary at 0, timelike interior determined by $\inf_\Psi \mathcal{I}_\Psi(\hat{Q}_x[k]) > 0$ (cf. Definitions 9.20 and 9.22). The IR window $K_{\mathrm{IR}}^{(\ell)}$ may *shrink* but never enlarge $\mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.10).

Lemma 9.99 (Causal gate and microcausality from $\hat{\Sigma}$)**.** *Let the Σ–pre-physical cone $\mathcal{C}_x^{\hat{\Sigma},*}$ be as in Definition 9.104 and let kernels be retarded and cone-gated as in Definition 9.106. If f, g have supports spacelike separated with respect to $\mathcal{C}^{\hat{\Sigma},*}$, then*

$$[\,\hat{\mathbf{\Phi}}(f), \hat{\mathbf{\Phi}}(g)\,] = [\,\hat{\mathbf{\Theta}}(f), \hat{\mathbf{\Theta}}(g)\,] = 0,$$

and every response kernel used in this section is supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ (i.e. retarded and cone-gated).

Proof. By Definition 9.106, any kernel $\mathcal{K}$ is replaced by its retarded, cone-gated version $\mathcal{K}^{\mathrm{ret}}(x, x') = \mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}(x, x')\,\mathcal{K}(x, x')$. Proposition 9.107 asserts that this gating preserves band-admissibility and graded covariance, and enforces retarded support inside $J^+(\mathcal{C}^{\hat{\Sigma},*})$. Hence all response kernels constructed downstream are retarded and cone-gated.

For the commutators, let f, g be test functions with supports spacelike separated relative to $\mathcal{C}^{\hat{\Sigma},*}$. The microcausality statement follows directly from Proposition 9.108, which states that, with respect to the Σ–cone, the smeared field commutators vanish outside the causal domain:

$$[\,\hat{\mathbf{\Phi}}(f), \hat{\mathbf{\Phi}}(g)\,] = [\,\hat{\mathbf{\Theta}}(f), \hat{\mathbf{\Theta}}(g)\,] = 0 \quad \text{whenever} \quad \mathrm{supp}(f) \text{ and } \mathrm{supp}(g) \text{ are spacelike.}$$

Equivalently, in distributional form the commutator kernels have support contained in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big) \cup J^-\big(\mathcal{C}^{\hat{\Sigma},*}\big)$; for spacelike-separated supports the double integral against $f \otimes g$ vanishes, yielding the identities above.

Therefore, $\hat{\Sigma}$ via the cone $\mathcal{C}^{\hat{\Sigma},*}$ supplies both the causal gate (retarded, cone-gated kernels by Definition 9.106 and Proposition 9.107) and microcausality (vanishing of spacelike commutators by Proposition 9.108). □

Definition 9.100 (Typed kinematic labels (pre-physical))**.** Typed labels χ (spins/helicities/polarizations) are *admissible* only within the diagonal blocks $\Phi\Phi$ (apeiron/Gaiamiti) and $\Theta\Theta$ (kymon/Tantrakyma) of $\hat{\mathbf{G}}_\Lambda$ (Definition 6.4), and are implemented by graded, cone-compatible projectors $\Pi^{[\chi]}$ constructed inside each block (cf. Definitions 9.7 and 9.31 and eq. (9.12)). No graviton/particle language is permitted below Planckian.

Definition 9.101 (Typed hyperbolicity (admission test))**.** A label χ is *typed-hyperbolic* at x if for every cone-timelike covector $k \in \mathcal{C}_x^{\hat{\Sigma},*}$,

$$\inf_{\Psi \in \mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[\, \hat{Q}_x[k] \,\Big|_{\Pi^{[\chi]}}\Big] \;>\; 0. \tag{9.42}$$

Proposition 9.102 (Permit ledger)**.** *The set of* admissible *typed labels is*

$$\mathcal{C}^{[\mathrm{apeiron}]}_{\mathrm{admissible}} \subset \mathrm{End}(\Phi\Phi), \qquad \mathcal{C}^{[\mathrm{kymon}]}_{\mathrm{admissible}} \subset \mathrm{End}(\Theta\Theta),$$

where $\chi \in \mathcal{C}^{[\cdot]}_{\mathrm{admissible}}$ iff $\Pi^{[\chi]}$ is band-finite, graded-covariant (Definition 9.7), cone-compatible (Definition 9.98), and satisfies typed hyperbolicity (9.42) with stability under small retunings of $(\lambda_{\mathrm{UV}}, \ell)$ (Definition 9.10).

Proof of Proposition 9.102. We prove necessity and sufficiency.

(⇒) Necessity. Assume $\chi \in \mathcal{C}^{[\bullet]}_{\text{admissible}}$ with $\bullet \in \{\Phi\Phi, \Theta\Theta\}$. By the very definition of the permit ledger (Definition 9.122), there exists a typed projector $\Pi^{[\chi]}$ admitted in block $\bullet$ that satisfies the axioms of Definition 9.116 together with the typed hyperbolicity condition (Definition 9.111, eq. (9.53)). Hence:

- *Block internality:* $\Pi^{[\chi]} \in \mathrm{End}(\bullet)$ by Definition 9.116(P2), so χ is recorded in the corresponding set $\mathcal{C}^{[\bullet]}_{\text{admissible}}$.
- *Band-finiteness:* $\Pi^{[\chi]}$ commutes with the band taggers and is supported on the band by Definition 9.116(P3) (cf. band instrumentation Definition 9.96).
- *Graded covariance:* under graded transport g, $\Pi^{[\chi]} \mapsto g\,\Pi^{[\chi]} g^{\dagger}$ by Definition 9.116(P5) (see also Definition 9.7).
- *Cone-compatibility:* positivity of the Σ–probe on timelike covectors within the Σ–cone holds after restriction by $\Pi^{[\chi]}$ by Definition 9.116(P6), using the cone of Definition 9.104.
- *Typed hyperbolicity:* the principal form positivity on $\mathcal{C}^{\hat{\Sigma},*}$ after restriction is precisely (9.53) (Definition 9.111).
- *Stability under retunings:* continuity in $(\lambda_{\mathrm{UV}}, \ell)$ holds by Definition 9.116(P7), with the parameters defined for the band in Definition 9.96.

Therefore every admitted χ satisfies all properties listed in the statement.

(⇐) Sufficiency. Conversely, let $\Pi^{[\chi]}$ be a projector in block $\bullet$ that is band-finite, graded-covariant (Definition 9.7), cone-compatible with the Σ–cone (Definition 9.104), satisfies typed hyperbolicity (9.53), and is stable under small retunings of $(\lambda_{\mathrm{UV}}, \ell)$ (Definition 9.96). Then $\Pi^{[\chi]}$ fulfills items (P1)–(P7) of Definition 9.116, so by Definition 9.122 the label χ is *admitted* and belongs to $\mathcal{C}^{[\bullet]}_{\text{admissible}}$. Moreover, the cone/hyperbolicity/stability data constitute the certificate attached to χ (Corollary 9.120).

Existence (constructive aside). When needed, such projectors can be constructed spectrally from Σ–weighted mode operators, with Riesz projectors onto isolated spectral bands (Proposition 9.119); this automatically yields band-finiteness, graded covariance, and the stability radius used above.

Thus, the admissible sets are exactly those stated, completing the proof. □

Corollary 9.103 (Scope discipline)**.** *Typed labels χ defined in Definition 9.100 are the only kinematic labels used below Planckian. Any map of χ-sectors to graviton/particle content is deferred to the expectation-level framework and lies outside the present operator-only regime (cf. Definition 5.25 vs. Definition 5.10).*

Remarks on consistency.

- The ingredients (9.36), (9.37), (9.38) re-state, with explicit band locality, the earlier definitions Definitions 5.25, 6.4 and 9.22. All subsequent typed diagnostics (contrasts/visibilities) that will be introduced in §1–§3 refer back to Definitions 9.45 and 9.47 and eq. (9.22) and will be restricted by $\Pi^{[\chi]}$ in the sense of Definition 9.100.

- BRST hygiene (9.39) and Proposition 9.97 implement band-level Nielsen safety exactly as in Lemma 9.54, but without any use of expectation values.
- The cone functoriality "IR shrinks, never enlarges" invoked in Definition 9.98 follows from the monotonicity of $K_{\mathrm{IR}}^{(\ell)}$ in Definition 9.10.

9.9 Σ–Pre-physical Cones and Causality (Operator Level)

Definition 9.104 (Σ–pre-physical covector cone at x)**.** Let $\hat{\Sigma}_{\mu\nu}$ and the Σ–probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ be as in Definitions 5.25 and 9.22 (see also the band-local restatement Definition 9.95). The Σ–*pre-physical covector cone* at x is

$$\mathcal{C}_x^{\hat{\Sigma},*} := \Big\{ k \in T_x^*\backslash\{0\} \ : \ \sup_{\Psi\in\mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x)\Big] \le 0 \Big\}, \tag{9.43}$$

with *null* boundary given by equality to 0 and *timelike interior* characterized by $\inf_{\Psi\in\mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\big[\hat{Q}_x[k]\big] > 0$. This definition is equivalent to the restated cone in Definition 9.98, but we fix here the label Definition 9.104 for subsequent use.

Lemma 9.105 (IR windowing shrinks, never enlarges, the cone)**.** *Let* $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ *be as in Definitions 7.26 and 9.10. If* $\ell' \le \ell$ *(stronger IR windowing), then*

$$\mathcal{C}_x^{\hat{\Sigma},*}\big[\ell'\big] \ \subseteq \ \mathcal{C}_x^{\hat{\Sigma},*}\big[\ell\big].$$

Proof of Lemma 9.105. Recall the Σ–pre-physical covector cone at x (Definition 9.104):

$$\mathcal{C}_x^{\hat{\Sigma},*}[\ell] \ := \ \Big\{ k \in T_x^*\backslash\{0\} \ : \ \sup_{\Psi\in\mathcal{S}_{\mathrm{band}}(\ell)} \mathcal{I}_\Psi\Big[k^\mu k^\nu \, \hat{\Sigma}_{\mu\nu}(x)\Big] \ \le \ 0 \Big\}, \tag{9.44}$$

where $\mathcal{S}_{\mathrm{band}}(\ell)$ denotes band-admissible states/functionals under $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.10). Equivalently, writing the IR-gating map $\Gamma_\ell(A) := K_{\mathrm{IR}}^{(\ell)} A K_{\mathrm{IR}}^{(\ell)}$, (9.44) is

$$\mathcal{C}_x^{\hat{\Sigma},*}[\ell] = \Big\{ k \neq 0 : \ \sup_{\Psi\in\mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[k^\mu k^\nu \, \Gamma_\ell(\hat{\Sigma}_{\mu\nu})(x)\Big] \ \le \ 0 \Big\},$$

since the band functionals act after the IR gate (Definition 9.10).

Step 1 (IR monotonicity of the gate). By Definition 7.26, the family $\{K_{\mathrm{IR}}^{(\ell)}\}$ is positive, cone-preserving, and *monotone in the sense that for* $\ell' \le \ell$ *one has*

$$\Gamma_{\ell'}(A) \ - \ \Gamma_\ell(A) \ \succeq \ 0 \quad \text{for every operator } A \text{ supported on the future cone sheet,} \tag{9.45}$$

i.e. a stronger IR window cannot add past-directed (or non-causal) support and can only *increase* the future-directed part of A (cf. the cone-gating of Definition 9.106 and causal support of Proposition 9.107).

Step 2 (Monotonicity of band readouts). Fix k and x. For future-sheet contributions of $k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x)$, Lemma 9.129 gives positivity of the induced quadratic form under band

functionals. Combining with (9.45) and positivity of $\mathcal{I}_\Psi$ on the band (Definition 9.10), we get, for every Ψ,

$$\mathcal{I}_\Psi\Big[k^\mu k^\nu\,\Gamma_{\ell'}(\hat{\Sigma}_{\mu\nu})(x)\Big] \;\geq\; \mathcal{I}_\Psi\Big[k^\mu k^\nu\,\Gamma_{\ell}(\hat{\Sigma}_{\mu\nu})(x)\Big] \qquad (\ell' \leq \ell). \tag{9.46}$$

Taking suprema over Ψ preserves the inequality:

$$\sup_\Psi\; \mathcal{I}_\Psi\Big[k^\mu k^\nu\,\Gamma_{\ell'}(\hat{\Sigma}_{\mu\nu})(x)\Big] \;\geq\; \sup_\Psi\; \mathcal{I}_\Psi\Big[k^\mu k^\nu\,\Gamma_{\ell}(\hat{\Sigma}_{\mu\nu})(x)\Big]. \tag{9.47}$$

Step 3 (Inclusion of cones). Suppose $k \in \mathcal{C}_x^{\hat{\Sigma},*}[\ell']$. By (9.44) (with gating) and (9.47),

$$0 \;\geq\; \sup_\Psi\; \mathcal{I}_\Psi\Big[k^\mu k^\nu\,\Gamma_{\ell'}(\hat{\Sigma}_{\mu\nu})(x)\Big] \;\geq\; \sup_\Psi\; \mathcal{I}_\Psi\Big[k^\mu k^\nu\,\Gamma_{\ell}(\hat{\Sigma}_{\mu\nu})(x)\Big],$$

hence $k \in \mathcal{C}_x^{\hat{\Sigma},*}[\ell]$. Therefore $\mathcal{C}_x^{\hat{\Sigma},*}[\ell'] \subseteq \mathcal{C}_x^{\hat{\Sigma},*}[\ell]$.

Conclusion. A stronger IR window (smaller ℓ) makes the Σ–cone test (9.44) *harder* to satisfy (the supremum moves upward by (9.47)), so membership can only be lost: the cone *shrinks*, never enlarges. □

Definition 9.106 (Future cone-gate and retarded domain)**.** Let $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ denote the *future cone domain* determined by $\mathcal{C}_x^{\hat{\Sigma},*}$, i.e. pairs (x,x') such that there exists a $\hat{\Sigma}$–causal curve from x' to x whose cotangent legs lie in $\mathcal{C}^{\hat{\Sigma},*}$. For any (graded-covariant) kernel $\mathcal{K}(x,x')$ we define its *retarded cone-gated* version by

$$(\mathcal{K}^{\mathrm{ret}})(x,x') \;:=\; \mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}(x,x')\,\mathcal{K}(x,x'),$$

where $\mathbf{1}_{J^+}$ is the characteristic function. (Graded covariance follows from Definition 9.7.)

Proposition 9.107 (Retardedness of band kernels)**.** *Let $\mathcal{K}$ be any band-admissible kernel (e.g. those used in defining the contrasts/visibilities of Definitions 9.45 and 9.47). Then $\mathcal{K}^{\mathrm{ret}}$ of Definition 9.106 is retarded and supported inside $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$; moreover, the operation $\mathcal{K} \mapsto \mathcal{K}^{\mathrm{ret}}$ is compatible with band instrumentation $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.10) and with BRST (ghost number 0, cf. Lemma 9.54).*

Proof of Proposition 9.107. Write any band-admissible kernel $\mathcal{K}$ as an integral operator on test functions,

$$(\mathcal{K}f)(x) \;=\; \int \mathcal{K}(x,x')\,f(x')\,\mathrm{d}x',$$

with $\mathcal{K}$ belonging to the band-closed operator class of Definition 9.10. By the cone gate definition (Definition 9.106) the retarded version is

$$\mathcal{K}^{\mathrm{ret}}(x,x') \;:=\; \mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}(x,x')\;\mathcal{K}(x,x'), \tag{9.48}$$

where $\mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}$ is the (idempotent) indicator of the Σ–causal future determined by the cone $\mathcal{C}^{\hat{\Sigma},*}$ (Definition 9.104).

(i) Retardedness and cone support. By (9.48), $\operatorname{supp}\mathcal{K}^{\mathrm{ret}} \subseteq J^+(\mathcal{C}^{\hat{\Sigma},*})$, so $\mathcal{K}^{\mathrm{ret}}$ is retarded and cone-gated by construction (restating Definition 9.106). No support can appear outside $J^+(\mathcal{C}^{\hat{\Sigma},*})$ because the gate $\mathbf{1}_{J^+}$ vanishes there.

(ii) Compatibility with band instrumentation $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$. Let the UV projector $P_x(\lambda_{\mathrm{UV}})$ act by left/right multiplication on the (x,x') slots (cf. Definition 9.10). Then

$$\Big(P_x(\lambda_{\mathrm{UV}})\,\mathcal{K}\Big)^{\mathrm{ret}}(x,x') = \mathbf{1}_{J^+}(x,x')\,P_x(\lambda_{\mathrm{UV}})\,\mathcal{K}(x,x') = P_x(\lambda_{\mathrm{UV}})\,\mathcal{K}^{\mathrm{ret}}(x,x'),$$

and similarly on the right slot with $P_{x'}(\lambda_{\mathrm{UV}})$. Thus the gate commutes with UV localization at the level of kernels, and band-admissibility is preserved.

For the IR filter $K_{\mathrm{IR}}^{(\ell)}$, let Γ_ℓ denote the IR-gating superoperator (Definition 9.10). Since Γ_ℓ acts at ghost number 0 and preserves the cone (Definition 9.106), we have

$$\Big(\Gamma_\ell\mathcal{K}\Big)^{\mathrm{ret}} = \mathbf{1}_{J^+}\,\Gamma_\ell(\mathcal{K}) = \Gamma_\ell\Big(\mathbf{1}_{J^+}\,\mathcal{K}\Big) = \Gamma_\ell\Big(\mathcal{K}^{\mathrm{ret}}\Big), \tag{9.49}$$

i.e. retarded gating and IR filtering commute within the admissible class. Hence the map $\mathcal{K}\mapsto\mathcal{K}^{\mathrm{ret}}$ is compatible with $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ and preserves band-admissibility.

(iii) BRST compatibility (ghost number 0). The indicator $\mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}$ is a c–number gate determined by the Σ–cone (it carries no ghost number). Therefore, for the BRST derivation one has

$$[\,\hat{Q}_{\mathrm{BRST}},\mathcal{K}^{\mathrm{ret}}\,] = [\,\hat{Q}_{\mathrm{BRST}},\ \mathbf{1}_{J^+}\,\mathcal{K}\,] = \mathbf{1}_{J^+}\,[\,\hat{Q}_{\mathrm{BRST}},\mathcal{K}\,] = \Big([\,\hat{Q}_{\mathrm{BRST}},\mathcal{K}\,]\Big)^{\mathrm{ret}}.$$

In particular, if $\mathcal{K}$ is BRST-closed at ghost number 0 (the case for our band kernels; see Lemma 9.54 and Definition 9.96), then so is $\mathcal{K}^{\mathrm{ret}}$. This establishes BRST compatibility.

Combining (i)–(iii) proves that the retarded gate (9.48) yields kernels supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$, preserves band-admissibility and UV/IR instrumentation (Definition 9.10), and is compatible with BRST at ghost number 0. Hence the claim. □

Proposition 9.108 (Microcausality from cone-gating)**.** *Let f,g be test functions with supports spacelike separated with respect to $\mathcal{C}^{\hat{\Sigma},*}$. Then*

$$\Big[\,\hat{\mathbf{\Phi}}(f),\hat{\mathbf{\Phi}}(g)\,\Big] \;=\; \Big[\,\hat{\mathbf{\Theta}}(f),\hat{\mathbf{\Theta}}(g)\,\Big] \;=\; 0, \tag{9.50}$$

for the generalized field $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}},\hat{\mathbf{\Theta}})^{\mathsf{T}}$ (Definition 9.94). In particular, any cone-gated retarded kernel $\mathcal{K}^{\mathrm{ret}}$ from Definition 9.106 yields vanishing commutators outside $J^+\Big(\mathcal{C}^{\hat{\Sigma},*}\Big)$.

Proof of Proposition 9.108. Let $\mathcal{C}_x^{\hat{\Sigma},*}$ be the Σ–pre-physical cone (Definition 9.104) and let the cone-gated retarded indicator be $\mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}$ as in Definition 9.106. By Definition 9.94, the unified field $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}},\hat{\mathbf{\Theta}})^{\mathsf{T}}$ is an operator-valued distribution, and for any test functions f,g we define the smeared operators $\hat{\mathbf{\Phi}}(f) = \int \hat{\mathbf{\Phi}}(x)\,f(x)\,\mathrm{d}x$ and similarly for $\hat{\mathbf{\Theta}}(g)$.

Step 1: Commutator as a distribution with causal support. Consider the bi-distribution (Pauli–Jordan–like kernel) for each block

$$\Delta_{\Phi\Phi}(x,x') \;:=\; \Big[\hat{\mathbf{\Phi}}(x),\hat{\mathbf{\Phi}}(x')\Big], \qquad \Delta_{\Theta\Theta}(x,x') \;:=\; \Big[\hat{\mathbf{\Theta}}(x),\hat{\mathbf{\Theta}}(x')\Big].$$

Any band-admissible kernel used to construct $\hat{\mathbf{F}}$ is replaced by its retarded, cone-gated form $\mathcal{K}^{\mathrm{ret}}(x,x') = \mathbf{1}_{J^+}(x,x')\,\mathcal{K}(x,x')$ (Definition 9.106), and this operation is compatible with

the band instrumentation (Definition 9.10) and preserves retarded (future-directed) support (Proposition 9.107). By antisymmetry of the commutator and the fact that advanced parts arise by exchanging the slots, it follows that

$$\operatorname{supp}\Delta_{\Phi\Phi} \;\subseteq\; J^{+}\!\big(\mathcal{C}^{\hat{\Sigma},*}\big) \;\cup\; J^{-}\!\big(\mathcal{C}^{\hat{\Sigma},*}\big), \qquad \operatorname{supp}\Delta_{\Theta\Theta} \;\subseteq\; J^{+}\!\big(\mathcal{C}^{\hat{\Sigma},*}\big) \;\cup\; J^{-}\!\big(\mathcal{C}^{\hat{\Sigma},*}\big), \tag{9.51}$$

i.e. the commutator kernels have no support at spacelike-separated pairs with respect to the Σ–cone.

Step 2: Vanishing for spacelike-separated test functions. Let f, g be test functions with $\operatorname{supp}(f)$ and $\operatorname{supp}(g)$ spacelike separated relative to $\mathcal{C}^{\hat{\Sigma},*}$. Smearing the commutators yields

$$\big[\hat{\mathbf{\Phi}}(f), \hat{\mathbf{\Phi}}(g)\big] = \iint \Delta_{\Phi\Phi}(x,x')\, f(x)\, g(x')\, \mathrm{d}x\, \mathrm{d}x',$$
$$\big[\hat{\mathbf{\Theta}}(f), \hat{\mathbf{\Theta}}(g)\big] = \iint \Delta_{\Theta\Theta}(x,x')\, f(x)\, g(x')\, \mathrm{d}x\, \mathrm{d}x'.$$

Because $\operatorname{supp}\Delta_{\bullet\bullet}$ is contained in the causal sets (9.51) while $\operatorname{supp}(f) \times \operatorname{supp}(g)$ is disjoint from those sets (spacelike separation), each double integral vanishes by the standard support property of distributions. Hence

$$\big[\,\hat{\mathbf{\Phi}}(f), \hat{\mathbf{\Phi}}(g)\,\big] = \big[\,\hat{\mathbf{\Theta}}(f), \hat{\mathbf{\Theta}}(g)\,\big] = 0,$$

which is (9.50).

Step 3: Cone-gated retarded kernels produce vanishing commutators outside J^+. Conversely, let $\mathcal{K}^{\mathrm{ret}}$ be any cone-gated retarded kernel (Definition 9.106). By Proposition 9.107, $\operatorname{supp}\mathcal{K}^{\mathrm{ret}} \subseteq J^{+}(\mathcal{C}^{\hat{\Sigma},*})$, so any commutator built from such kernels has bi-support contained in $J^{+} \cup J^{-}$ as in (9.51). Therefore commutators vanish whenever the argument supports fall outside $J^{+}(\mathcal{C}^{\hat{\Sigma},*})$.

Combining Steps 1–3 establishes microcausality with respect to the Σ–cone and the stated property for cone-gated retarded kernels. □

Definition 9.109 (Typed restriction of the Σ–probe)**.** For a typed projector $\Pi^{[\chi]}$ (constructed within the diagonal blocks as in Definitions 9.100 and 9.116), define the *typed* Σ–probe by

$$\hat{Q}^{[\chi]}_x[k] \;:=\; \Pi^{[\chi]}\, \hat{Q}_x[k]\, \Pi^{[\chi]} \;=\; \Pi^{[\chi]}\, k^{\mu} k^{\nu} \hat{\Sigma}_{\mu\nu}(x)\, \Pi^{[\chi]}. \tag{9.52}$$

Lemma 9.110 (Typed principal form is Hermitian and gauge-covariant)**.** *For any timelike $k \in \mathcal{C}^{\hat{\Sigma},*}_x$ the operator $\hat{Q}^{[\chi]}_x[k]$ of (9.52) is Hermitian and transforms covariantly under local graded-gauge changes (by Definitions 5.25 and 9.7). Hence its band functionals $\mathcal{I}_{\Psi}\big[\hat{Q}^{[\chi]}_x[k]\big]$ are real and frame-independent on the band (Definition 9.96).*

Proof of Lemma 9.110. Recall the Σ–probe and its typed restriction:

$$\hat{Q}_x[v] := v^{\mu} v^{\nu}\, \hat{\Sigma}_{\mu\nu}(x) \quad \text{(Definition 9.95)},$$
$$\hat{Q}^{[\chi]}_x[v] := \Pi^{[\chi]}\, \hat{Q}_x[v]\, \Pi^{[\chi]} \quad \text{(cf. (9.52), Definitions 9.109 and 9.116)}.$$

Fix $k \in \mathcal{C}_x^{\hat{\Sigma},*}$ timelike (Definition 9.104).

(a) Hermiticity. By the operator-unified chronogeometry (Definition 5.25), $\hat{\Sigma}_{\mu\nu}(x)$ is Hermitian (self-adjoint) for each index pair, and for real covectors k^μ one has

$$\hat{Q}_x[k]^\dagger = \big(k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x)\big)^\dagger = k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x) = \hat{Q}_x[k].$$

Typed projectors $\Pi^{[\chi]}$ are Hermitian idempotents in the block algebra (Definition 9.116), hence

$$\big(\hat{Q}_x^{[\chi]}[k]\big)^\dagger = \Pi^{[\chi]}\,\hat{Q}_x[k]\,\Pi^{[\chi]} = \hat{Q}_x^{[\chi]}[k],$$

so $\hat{Q}_x^{[\chi]}[k]$ is Hermitian.

(b) Graded-gauge covariance. Under a local graded-gauge transport g (Definition 9.7), $\hat{\Sigma}_{\mu\nu} \mapsto \mathrm{Ad}_{g(x)}\,\hat{\Sigma}_{\mu\nu}$, whence $\hat{Q}_x[k] \mapsto \mathrm{Ad}_{g(x)}\,\hat{Q}_x[k]$. Typed projectors transform covariantly as $\Pi^{[\chi]} \mapsto \mathrm{Ad}_{g(x)}\,\Pi^{[\chi]}$ (Definition 9.116). Therefore

$$\hat{Q}_x^{[\chi]}[k] \;\mapsto\; \mathrm{Ad}_{g(x)}\big(\Pi^{[\chi]}\hat{Q}_x[k]\Pi^{[\chi]}\big) = \big(\mathrm{Ad}_{g(x)}\,\Pi^{[\chi]}\big)\big(\mathrm{Ad}_{g(x)}\,\hat{Q}_x[k]\big)\big(\mathrm{Ad}_{g(x)}\,\Pi^{[\chi]}\big),$$

i.e. $\hat{Q}_x^{[\chi]}[k]$ transforms by conjugation (covariantly) under graded-gauge changes.

(c) Reality and frame-independence of band evaluations. Band functionals $\mathcal{I}, \mathcal{I}_\Psi$ act at ghost number 0 and satisfy $\mathcal{I}(A^\dagger) = \overline{\mathcal{I}(A)}$, $\mathcal{I}_\Psi(A^\dagger) = \overline{\mathcal{I}_\Psi(A)}$, with real range on Hermitian inputs (Definition 9.96). Since $\hat{Q}_x^{[\chi]}[k]$ is Hermitian by (a), $\mathcal{I}_\Psi\big[\hat{Q}_x^{[\chi]}[k]\big] \in \mathbb{R}$. For frame-independence, use graded covariance: for any local g,

$$\mathcal{I}_{g\cdot\Psi}\big[\hat{Q}_x^{[\chi]}[k]\big] = \mathcal{I}_\Psi\big[\,\mathrm{Ad}_{g(x)}\,\hat{Q}_x^{[\chi]}[k]\big] \quad \text{(Definitions 9.7 and 9.127)},$$

so the scalar readout is invariant under simultaneous (co-)transform of observable and band state. Moreover, by Nielsen safety on the band (Proposition 9.97) any gauge-parameter variation that is BRST-exact leaves $\mathcal{I}, \mathcal{I}_\Psi$ unchanged; hence the value is independent of the choice of graded-gauge frame within the band.

Combining (a)–(c) proves the claim: $\hat{Q}_x^{[\chi]}[k]$ is Hermitian, transforms covariantly, and its band evaluations are real and frame-independent.

□

Definition 9.111 (Typed hyperbolicity (operator test, rephrased))**.** A typed subspace χ is *hyperbolic* at x if

$$\inf_{\Psi \in \mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\big[\,\hat{Q}_x^{[\chi]}[k]\,\big] \;>\; 0 \quad \text{for all timelike } k \in \mathcal{C}_x^{\hat{\Sigma},*}, \tag{9.53}$$

which is the typed version of (9.42) (cf. Definition 9.101).

Proposition 9.112 (Typed hyperbolicity ⇒ well-posedness on the band)**.** *Assume Definition 9.111. Then for every compact band window and for every timelike covector k, the quadratic form $\Psi \mapsto \mathcal{I}_\Psi\big[\hat{Q}_x^{[\chi]}[k]\big]$ is strictly positive, yielding an a priori energy estimate for the typed sector χ. In particular, χ admits a retarded Green operator supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$, compatible with Proposition 9.107.*

Proof of Proposition 9.112. Fix a permitted type χ and a compact band window $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.96). Recall the typed principal operator and its quadratic form

$$\hat{Q}_x^{[\chi]}[k] \;:=\; \Pi^{[\chi]}\,\hat{Q}_x[k]\,\Pi^{[\chi]} \quad \text{with} \quad \hat{Q}_x[k] = k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x) \quad \text{(Definitions 9.95 and 9.109)}.$$

By Lemma 9.110, $\hat{Q}_x^{[\chi]}[k]$ is Hermitian and gauge-covariant; hence $\mathcal{I}_\Psi[\hat{Q}_x^{[\chi]}[k]] \in \mathbb{R}$ for all band functionals $\mathcal{I}_\Psi$ (Definition 9.96).

Step 1: Strict positivity (coercivity) on the band. Typed hyperbolicity (Definition 9.111, eq. (9.53)) asserts that for every cone-timelike $k \in \mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104)

$$\inf_{\Psi \in \mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[\hat{Q}_x^{[\chi]}[k]\Big] \;>\; 0. \tag{9.54}$$

Consequently, the band energy functional $\mathcal{E}_k^{[\chi]}[\Psi] := \mathcal{I}_\Psi[\hat{Q}_x^{[\chi]}[k]]$ is a strictly positive quadratic form on the (ghost number 0) band class. For any fixed compact band window the infimum in (9.54) is bounded away from 0 uniformly in x (by compactness plus the stability clause of Definition 9.116); thus $\mathcal{E}_k^{[\chi]}$ is *coercive* on the band. This yields the claimed "a priori energy" estimate:

$$\mathcal{E}_k^{[\chi]}[\Psi] \;\geq\; c_k\,\|\Psi\|_{\mathrm{band}}^2, \qquad c_k > 0, \tag{9.55}$$

for some band norm $\|\cdot\|_{\mathrm{band}}$ equivalent to $\Psi \mapsto \mathcal{E}_k^{[\chi]}[\Psi]^{1/2}$ on the window.

Step 2: Retarded parametrix and Green operator. Let $\mathcal{L}^{[\chi]}$ denote any band-evolution operator whose principal quadratic form at $(x;k)$ is $\hat{Q}_x^{[\chi]}[k]$ (e.g. the typed reduction of the dynamical operator in the χ-channel; its explicit subprincipal content is immaterial here). By (9.54), the principal symbol is (cone-)elliptic on timelike k, so one can construct a microlocal inverse symbol on $\mathcal{C}^{\hat{\Sigma},*}$ and hence a *retarded parametrix* G_0^{ret} supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$ by cone-gating (Definition 9.106) and Proposition 9.107. The defect $R := \mathbf{1} - \mathcal{L}^{[\chi]}G_0^{\mathrm{ret}}$ is a band-smoothing, retarded, cone-gated operator (closure properties in Definitions 9.96 and 9.106 and Proposition 9.107). On a compact band window, R has small operator norm after possibly refining the retarded partition (Volterra structure in time along a cone-timelike flow), so the Neumann series

$$G^{\mathrm{ret}} \;:=\; G_0^{\mathrm{ret}} \sum_{m=0}^{\infty} R^m$$

converges in the band operator norm and defines a *retarded Green operator* with the same cone support: $\mathcal{L}^{[\chi]}G^{\mathrm{ret}} = \mathbf{1}$, $\operatorname{supp} G^{\mathrm{ret}} \subseteq J^+(\mathcal{C}^{\hat{\Sigma},*})$ (Proposition 9.107).

Step 3: Uniqueness and continuous dependence (well-posedness). Let u solve $\mathcal{L}^{[\chi]}u = f$ with past-compact support. Applying the energy functional to a standard retarded regularization of u and using the Hermiticity of $\hat{Q}_x^{[\chi]}[k]$ (Lemma 9.110) yields $\partial_\tau \mathcal{E}_k^{[\chi]}[u(\tau)] \leq C\,\mathcal{E}_k^{[\chi]}[u(\tau)] + C'\,\|f(\tau)\|_{\mathrm{band}}^2$, for some band-bounded C, C' (subprincipal contributions). Grönwall's inequality and (7.490) give the a priori bound

$$\|u\|_{\mathrm{band};\,J^+(\tau_0)}^2 \;\lesssim\; \mathcal{E}_k^{[\chi]}[u(\tau_0)] + \int_{\tau_0}^{\infty} \|f(\tau)\|_{\mathrm{band}}^2\,\mathrm{d}\tau,$$

which implies uniqueness for retarded solutions with vanishing past data and continuous dependence on f (well-posedness on the band). Existence is furnished by $u = G^{\mathrm{ret}}f$ from Step 2. Cone-gating ensures microcausal support (Proposition 9.108).

Combining Steps 1–3: typed hyperbolicity provides coercivity; the cone-gated parametrix yields a retarded Green operator supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$ (Proposition 9.107); and the energy estimate establishes uniqueness and continuous dependence. Hence the typed sector χ is well-posed on the band, as claimed. □

Corollary 9.113 (Exclusion rule)**.** *If* (9.53) *fails for some timelike k, then χ is excluded from the permit ledger of Proposition 9.102; i.e.,*

$$\chi \notin \mathcal{C}^{[\text{apeiron}]}_{\text{admissible}} \ \textit{(resp. } \mathcal{C}^{[\text{kymon}]}_{\text{admissible}}\textit{)}.$$

Proof of Corollary 9.113. Assume that (9.53) fails for some cone–timelike covector $k \in \mathcal{C}^{\hat{\Sigma},*}_x$; explicitly,

$$\inf_{\Psi\in\mathcal{S}_{\text{band}}} \mathcal{I}_\Psi\big[\hat{Q}^{[\chi]}_x[k]\big] \ \le\ 0,$$

contradicting the typed hyperbolicity requirement of Definition 9.111. By the *necessity* direction in the permit–ledger characterization (Proposition 9.102, using Definitions 9.116 and 9.122), membership $\chi \in \mathcal{C}^{[\bullet]}_{\text{admissible}}$ for either block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ requires typed hyperbolicity to hold for all cone–timelike k. Hence the failure at this k forces $\chi \notin \mathcal{C}^{[\bullet]}_{\text{admissible}}$.

Moreover, by Proposition 9.112 typed hyperbolicity implies a coercive energy estimate and the existence of a retarded Green operator supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$; the failure of (9.53) precludes this certificate, which is part of the ledger entry (Definition 9.122). Therefore χ is excluded from the permit ledger, as claimed. □

Remark 9.114 (Gauge-covariant transport and frame choice)**.** Let g be a local graded-gauge element and $\mathcal{U}_\gamma(x \leftarrow y)$ the parallel transport along a path γ as in Definition 9.7. All typed objects used above transform by conjugation:

$$\begin{aligned}
\hat{\Sigma}_{\mu\nu} &\mapsto \mathrm{Ad}_g\, \hat{\Sigma}_{\mu\nu},\\
\hat{Q}_x[v] &\mapsto \mathrm{Ad}_{g(x)}\, \hat{Q}_x[v] \quad (\textit{Definition 9.95}),\\
\Pi^{[\chi]} &\mapsto \mathrm{Ad}_{g(x)}\, \Pi^{[\chi]} \quad (\textit{Definition 9.116}).
\end{aligned}$$

Hence the typed principal form transforms covariantly, $\hat{Q}^{[\chi]}_x[v] \mapsto \mathrm{Ad}_{g(x)}\, \hat{Q}^{[\chi]}_x[v]$, and retains Hermiticity (Lemma 9.110). Band readouts obey the co-variance rule

$$\mathcal{I}_{g\cdot\Psi}\big[\hat{O}\big] = \mathcal{I}_\Psi\big[\,\mathrm{Ad}_g\, \hat{O}\big], \qquad \mathcal{I}_{g\cdot\Psi}\big[\hat{O}^{[\chi]}\big] = \mathcal{I}_\Psi\big[\,\mathrm{Ad}_g\, \hat{O}^{[\chi]}\big],$$

so any scalar diagnostic built from $(\hat{O}, \Psi)$ is invariant under a simultaneous gauge-frame change. In particular, the typed visibilities $\Lambda^{\Sigma;[\chi]}_{\text{law/state}}$ (Definition 9.133), the quadrant predicate $\mathrm{Quad}^{[\chi]}$ (Definition 9.137), and the parasymmetric valuations $v^{(\cdot);[\chi]}_{\text{Synthesis}}$ (Definitions 9.143 and 9.144) are preserved under (i) local changes of modal frames inside the $\{\Phi\Phi, \Theta\Theta\}$ blocks and the dialectical basis $\{0, 1, p, s\}$ (Definition 9.94), and (ii) graded parallel transport $\mathcal{U}_\gamma$ between nearby points, because the cone gate and retardedness are transported functorially (Definition 9.106 and Proposition 9.107). Moreover, any residual gauge-parameter dependence that is BRST-exact is annihilated by the band functionals (Proposition 9.97), ensuring Nielsen safety throughout.

Remark 9.115 (Quasi-classical limit)**.** Outside the scope fixed by the operator-only axiom (Axiom 9.89), suppose an expectation layer is admissible with $\bar{\Sigma}_{\mu\nu} := E_\omega[\hat{\Sigma}_{\mu\nu}]$ (Definition 9.88). Then the Σ–pre-physical cone $\mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104) approaches the Lorentzian covector cone associated with $\bar{\Sigma}$:

$$\mathcal{C}_x^{\bar{\Sigma},*} = \Big\{ k \neq 0 : \; k^\mu k^\nu \, \bar{\Sigma}_{\mu\nu}(x) \leq 0 \Big\},$$

in the following sense. If (a) the band is tightened ($\ell \downarrow$, $\lambda_{\mathrm{UV}} \uparrow$) so that the uncertainty rectangles for the visibilities collapse (Definition 9.168 and Lemma 9.169), (b) the BRST-closed band functionals converge weak* to the expectation E_ω on BRST cohomology classes (Proposition 9.97), and (c) the typed projectors remain stable under this retuning (Definition 9.116), then the defining supremum in Definition 9.104 Γ–converges to the classical quadratic test with $\bar{\Sigma}$. Consequently, the cone gate and retardedness limit to their classical forms (Proposition 9.107), and microcausality reduces to the standard vanishing of spacelike commutators with respect to $\bar{\Sigma}$ (Proposition 9.108). Within the present section we do *not* invoke $\bar{\Sigma}_{\mu\nu}$; the operator-level $\mathcal{C}_x^{\hat{\Sigma},*}$ remains the primitive causal structure, and all diagnostics (typed hyperbolicity Definition 9.111, well-posedness Proposition 9.112, and permit ledgers Proposition 9.102) are established purely on that substrate. Any mapping of permitted χ–sectors to quasi-particle/graviton content belongs to the expectation-level regime and is thus outside the scope here (cf. Axiom 9.89).

9.10 Kinematic Permit Census for Apeiron/Kymon (No *a priori* Spins)

2.1 Typed band-local projectors

Definition 9.116 (Typed band-local projectors, block-internal and graded-covariant)**.** Let $\hat{\mathbf{G}}_\Lambda$ be the unified block correlator of Definition 9.94 with diagonal sector idempotents

$$E_{\Phi\Phi} := \left(\begin{smallmatrix} \mathbb{I} & 0 \\ 0 & 0 \end{smallmatrix}\right), \qquad E_{\Theta\Theta} := \left(\begin{smallmatrix} 0 & 0 \\ 0 & \mathbb{I} \end{smallmatrix}\right) \quad \text{(cf. eq. (9.36))}.$$

A *typed band-local projector* $\Pi^{[\chi]}$ is a bounded operator on $\mathcal{H}_{\mathrm{em}}$ satisfying:

(P1) **Projector & Hermiticity:** $(\Pi^{[\chi]})^2 = \Pi^{[\chi]}$ and $(\Pi^{[\chi]})^\dagger = \Pi^{[\chi]}$.

(P2) **Block-internality:** either $E_{\Phi\Phi}\Pi^{[\chi]} = \Pi^{[\chi]}E_{\Phi\Phi} = \Pi^{[\chi]}$ (apeiron, $\Phi\Phi$) or $E_{\Theta\Theta}\Pi^{[\chi]} = \Pi^{[\chi]}E_{\Theta\Theta} = \Pi^{[\chi]}$ (kymon, $\Theta\Theta$).

(P3) **Band-finiteness:** $P_x(\lambda_{\mathrm{UV}})\,\Pi^{[\chi]} = \Pi^{[\chi]} = \Pi^{[\chi]}P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}\,\Pi^{[\chi]} = \Pi^{[\chi]} = \Pi^{[\chi]}K_{\mathrm{IR}}^{(\ell)}$ (Definition 9.96).

(P4) **BRST-closedness (ghost 0):** $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ and $\mathrm{gh}(\Pi^{[\chi]}) = 0$ (Lemma 9.54).

(P5) **Graded-gauge covariance:** under a local graded frame $g(x)$ (Definition 9.7), $\Pi^{[\chi]} \mapsto g\,\Pi^{[\chi]}g^\dagger$.

(P6) **Cone-compatibility:** for every timelike $k \in \mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104), the typed probe $\hat{Q}_x^{[\chi]}[k] = \Pi^{[\chi]}\hat{Q}_x[k]\Pi^{[\chi]}$ (Definition 9.109) is positive in the band-functional sense (see Definition 9.111).

(P7) **Retuning-stability:** there exists $\delta > 0$ such that for all $(\lambda'_{\mathrm{UV}}, \ell')$ with $|\lambda'_{\mathrm{UV}} - \lambda_{\mathrm{UV}}| + |\ell' - \ell| < \delta$, the map $(\lambda'_{\mathrm{UV}}, \ell') \mapsto \Pi^{[\chi]}(\lambda'_{\mathrm{UV}}, \ell')$ is norm-continuous and preserves (P1)–(P6).

Remark 9.117 (Typed structures per sector)**.** Within **apeiron** ($\Phi\Phi$) the standard constructions are: Σ-trace / trace-free split; Σ-divergence transverse/longitudinal split; symmetric / TT-like subspaces; and, whenever a Σ-spatial direction $\hat{\mathbf{k}}$ is meaningful (timelike k picks a spatial hyperplane), helicity-refined projectors. Within **kymon** ($\Theta\Theta$): Σ-transverse / Σ-longitudinal, helicity $\lambda = \pm$, and the torsional/temporal *Chrono–Kymon* channel via $\hat{t}^{(\Theta)}_{\mu\nu} \subset \hat{\Sigma}^{(\Theta)}$ (cf. Definition 5.25 and the Σ-weighted mode extraction of Proposition 9.36 and eq. (9.16)).

Lemma 9.118 (Σ-orthogonality on the band)**.** *If $\Pi^{[\chi]}$ and $\Pi^{[\chi']}$ satisfy (P1)–(P6) of Definition 9.116 and $\Pi^{[\chi]}\Pi^{[\chi']} = 0$, then for any timelike k*

$$\mathcal{I}_\Psi\Big[\hat{Q}^{[\chi]}_x[k]\Pi^{[\chi']}\Big] \;=\; 0 \quad \textit{and} \quad \mathcal{I}_\Psi\Big[\Pi^{[\chi]}\hat{Q}^{[\chi']}_x[k]\Big] \;=\; 0,$$

for all $\Psi \in \mathcal{S}_{\mathrm{band}}$. Hence distinct typed subspaces are orthogonal with respect to the Σ-induced quadratic form (Definition 9.22).

Proof of Lemma 9.118. Recall the Σ–probe and its typed restriction

$$\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x) \quad \text{(Definition 9.95)},$$
$$\hat{Q}^{[\chi]}_x[v] = \Pi^{[\chi]}\,\hat{Q}_x[v]\,\Pi^{[\chi]} \quad \text{(cf. (9.52), Definitions 9.109 and 9.116)}.$$

Let $\Pi^{[\chi]}$ and $\Pi^{[\chi']}$ satisfy items (P1)–(P6) of Definition 9.116, and assume $\Pi^{[\chi]}\Pi^{[\chi']} = 0$ (orthogonal projectors in the block algebra).

Step 1: Algebraic annihilation of cross-typed factors. Using idempotence and orthogonality (Definition 9.116(P1)),

$$\hat{Q}^{[\chi]}_x[k]\;\Pi^{[\chi']} = \Big(\Pi^{[\chi]}\,\hat{Q}_x[k]\,\Pi^{[\chi]}\Big)\Pi^{[\chi']} = \Pi^{[\chi]}\,\hat{Q}_x[k]\,\underbrace{\Big(\Pi^{[\chi]}\Pi^{[\chi']}\Big)}_{=0} = 0,$$

and symmetrically,

$$\Pi^{[\chi]}\,\hat{Q}^{[\chi']}_x[k] = \Pi^{[\chi]}\Big(\Pi^{[\chi']}\,\hat{Q}_x[k]\,\Pi^{[\chi']}\Big) = \underbrace{\Big(\Pi^{[\chi]}\Pi^{[\chi']}\Big)}_{=0}\,\hat{Q}_x[k]\,\Pi^{[\chi']} = 0.$$

These identities hold in the band algebra for any covector k; the timelike assumption (from Definition 9.104) is only needed elsewhere for positivity, not for orthogonality.

Step 2: Vanishing of band evaluations. By linearity of the band functionals (Definition 9.96),

$$\mathcal{I}_\Psi\Big[\hat{Q}^{[\chi]}_x[k]\Pi^{[\chi']}\Big] = \mathcal{I}_\Psi[0] = 0, \qquad \mathcal{I}_\Psi\Big[\Pi^{[\chi]}\hat{Q}^{[\chi']}_x[k]\Big] = \mathcal{I}_\Psi[0] = 0,$$

for all $\Psi \in \mathcal{S}_{\mathrm{band}}$.

Step 3: Σ–orthogonality of typed subspaces. Denote the Σ–induced quadratic form by $\hat{Q}_x[k]$ (Definitions 9.22 and 9.95). For vectors $u \in \operatorname{Ran}\Pi^{[\chi]}$ and $v \in \operatorname{Ran}\Pi^{[\chi']}$,

$$\mathcal{I}_\Psi\Big[u^\dagger\,\hat{Q}_x[k]\,v\Big] = \mathcal{I}_\Psi\Big[u^\dagger\,\Pi^{[\chi]}\hat{Q}_x[k]\Pi^{[\chi']}\,v\Big] = \mathcal{I}_\Psi\Big[u^\dagger\,\Pi^{[\chi]}\hat{Q}^{[\chi']}_x[k]\,v\Big] = 0,$$

by Step 1. Thus distinct typed subspaces are orthogonal with respect to the Σ–induced quadratic form, as claimed. □

Proposition 9.119 (Constructive existence via Σ-weighted mode operators)**.** *Let $K_\bullet$ be the Σ-weighted positive compact operator constructed as in Proposition 9.36 and eq. (9.16) inside a fixed block ($\Phi\Phi$ or $\Theta\Theta$). Then the spectral Riesz projectors of $K_\bullet$ onto any finite union of isolated spectral clusters yield band-finite, BRST-closed, graded-covariant projectors that satisfy (P1)–(P7). In particular, helicity and TT-like subspaces are obtained by choosing $K_\bullet$ that commute with the appropriate stabilizer generators (little group) on the Σ-spatial hyperplane determined by a timelike k (Definition 9.104).*

Proof of Proposition 9.119. Fix a block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and the Σ-weighted positive compact operator $K_\bullet$ constructed in Proposition 9.36 (generalized Σ-eigenproblem (9.16)), with UV/IR band instrumentation $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.96) and cone-gating (Definition 9.106). Let $\{\lambda_j\}$ be the (discrete) spectrum of $K_\bullet$, with each nonzero $\lambda_j > 0$ of finite multiplicity (compact positivity). Let $\Gamma = \bigsqcup_{m=1}^{M} \Gamma_m$ be a finite union of pairwise disjoint Jordan curves, each enclosing an *isolated* spectral cluster σ_m and no other spectrum. Define the Riesz projector

$$\Pi_\Gamma \;:=\; \frac{1}{2\pi i} \oint_\Gamma (z\mathbf{1} - K_\bullet)^{-1}\, \mathrm{d}z. \tag{9.56}$$

We prove that Π_Γ satisfies items (P1)–(P7) of Definition 9.116.

(i) Projector & block internality ((P1)). By the holomorphic functional calculus, (9.56) yields an idempotent that commutes with $K_\bullet$, and since $K_\bullet$ is self-adjoint/positive on the block Hilbert module, Π_Γ is the *orthogonal* spectral projector onto $\mathcal{H}_\Gamma = \bigoplus_{\lambda_j \in \cup_m \sigma_m} \ker(K_\bullet - \lambda_j)$. Thus $\Pi_\Gamma^\dagger = \Pi_\Gamma = \Pi_\Gamma^2$ and $\Pi_\Gamma \in \mathrm{End}(\bullet)$.

(ii) Band-finiteness ((P3)). By construction of $K_\bullet$ (Proposition 9.36) the kernel defining $K_\bullet$ is band-admissible (UV-projected, IR-filtered, cone-gated: $P_x(\lambda_{\mathrm{UV}})K_\bullet = K_\bullet = K_\bullet P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)} K_\bullet = K_\bullet K_{\mathrm{IR}}^{(\ell)}$; see Definition 9.96). Resolvents $(z\mathbf{1} - K_\bullet)^{-1}$ preserve band-admissibility for $z \notin \sigma(K_\bullet)$, hence the contour integral (9.56) is band-admissible. Moreover, each cluster σ_m has finite rank in the band window, so Π_Γ is *band-finite*.

(iii) BRST-closedness. $K_\bullet$ is built from BRST-closed ingredients (cone-gated $\hat{\Sigma}$, band taggers of ghost number 0; Definitions 5.25 and 9.96), hence $[\,\hat{Q}_{\mathrm{BRST}}, K_\bullet\,] = 0$. Applying the functional calculus under the BRST derivation gives $[\,\hat{Q}_{\mathrm{BRST}}, \Pi_\Gamma\,] = \frac{1}{2\pi i} \oint_\Gamma (z\mathbf{1} - K_\bullet)^{-1} [\,\hat{Q}_{\mathrm{BRST}}, K_\bullet\,] (z\mathbf{1} - K_\bullet)^{-1} \mathrm{d}z = 0$, so Π_Γ is BRST-closed.

(iv) Graded covariance ((P5)). Under local graded transport g (Definition 9.7), $K_\bullet \mapsto \mathrm{Ad}_g\, K_\bullet$. Hence $(z\mathbf{1} - \mathrm{Ad}_g\, K_\bullet)^{-1} = \mathrm{Ad}_g (z\mathbf{1} - K_\bullet)^{-1}$, and

$$\Pi_\Gamma \;\mapsto\; \frac{1}{2\pi i} \oint_\Gamma (z\mathbf{1} - \mathrm{Ad}_g\, K_\bullet)^{-1} \mathrm{d}z = \mathrm{Ad}_g \Big(\frac{1}{2\pi i} \oint_\Gamma (z\mathbf{1} - K_\bullet)^{-1} \mathrm{d}z \Big) = \mathrm{Ad}_g\, \Pi_\Gamma,$$

so Π_Γ transforms covariantly.

(v) Cone-compatibility ((P6)). By construction $K_\bullet$ is Σ-weighted and cone-gated (Proposition 9.36 and Definition 9.106); its eigenmodes are obtained from kernels supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$ and therefore lie in the domain on which the Σ–principal form is defined. For any timelike $k \in \mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104), the typed principal form $\hat{Q}_x^{[\Pi_\Gamma]}[k] = \Pi_\Gamma\, \hat{Q}_x[k] \Pi_\Gamma$ is Hermitian and gauge-covariant (Lemma 9.110). Since $K_\bullet$ is built from $\hat{\Sigma}$ and its cone-gated

propagators, the range of Π_Γ is a Σ–compatible subspace in which timelike directions remain timelike for the quadratic form (*compatibility* in the sense of (P6)). (If one additionally demands *positivity* to certify typed hyperbolicity, this is precisely the test of Definition 9.111, verified separately when admitting the type.)

(vi) Stability under small retunings ((P7)). Retuning the band parameters $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\lambda'_{\mathrm{UV}}, \ell')$ produces a bounded perturbation of $K_\bullet$ that is continuous in operator norm ($\|K'_\bullet - K_\bullet\| \to 0$; see Definition 9.96 and Lemma 9.105). By Kato's perturbation theory for isolated spectral clusters (norm-resolvent continuity), the Riesz projector Π_Γ varies continuously provided Γ stays separated from the rest of the spectrum. Thus there exists a stability radius $\delta > 0$ such that for $|\lambda'_{\mathrm{UV}} - \lambda_{\mathrm{UV}}| + |\ell' - \ell| < \delta$ the spectral gap persists and $\|\Pi'_\Gamma - \Pi_\Gamma\| \to 0$, realizing (P7).

Items (P1)–(P7) of Definition 9.116 are therefore satisfied.

Helicity and TT-like subspaces. Let W_k denote the stabilizer (little group) of a timelike k in the Σ-spatial hyperplane (Definition 9.104). Choose $K_\bullet$ so that it *commutes* with the representation of W_k (e.g. by averaging the kernel over W_k inside the band). Then the spectral subspaces of $K_\bullet$ carry W_k-representations and decompose into helicity (or TT-like) sectors; the corresponding Riesz projectors Π_Γ are the helicity-/TT-type projectors. These inherit band-finiteness, BRST-closedness, graded covariance, cone-compatibility, and stability from the preceding steps, completing the constructive existence.

□

Corollary 9.120 (Typed hyperbolicity certificates)**.** *For each $\Pi^{[\chi]}$ produced by Proposition 9.119, the positivity condition (9.53) holds if and only if the corresponding Σ-weighted spectral band is separated from 0. The* cone/hyperbolicity certificate *attached to χ consists of: (i) the admissible timelike interval in $\mathcal{C}_x^{\hat{\Sigma},*}$; (ii) the spectral gap margin of $K_\bullet$; and (iii) the retuning-stability radius from (P7).*

Proof of Corollary 9.120. Let $\Pi^{[\chi]} = \Pi_\Gamma$ be a Riesz projector produced by Proposition 9.119 from the Σ–weighted positive compact operator $K_\bullet$ (constructed in Proposition 9.36 via the generalized eigenproblem (9.16)) inside a fixed block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$. Write $\sigma_\Gamma := \sigma(K_\bullet) \cap \mathrm{int}(\Gamma)$ for the enclosed spectral band.

Step 1: Equivalence between typed quadratic energy and $K_\bullet$–energy on $\mathrm{Ran}\,\Pi_\Gamma$. By construction of $K_\bullet$ and the typed reduction $\hat{Q}_x^{[\chi]}[k] = \Pi_\Gamma\, \hat{Q}_x[k] \Pi_\Gamma$ (with $\hat{Q}_x[k] = k^\mu k^\nu \hat{\Sigma}_{\mu\nu}(x)$, Definitions 9.95 and 9.109), there exist band–window–uniform positive constants $c_1(k), c_2(k)$ such that for every band-admissible vector/mode $u \in \mathrm{Ran}\,\Pi_\Gamma$ and every band functional $\mathcal{I}_\Psi$ (Definition 9.96),

$$c_1(k)\,\langle u,\, K_\bullet u\rangle \;\le\; \mathcal{I}_\Psi\Big[u^\dagger\, \hat{Q}_x^{[\chi]}[k]\, u\Big] \;\le\; c_2(k)\,\langle u,\, K_\bullet u\rangle. \tag{9.57}$$

This is the "principal-modes equivalence" induced by the Σ–weighting in Proposition 9.36 (and the cone-gated construction of kernels, Definition 9.106 and Proposition 9.107), together with Hermiticity/covariance of the typed principal form (Lemma 9.110). Equation (9.57) expresses that, on $\mathrm{Ran}\,\Pi_\Gamma$, the band evaluation of the typed principal quadratic form is equivalent to the $K_\bullet$–energy.

Step 2: "If" direction. Assume the spectral band is separated from zero:

$$\delta_\Gamma \;:=\; \operatorname{dist}\big(0, \sigma_\Gamma\big) \;>\; 0.$$

Then $\langle u, K_\bullet u\rangle \geq \delta_\Gamma \, \|u\|^2$ for all $u \in \operatorname{Ran} \Pi_\Gamma$. Combining with (9.57) gives, for every band functional $\mathcal{I}_\Psi$ and every timelike $k \in \mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104),

$$\mathcal{I}_\Psi\Big[u^\dagger \, \hat{Q}_x^{[\chi]}[k] \, u\Big] \;\geq\; c_1(k) \, \delta_\Gamma \, \|u\|^2.$$

Since the band functionals separate the positive cone on the band algebra (Definition 9.96), taking the infimum over admissible Ψ yields

$$\inf_{\Psi \in \mathcal{S}_{\text{band}}} \; \mathcal{I}_\Psi\Big[\hat{Q}_x^{[\chi]}[k]\Big] \;>\; 0,$$

which is exactly the typed hyperbolicity condition (9.53) (Definition 9.111). Hence spectral separation from 0 implies typed hyperbolicity.

Step 3: "Only if" direction. Conversely, suppose (9.53) holds but σ_Γ is *not* separated from 0. Then there exists a sequence $u_n \in \operatorname{Ran} \Pi_\Gamma$ with $\|u_n\| = 1$ and $\langle u_n, K_\bullet u_n\rangle \to 0$. By (9.57) we obtain

$$\inf_{\Psi} \; \mathcal{I}_\Psi\Big[u_n^\dagger \, \hat{Q}_x^{[\chi]}[k] \, u_n\Big] \;\leq\; c_2(k) \, \langle u_n, K_\bullet u_n\rangle \;\longrightarrow\; 0,$$

contradicting (9.53). Therefore, typed hyperbolicity forces $\delta_\Gamma > 0$, i.e. σ_Γ is separated from 0.

Step 4: Certificate components. Given $\Pi^{[\chi]} = \Pi_\Gamma$ with $\delta_\Gamma > 0$, the *cone/hyperbolicity certificate* attached to χ is:

(i) the admissible timelike interval of k in $\mathcal{C}_x^{\hat{\Sigma},*}$ (where the constants $c_{1,2}(k)$ and the inequality (9.57) hold; cf. Definition 9.104);

(ii) the spectral gap margin $\delta_\Gamma = \operatorname{dist}(0, \sigma_\Gamma)$ controlling the positive lower bound in (9.57) and thus in (9.53);

(iii) the retuning-stability radius supplied by item (P7) of Definition 9.116, realized via norm–resolvent stability of Riesz projectors under band retunings in Proposition 9.119 (see also IR/UV monotonicity Lemma 9.105 and Definition 9.96).

These three data together certify typed hyperbolicity on the band and its robustness under the allowed instrumentation.

The equivalence and the stated certificate are thus established. □

Lemma 9.121 (BRST/Nielsen safety of $\Pi^{[\chi]}$)**.** *If $\Pi^{[\chi]}$ satisfies (P4) of Definition 9.116, then for any BRST-exact variation $\delta_\theta \Pi^{[\chi]} = [\hat{Q}_{\text{BRST}}, X_\theta]$ one has $\mathcal{I}(\delta_\theta \Pi^{[\chi]}) = \mathcal{I}_\Psi(\delta_\theta \Pi^{[\chi]}) = 0$ by Proposition 9.97. Thus all downstream typed contrasts/visibilities (Definitions 9.45 and 9.47) are gauge-parameter independent.*

Proof of Lemma 9.121. Assume $\Pi^{[\chi]}$ satisfies the BRST-closedness item (P4) of Definition 9.116, i.e. $[\hat{Q}_{\text{BRST}}, \Pi^{[\chi]}] = 0$. Let a gauge-parameter variation act by a BRST-exact commutator $\delta_\theta \Pi^{[\chi]} = [\hat{Q}_{\text{BRST}}, X_\theta]$ (band-admissible X_θ).

Step 1: Scalar band evaluations of $\delta_\theta \Pi^{[\chi]}$ vanish. By the Nielsen safety on the band (Proposition 9.97) the band functionals annihilate BRST-exact insertions:

$$\mathcal{I}\big([\hat{Q}_{\mathrm{BRST}}, Y]\big) = \mathcal{I}_\Psi\big([\hat{Q}_{\mathrm{BRST}}, Y]\big) = 0 \qquad \text{for all band-admissible } Y.$$

With $Y = X_\theta$, this gives

$$\mathcal{I}(\delta_\theta \Pi^{[\chi]}) = \mathcal{I}\big([\hat{Q}_{\mathrm{BRST}}, X_\theta]\big) = 0, \qquad \mathcal{I}_\Psi(\delta_\theta \Pi^{[\chi]}) = \mathcal{I}_\Psi\big([\hat{Q}_{\mathrm{BRST}}, X_\theta]\big) = 0,$$

proving the first claim in the lemma.

Step 2: Typed contrasts/visibilities are independent of the frame choice of $\Pi^{[\chi]}$. Let A be any band operator entering the typed restriction (e.g. $A = \hat{Q}_x[v]$ or $A = \hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]$ in the definitions of the typed contrasts, Definition 9.127). Consider the scalar readout $\mathcal{I}\big(\Pi^{[\chi]} A \Pi^{[\chi]}\big)$ (and similarly with $\mathcal{I}_\Psi$). Varying only the projector (holding A fixed) yields

$$\partial_\theta\, \mathcal{I}\big(\Pi^{[\chi]} A \Pi^{[\chi]}\big) = \mathcal{I}\big((\delta_\theta \Pi^{[\chi]}) A \Pi^{[\chi]}\big) + \mathcal{I}\big(\Pi^{[\chi]} A (\delta_\theta \Pi^{[\chi]})\big).$$

Using $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ and the graded derivation property, each term can be re-expressed as a BRST-exact insertion:

$$(\delta_\theta \Pi^{[\chi]}) A \Pi^{[\chi]} = \big[\hat{Q}_{\mathrm{BRST}},\ X_\theta A \Pi^{[\chi]}\big] \ -\ X_\theta\,[\hat{Q}_{\mathrm{BRST}}, A \Pi^{[\chi]}],$$

and analogously for $\Pi^{[\chi]} A (\delta_\theta \Pi^{[\chi]})$. The second pieces above vanish inside $\mathcal{I}$ and $\mathcal{I}_\Psi$ because the inputs used for typed contrasts are BRST-closed modulo exact terms by construction of the diagnostics (Definitions 9.96 and 9.127; see also the pointwise Nielsen consequence Lemma 9.128). The remaining pieces are of the form $\mathcal{I}([\hat{Q}_{\mathrm{BRST}}, \cdot])$ and hence vanish by Proposition 9.97. Therefore

$$\partial_\theta\, \mathcal{I}\big(\Pi^{[\chi]} A \Pi^{[\chi]}\big) = 0, \qquad \partial_\theta\, \mathcal{I}_\Psi\big(\Pi^{[\chi]} A \Pi^{[\chi]}\big) = 0.$$

Applying this with A chosen as in Definition 9.127 shows that both $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law}}$ and $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{state}}$ are insensitive to the gauge-parameter variation of $\Pi^{[\chi]}$. Aggregation and normalization to visibilities (Definition 9.133) are algebraic operations on these scalars and therefore inherit the invariance.

Altogether, BRST-closedness of $\Pi^{[\chi]}$ combined with Nielsen safety of the band functionals (Proposition 9.97) implies $\mathcal{I}(\delta_\theta \Pi^{[\chi]}) = \mathcal{I}_\Psi(\delta_\theta \Pi^{[\chi]}) = 0$, and all downstream typed contrasts and visibilities (Definitions 9.127 and 9.133) are gauge-parameter independent with respect to variations of $\Pi^{[\chi]}$. □

2.2 Output: permit ledgers

Definition 9.122 (Permit ledgers (apeiron/kymon))**.** The *permit ledger* of admissible types in a sector is

$$\mathcal{C}^{[\mathrm{apeiron}]}_{\mathrm{admissible}} \subset \mathrm{End}(\Phi\Phi), \qquad \mathcal{C}^{[\mathrm{kymon}]}_{\mathrm{admissible}} \subset \mathrm{End}(\Theta\Theta),$$

consisting of all labels χ for which there exists a projector $\Pi^{[\chi]}$ satisfying (P1)–(P7) of Definition 9.116 and the typed hyperbolicity condition (9.53) (Definition 9.111). Each entry χ carries its *cone/hyperbolicity certificate* as in Corollary 9.120.

Proposition 9.123 (Ledger covariance and functoriality)**.** *Under graded local frames g, the ledger transforms by conjugation: $\Pi^{[\chi]} \mapsto g\Pi^{[\chi]}g^\dagger$, and $\mathcal{C}^{[\cdot]}_{\text{admissible}}$ is invariant up to this equivalence. Moreover, refining the band tag $\mathfrak{B}_{\lambda_{\text{UV}},\ell}$ (Definition 9.96) functorially* shrinks *the ledger but cannot add a χ that previously failed* (9.53) *(by Lemma 9.105 and* (P7)*).*

Proof of Proposition 9.123. We split the proof into covariance under graded frames and functorial monotonicity under band refinement.

(A) Covariance under graded local frames. Let g be a graded-gauge transport as in Definition 9.7. For any admitted label χ with projector $\Pi^{[\chi]}$ (in the block $\Phi\Phi$ or $\Theta\Theta$), items (P1), (P4), and (P5) of Definition 9.116 give

$$\Pi^{[\chi]} \mapsto \mathrm{Ad}_g\,\Pi^{[\chi]} := g\,\Pi^{[\chi]}g^\dagger, \qquad [\,\hat{Q}_{\text{BRST}}, \Pi^{[\chi]}] = 0 \implies [\,\hat{Q}_{\text{BRST}}, \mathrm{Ad}_g\,\Pi^{[\chi]}] = 0.$$

The principal Σ–probe and its typed restriction transform covariantly: $\hat{Q}_x[v] \mapsto \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]$ and $\hat{Q}^{[\chi]}_x[v] = \Pi^{[\chi]}\hat{Q}_x[v]\Pi^{[\chi]} \mapsto \mathrm{Ad}_{g(x)}\,\hat{Q}^{[\chi]}_x[v]$

(Definition 9.95 and Lemma 9.110). Hence the typed hyperbolicity condition (9.53) is frame-invariant, either directly from covariance of the quadratic form or via the gauge-parameter independence of the band readouts $\mathcal{I}, \mathcal{I}_\Psi$ (Propositions 9.91 and 9.97). Band-finiteness and stability ((P3), (P7)) are preserved under conjugation as well, because g acts by unitary equivalence on the band class (Definition 9.96). Thus, if χ is admitted then so is its conjugate class; conversely the inverse frame g^{-1} implies the equivalence. Therefore the ledger $\mathcal{C}^{[\cdot]}_{\text{admissible}}$ is invariant up to g–conjugation.

(B) Functoriality under band refinement; monotonicity (no additions). Consider a refinement of the band tag $\mathfrak{B}_{\lambda_{\text{UV}},\ell} \rightsquigarrow \mathfrak{B}_{\lambda'_{\text{UV}},\ell'}$ with $\lambda'_{\text{UV}} \geq \lambda_{\text{UV}}$ and $\ell' \leq \ell$ (Definition 9.96). By Lemma 9.105, the Σ–covector cone $\mathcal{C}^{\hat{\Sigma},*}_x[\ell'] \subseteq \mathcal{C}^{\hat{\Sigma},*}_x[\ell]$ *shrinks*. The cone gate and retardedness commute with the UV/IR instrumentation (Definition 9.106 and Proposition 9.107), so all typed objects restrict functorially to the refined band.

We show that refinement cannot add a label χ that previously failed (9.53). Suppose χ is *not* admitted at $(\lambda_{\text{UV}}, \ell)$. By the permit-criterion (Proposition 9.102) and the typed-certificate equivalence (Corollary 9.120), either:

(i) *Hyperbolicity failure:* there exists a timelike $k \in \mathcal{C}^{\hat{\Sigma},*}_x[\ell]$ with $\inf_\Psi \mathcal{I}_\Psi[\hat{Q}^{[\chi]}_x[k]] \leq 0$ (i.e. the Σ–weighted spectral band for $\Pi^{[\chi]}$ touches 0; equivalently, the gap margin $\delta_\Gamma = 0$ in Corollary 9.120); or

(ii) *Stability failure:* a nonzero retuning-stability radius ((P7)) cannot be certified.

Assume for contradiction that χ becomes admitted after refinement to $(\lambda'_{\text{UV}}, \ell')$. Then *both* typed hyperbolicity and stability must hold on the refined band. In particular, by Corollary 9.120 there is a positive spectral gap $\delta'_\Gamma > 0$ and a stability radius $r' > 0$ such that typed hyperbolicity persists under all retunings within distance r' of $(\lambda'_{\text{UV}}, \ell')$ (item (P7) of Definition 9.116).

Now enlarge the IR window slightly within this radius: choose $\ell'' \in (\ell', \min\{\ell' + r', \ell\})$. By Lemma 9.105 (applied in reverse), the cone expands $\mathcal{C}^{\hat{\Sigma},*}_x[\ell'] \subseteq \mathcal{C}^{\hat{\Sigma},*}_x[\ell'']$, and by stability the typed positivity and the gap $\delta'_\Gamma/2$ persist at ℓ''. Iterating finitely many times (partitioning the interval $[\ell', \ell]$ into steps of size $< r'$) yields a band parameter $\tilde{\ell}$ arbitrarily close to ℓ

for which typed hyperbolicity holds with a *uniform* positive margin. Passing to the limit (norm–resolvent continuity from Proposition 9.119 and the continuity of band functionals Definition 9.96) we conclude that typed hyperbolicity must also hold at ℓ, contradicting (i). Thus case (i) cannot occur.

If (ii) held at $(\lambda_{\mathrm{UV}}, \ell)$, then admission at the refined point would supply a positive stability radius $r' > 0$ there. The same stepping argument as above shows that stability propagates along a chain of small retunings, contradicting the original failure of stability. Hence case (ii) cannot occur either.

Therefore refinement cannot *add* a label that was excluded before. On the other hand, refinement may *remove* labels (the cone shrinks and spectral clusters may lose a uniform gap or band-finiteness under stricter UV/IR gates), so the ledger can only *shrink*. This proves functorial monotonicity:

$$\mathcal{C}^{[\cdot]}_{\mathrm{admissible}}(\lambda'_{\mathrm{UV}}, \ell') \;\subseteq\; \mathcal{C}^{[\cdot]}_{\mathrm{admissible}}(\lambda_{\mathrm{UV}}, \ell).$$

Combining (A) and (B) establishes the proposition. □

Proposition 9.124 (Partial Σ-orthogonal decomposition)**.** *Let* $\{\Pi^{[\chi_j]}\}_{j=1}^{N} \subset \mathcal{C}^{[\cdot]}_{\mathrm{admissible}}$ *be mutually orthogonal projectors (Lemma 9.118). Then, within the chosen block,*

$$\Pi_{\mathrm{adm}} := \sum_{j=1}^{N} \Pi^{[\chi_j]}$$

is again a band-finite, BRST-closed projector, and the residual $\Pi_{\mathrm{res}} := E_{\bullet\bullet} - \Pi_{\mathrm{adm}}$ *is* Σ*-orthogonal to each* $\Pi^{[\chi_j]}$ *on the band. If* Π_{res} *fails* (9.53)*, its image is excluded from the ledger (Corollary 9.113).*

Proof of Proposition 9.124. Fix a block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and let $\{\Pi^{[\chi_j]}\}_{j=1}^{N} \subset \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}$ be mutually orthogonal typed projectors:

$$\Pi^{[\chi_j]}\Pi^{[\chi_{j'}]} = \delta_{jj'}\,\Pi^{[\chi_j]}, \qquad \left(\Pi^{[\chi_j]}\right)^{\dagger} = \Pi^{[\chi_j]} \quad \text{(item (P1) of Definition 9.116)}.$$

(i) Π_{adm} *is a band-finite, BRST-closed projector.* Define $\Pi_{\mathrm{adm}} := \sum_{j=1}^{N} \Pi^{[\chi_j]}$. Orthogonality gives

$$\Pi_{\mathrm{adm}}^2 = \sum_{j,j'} \Pi^{[\chi_j]}\Pi^{[\chi_{j'}]} = \sum_{j} \Pi^{[\chi_j]} = \Pi_{\mathrm{adm}}, \qquad \Pi_{\mathrm{adm}}^{\dagger} = \sum_{j} \left(\Pi^{[\chi_j]}\right)^{\dagger} = \Pi_{\mathrm{adm}},$$

so Π_{adm} is a projector in $\mathrm{End}(\bullet)$. Each $\Pi^{[\chi_j]}$ is band-finite (item (P3) of Definition 9.116), hence the finite sum Π_{adm} is band-finite as the band class is closed under finite sums (Definition 9.96). BRST-closedness is preserved by linearity:

$$[\,\hat{Q}_{\mathrm{BRST}}, \Pi_{\mathrm{adm}}\,] = \sum_{j} [\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi_j]}] = 0 \quad \text{(item (P4) of Definition 9.116)}.$$

(ii) Residual projector and Σ*–orthogonality to each typed sector.* Let $1_\bullet$ denote the identity in $\mathrm{End}(\bullet)$ and set $\Pi_{\mathrm{res}} := 1_\bullet - \Pi_{\mathrm{adm}}$. Then

$$\Pi_{\mathrm{res}}^2 = (1_\bullet - \Pi_{\mathrm{adm}})^2 = 1_\bullet - 2\Pi_{\mathrm{adm}} + \Pi_{\mathrm{adm}} = 1_\bullet - \Pi_{\mathrm{adm}} = \Pi_{\mathrm{res}},$$

so Π_{res} is a projector (self-adjoint by construction). Algebraically,

$$\Pi_{\mathrm{res}}\,\Pi^{[\chi_j]} = (1_\bullet - \Pi_{\mathrm{adm}})\Pi^{[\chi_j]} = \Pi^{[\chi_j]} - \sum_{m=1}^{N} \Pi^{[\chi_m]}\Pi^{[\chi_j]} = \Pi^{[\chi_j]} - \Pi^{[\chi_j]} = 0,$$

and similarly $\Pi^{[\chi_j]}\Pi_{\mathrm{res}} = 0$. Consequently, for any timelike $k \in \mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104),

$$\hat{Q}_x^{[\chi_j]}[k]\ \Pi_{\mathrm{res}} = \Big(\Pi^{[\chi_j]}\hat{Q}_x[k]\Pi^{[\chi_j]}\Big)\Pi_{\mathrm{res}} = \Pi^{[\chi_j]}\hat{Q}_x[k]\underbrace{\Big(\Pi^{[\chi_j]}\Pi_{\mathrm{res}}\Big)}_{=0} = 0,$$

and likewise $\Pi_{\mathrm{res}}\hat{Q}_x^{[\chi_j]}[k] = 0$. Applying any band functional (Definition 9.96) yields

$$\mathcal{I}_\Psi\Big[\hat{Q}_x^{[\chi_j]}[k]\Pi_{\mathrm{res}}\Big] = \mathcal{I}_\Psi[0] = 0, \qquad \mathcal{I}_\Psi\Big[\Pi_{\mathrm{res}}\hat{Q}_x^{[\chi_j]}[k]\Big] = \mathcal{I}_\Psi[0] = 0,$$

which is precisely the Σ–orthogonality on the band (Definition 9.22 and Lemma 9.118).

(iii) Exclusion of the residual image if typed hyperbolicity fails. If Π_{res} fails the typed hyperbolicity condition (9.53) (Definition 9.111) for some timelike k, then by the exclusion rule (Corollary 9.113) its image cannot be admitted to the permit ledger. Equivalently, no additional χ supported in $\operatorname{Ran}\Pi_{\mathrm{res}}$ may be added to $\mathcal{C}^{[\bullet]}_{\mathrm{admissible}}$.

Combining (i)–(iii) proves the proposition. □

Corollary 9.125 (Chrono–Kymon admission)**.** *In the $\Theta\Theta$ sector, let $T := \hat{t}^{(\Theta)}_{\mu\nu}\hat{\Sigma}^{(\Theta)\,\mu\nu}$ be the Σ-weighted torsional operator (cf. Definition 5.25). The Riesz projector $\Pi^{[\mathrm{CK}]}$ onto a nonzero isolated spectral band of T defines a typed projector. If the band is separated from 0, then (9.53) holds and $\mathrm{CK} \in \mathcal{C}^{[\mathrm{kymon}]}_{\mathrm{admissible}}$.*

Proof of Corollary 9.125. Work in the $\Theta\Theta$ block. By the operator-unified chronogeometry (Definition 5.25), both $\hat{t}^{(\Theta)}_{\mu\nu}$ and $\hat{\Sigma}^{(\Theta)\,\mu\nu}$ are Hermitian, band-admissible (UV/IR) and cone-gated (Definitions 9.96 and 9.106 and Proposition 9.107). Hence the Σ-weighted torsional operator

$$T \;:=\; \hat{t}^{(\Theta)}_{\mu\nu}\,\hat{\Sigma}^{(\Theta)\,\mu\nu}$$

is a self-adjoint, band-admissible operator on the $\Theta\Theta$ sector (ghost number 0 and BRST-closed by construction).

Step 1: Typed projector from a Riesz construction. Let $\sigma(T)$ be the spectrum of T and let Γ encircle a nonzero *isolated* spectral band $\sigma_\Gamma \subset \sigma(T)$ disjoint from the rest of the spectrum. The Riesz projector $\Pi^{[\mathrm{CK}]} \equiv \Pi_\Gamma := \frac{1}{2\pi i}\oint_\Gamma (z\mathbf{1} - T)^{-1}\mathrm{d}z$ is band-finite, BRST-closed, and graded-covariant; moreover it lies in $\mathrm{End}(\Theta\Theta)$ (block internality). All these properties follow from the functional-calculus argument in Proposition 9.119 (applied to the normal, band-admissible operator T), together with Definition 9.116 (items (P1), (P3), (P4), (P5), (P7)). By the sector semantics of Definition 9.116 (Chrono–Kymon channel in the $\Theta\Theta$ block), $\Pi^{[\mathrm{CK}]}$ is a *typed projector* in the sense used throughout.

Step 2: Hyperbolicity via separation from 0. Assume now that the band σ_Γ is separated from 0: $\delta_\Gamma := \mathrm{dist}\big(0, \sigma_\Gamma\big) > 0$. Define the positive compact operator $K_\bullet := |T| = (T^2)^{1/2}$ on the

same block. Since Γ does not intersect 0, the spectral subspace of $|T|$ associated with $|\sigma_\Gamma|$ coincides with $\operatorname{Ran}\Pi_\Gamma$; thus Π_Γ is also the Riesz projector for $K_\bullet$ onto the corresponding positive cluster. Applying Corollary 9.120 with this $K_\bullet$ gives the equivalence

$$\delta_\Gamma > 0 \quad\Longleftrightarrow\quad \inf_{\Psi\in\mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[\hat{Q}_x^{[\mathrm{CK}]}[k]\Big] \;>\; 0 \quad \text{for all timelike } k \in \mathcal{C}_x^{\hat{\Sigma},*} \text{ (Definition 9.104)},$$

i.e. the typed hyperbolicity condition (9.53) (Definition 9.111) holds for the Chrono–Kymon projector.

Step 3: Admission to the ledger. Once typed hyperbolicity holds and items (P1)–(P7) of Definition 9.116 are satisfied (Step 1), the admission criterion of the permit ledger (Proposition 9.102) yields $\mathrm{CK} \in \mathcal{C}^{[\mathrm{kymon}]}_{\mathrm{admissible}}$, with the cone/hyperbolicity certificate recorded as in Corollary 9.120 (admissible timelike interval, gap margin δ_Γ, and stability radius).

Combining Steps 1–3 proves the corollary. □

Remark 9.126 (Interface with typed contrasts and visibilities)**.** Once $\Pi^{[\chi]}$ is admitted, all typed diagnostics in §3—namely $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law/state}}$, $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}$ and the quadrant $\mathrm{Quad}^{[\chi]}$—are computed by restricting the kernels and probes with $\Pi^{[\chi]}$ (cf. Definitions 9.28, 9.45, 9.47 and 9.109). Band retardedness and microcausality follow from Propositions 9.107 and 9.108.

9.11 Typed Σ–Contrasts & Visibilities (Pre-Physical)

All evaluations below use *retarded, cone-gated* kernels (Definition 9.106 and Proposition 9.107) and BRST-closed taggers (Definition 9.96 and Proposition 9.97). Typed restrictions are taken with the band-admissible projectors $\Pi^{[\chi]}$ constructed in Definition 9.116 and admitted by the ledger Definition 9.122.

3.1 Pointwise typed Σ–contrasts

Definition 9.127 (Pointwise typed Σ–contrasts)**.** Let the Σ–probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ be as in Definitions 9.22 and 9.95 and let $\Pi^{[\chi]}$ be a typed projector (Definition 9.116). For a local graded gauge frame $g(x)$ (Definition 9.7) define the *typed law-contrast* and *typed state-contrast* at $(x;v)$ by

$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law}}(g;x;v) := \Big(\mathcal{I}\Big[\big(\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\big)\Big|_{\Pi^{[\chi]}}\Big] \Big)^{1/2}, \tag{9.58}$$

$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{state}}(g;x;v) := \Big| \mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big] - \mathcal{I}_{g\cdot\Psi}\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big] \Big|^{1/2}, \tag{9.59}$$

where $\mathcal{I}, \mathcal{I}_\Psi$ are band functionals as in Definition 9.45. The restriction $\big|_{\Pi^{[\chi]}}$ abbreviates $\Pi^{[\chi]}(\cdot)\Pi^{[\chi]}$ (Definition 9.109).

Lemma 9.128 (BRST/Nielsen safety of pointwise typed contrasts)**.** *Under a gauge-parameter variation for which $\delta_\theta \hat{Q}_x[v] = [\hat{Q}_{\mathrm{BRST}}, X_\theta]$, the quantities in (9.58)–(9.59) are invariant: $\partial_\theta \Delta^{\mathrm{pre},\Sigma;[\chi]}_\bullet(g;x;v) = 0$ for $\bullet \in \{\mathrm{law},\mathrm{state}\}$, by Proposition 9.97 and $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116).*

Proof of Lemma 9.128. Recall the pointwise typed contrasts (9.58)–(9.59) from Definition 9.127, with typed restriction $A\big|_{\Pi^{[\chi]}} := \Pi^{[\chi]} A\, \Pi^{[\chi]}$ and BRST–closed projector $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116). Band functionals $\mathcal{I}, \mathcal{I}_\Psi$ annihilate BRST–exact insertions (Proposition 9.97) and act at ghost number 0 (Definition 9.96).

Step 1: Typed variation of the Σ–probe is BRST–exact. By hypothesis, $\delta_\theta \hat{Q}_x[v] = [\,\hat{Q}_{\mathrm{BRST}}, X_\theta\,]$. Using $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ we obtain

$$\delta_\theta\Big(\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big) = \Pi^{[\chi]}[\,\hat{Q}_{\mathrm{BRST}}, X_\theta\,]\Pi^{[\chi]} = \Big[\,\hat{Q}_{\mathrm{BRST}},\, \Pi^{[\chi]} X_\theta \Pi^{[\chi]}\,\Big]. \tag{9.60}$$

Thus the typed variation is itself BRST–exact.

Step 2: Invariance of the pointwise typed law contrast. Let $A_\theta(x; v) := \hat{Q}_x[v] - \mathrm{Ad}_{g_\theta(x)}\, \hat{Q}_x[v]$ be the (untyped) law–contrast operand (Definition 9.127). A gauge–parameter shift changes A_θ by a BRST–exact commutator on the band algebra (graded covariance, Definition 9.7; cf. the mechanism used in Proposition 9.91):

$$\delta_\theta A_\theta(x; v) = \Big[\,\hat{Q}_{\mathrm{BRST}}, Y_\theta(x; v)\,\Big] \quad \text{for some band–admissible } Y_\theta.$$

Restricting to the typed subspace and using (9.60),

$$\delta_\theta\Big(A_\theta\Big|_{\Pi^{[\chi]}}\Big) = \Big[\,\hat{Q}_{\mathrm{BRST}},\, \Pi^{[\chi]} Y_\theta \Pi^{[\chi]}\,\Big].$$

Applying $\mathcal{I}$ and Proposition 9.97 gives $\partial_\theta\, \mathcal{I}\Big(A_\theta\Big|_{\Pi^{[\chi]}}\Big) = 0$. Since $\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma;[\chi]}(g; x; v)$ is the nonnegative square root of this scalar (Definition 9.127), the chain rule yields

$$\partial_\theta\, \Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma;[\chi]}(g; x; v) = 0.$$

Step 3: Invariance of the pointwise typed state contrast. For the state contrast operand, write $B_\theta(x; v) := \mathcal{I}_\Psi\Big(\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big) - \mathcal{I}_{g_\theta\cdot\Psi}\Big(\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big)$ (Definition 9.127, Definition 9.7). Using (9.60) and the covariance rule of the band functionals (Definitions 9.7 and 9.96), each θ–variation produces BRST–exact insertions inside $\mathcal{I}_\Psi$ and $\mathcal{I}_{g_\theta\cdot\Psi}$, which are killed by Proposition 9.97. Hence $\partial_\theta B_\theta(x; v) = 0$, and taking the absolute value and square root (definition (9.59)) preserves the zero derivative:

$$\partial_\theta\, \Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma;[\chi]}(g; x; v) = 0.$$

Combining Steps 2–3 proves the claimed invariance for $\bullet \in \{\mathrm{law}, \mathrm{state}\}$. □

Lemma 9.129 (Cone causality & positivity)**.** *If v is chosen with $k := k(v) \in \mathcal{C}_x^{\hat{\Sigma},*}$ timelike (Definition 9.104) and kernels are retarded cone-gated (Definition 9.106), then $\mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big] \geq 0$ and the commutators entering (9.58)–(9.59) vanish for spacelike separations (Proposition 9.108). Thus both $\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma;[\chi]}$ and $\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma;[\chi]}$ are well-defined and real.*

Proof of Lemma 9.129. Fix x and choose v so that $k := k(v) \in \mathcal{C}_x^{\hat{\Sigma},*}$ is timelike (Definition 9.104). Recall the Σ–probe and its typed restriction

$$\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x) \quad (\textit{Definition 9.95}),$$
$$\hat{Q}_x^{[\chi]}[v] := \Pi^{[\chi]}\, \hat{Q}_x[v]\, \Pi^{[\chi]} \quad (\text{cf. (9.52), Definition 9.109}).$$

(a) Positivity of the typed quadratic evaluation. By cone-compatibility of typed projectors (item (P6) of Definition 9.116) the principal quadratic form restricted by $\Pi^{[\chi]}$ is nonnegative on cone–timelike covectors. Equivalently, for all band functionals $\mathcal{I}_\Psi$ (Definition 9.96),

$$\mathcal{I}_\Psi\big[\hat{Q}_x^{[\chi]}[k]\big] \;\geq\; 0. \tag{9.61}$$

(If χ is admitted to the ledger, (9.61) strengthens to a strict lower bound by typed hyperbolicity, Definition 9.111.) Moreover, $\hat{Q}_x^{[\chi]}[k]$ is Hermitian (Lemma 9.110), hence the scalar in (9.61) is *real*.

(b) Cone-gated retardedness and microcausality. All kernels are replaced by their retarded, cone-gated versions $\mathcal{K}^{\mathrm{ret}} = \mathbf{1}_{J^+(\mathcal{C}^{\hat{\Sigma},*})}\mathcal{K}$ (Definition 9.106), which are supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$ (Proposition 9.107). Therefore the Pauli–Jordan bi-distributions of the unified field $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^{\mathsf{T}}$ have support contained in $J^+ \cup J^-$ with respect to the Σ–cone. Consequently, for spacelike separated supports (w.r.t. $\mathcal{C}^{\hat{\Sigma},*}$) one has

$$[\,\hat{\mathbf{\Phi}}(f), \hat{\mathbf{\Phi}}(g)\,] = [\,\hat{\mathbf{\Theta}}(f), \hat{\mathbf{\Theta}}(g)\,] = 0,$$

by microcausality from cone-gating (Proposition 9.108).

(c) Well-definedness and reality of the typed pointwise contrasts. For the *state* contrast, the definition $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{state}}(g;x;v) = \big|\mathcal{I}_\Psi[\hat{Q}_x[v]\big|_{\Pi^{[\chi]}}] - \mathcal{I}_{g\cdot\Psi}[\hat{Q}_x[v]\big|_{\Pi^{[\chi]}}]\big|^{1/2}$ (Definition 9.127, eq. (9.59)) uses an absolute value and the arguments are real by Hermiticity (Lemma 9.110), so the square root is real and well-defined.

For the *law* contrast,

$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law}}(g;x;v) = \Big(\mathcal{I}\big[(\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v])\big|_{\Pi^{[\chi]}}\big]\Big)^{1/2} \quad \text{(Definition 9.127, eq. (9.58))},$$

the operand is Hermitian and evaluated by a positive band functional (Definitions 9.45 and 9.96), and the cone-gated retardedness ensures causal support (Proposition 9.107). Thus the inner scalar is real and nonnegative, so the square root is well-defined and real. In both cases, microcausality from (b) guarantees the vanishing of commutators entering the contrasts for spacelike separations (Proposition 9.108).

Combining (a)–(c) establishes the stated nonnegativity $\mathcal{I}_\Psi[\hat{Q}_x[v]\big|_{\Pi^{[\chi]}}] \geq 0$, the spacelike vanishing of commutators, and the well-defined, real-valued nature of $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law}}$ and $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{state}}$. □

Proposition 9.130 (Gauge covariance and frame independence)**.** *Let g and $\tilde{g}$ be related by a band-admissible graded gauge transformation. Then the contrasts in (9.58)–(9.59) coincide. In particular, any change $g \mapsto g'$ with*

$$\mathrm{Ad}_{g'(x)}\,\hat{Q}_x[v] = \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v] + [\,\hat{Q}_{\mathrm{BRST}}, Y\,]$$

leaves the contrasts invariant by Lemma 9.128.

Proof of Proposition 9.130. Let $\tilde{g} = h\,g$ with h a band-admissible graded-gauge element (Definitions 9.7 and 9.96). Consider a smooth path $\theta \mapsto h_\theta$ in the graded-gauge group with $h_0 = \mathbf{1}$ and $h_1 = h$, and set $g_\theta := h_\theta g$. Define the pointwise typed law/state contrasts $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g_\theta; x; v)$ by Definition 9.127, i.e. via (9.58)–(9.59) with the typed restriction $A\big|_{\Pi^{[\chi]}} = \Pi^{[\chi]} A\, \Pi^{[\chi]}$ and $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116).

Step 1: Infinitesimal gauge change is BRST-exact on the band. By graded covariance and BRST hygiene (Definitions 9.7 and 9.96), the θ–variation of the Σ–probe under g_θ is BRST-exact on the band algebra:

$$\partial_\theta\Big(\,\mathrm{Ad}_{g_\theta(x)}\,\hat{Q}_x[v]\Big) = \Big[\,\hat{Q}_{\mathrm{BRST}},\; X_\theta(x;v)\,\Big] \qquad \text{for some band-admissible } X_\theta, \tag{9.62}$$

cf. the gauge-parameter mechanism used in Proposition 9.91.

Step 2: Pointwise invariance along the path. Applying Lemma 9.128 to (9.62) and using $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116) yields

$$\partial_\theta \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g_\theta; x; v) = 0, \qquad \bullet \in \{\mathrm{law}, \mathrm{state}\}.$$

Integrating from $\theta = 0$ to $\theta = 1$ gives

$$\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(\tilde{g}; x; v) = \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g; x; v) \quad \text{for } \bullet \in \{\mathrm{law}, \mathrm{state}\},$$

i.e. the contrasts coincide for g and $\tilde{g}$.

Step 3: The stated special case. If a change $g \mapsto g'$ satisfies $\mathrm{Ad}_{g'(x)}\,\hat{Q}_x[v] = \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v] + [\,\hat{Q}_{\mathrm{BRST}}, Y\,]$, then the contrasts are invariant by a one-step application of Lemma 9.128 (no path integration needed), since the typed variation is BRST-exact and is annihilated by the band functionals (Proposition 9.97).

Combining Steps 1–3 proves gauge covariance and frame independence of the pointwise typed contrasts (9.58)–(9.59). □

3.2 Aggregation and normalization (typed Σ–visibilities)

Definition 9.131 (Typed aggregation on a probe family)**.** Fix a band-admissible probe family $\mathcal{V} = \{v_k\}_{k=1}^m$ and convex weights $w_k > 0$, $\sum_k w_k = 1$. Define the aggregated typed contrasts

$$\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x; \mathcal{V}, w) := \Big(\,\sum_{k=1}^{m} w_k\,\Big(\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g; x; v_k)\Big)^2\,\Big)^{1/2}, \quad \bullet \in \{\mathrm{law}, \mathrm{state}\}. \tag{9.63}$$

Lemma 9.132 (Monotonicity and stability of aggregation)**.** *If $\mathcal{V} \subseteq \mathcal{V}'$ and w' extends w by assigning nonnegative weights to new probes, then $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x; \mathcal{V}, w) \le \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x; \mathcal{V}', w')$. Moreover, under retunings $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\lambda'_{\mathrm{UV}}, \ell')$ within the stability radius of Definition 9.116, the map $(\lambda_{\mathrm{UV}}, \ell) \mapsto \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x; \mathcal{V}, w)$ is continuous.*

Proof of Lemma 9.132. Recall the pointwise typed contrasts from Definition 9.127,

$$\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma;[\chi]}(g; x; v) := \Big(\,\mathcal{I}\Big[(\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v])\Big|_{\Pi^{[\chi]}}\Big]\Big)^{1/2}, \tag{9.64}$$

$$\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma;[\chi]}(g; x; v) := \Big|\;\mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big] - \mathcal{I}_{g\cdot\Psi}\Big[\hat{Q}_x[v]\Big|_{\Pi^{[\chi]}}\Big]\;\Big|^{1/2}, \tag{9.65}$$

and the aggregation/normalization step producing the (pre-normalized) typed Σ–aggregates $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)$ from a probe set $\mathcal{V}=\{v_k\}$ and weights $w=\{w_k\}_{v_k\in\mathcal{V}}$, as specified in Definition 9.133. In particular, the admissible aggregators include the (weighted) root-sum-square (RSS),

$$\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)=\Big(\sum_{v_k\in\mathcal{V}} w_k\,\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g;x;v_k)^2\Big)^{1/2},\qquad w_k\ge 0, \tag{9.66}$$

and, more generally, any norm-like, coordinatewise-monotone aggregator registered in Definition 9.133 (cf. Definition 9.47 when available).

Monotonicity under $\mathcal{V}\subseteq\mathcal{V}'$ and $w'\supset w$ with nonnegative new weights. By Lemma 9.129, each pointwise contrast $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g;x;v)$ is real and nonnegative (the typed quadratic evaluation is nonnegative on cone–timelike covectors, and the square roots in (9.64)–(9.65) ensure ≥ 0). Let $\mathcal{V}'=\mathcal{V}\cup\mathcal{W}$ and let w' extend w by assigning nonnegative weights $\{w'_j\}_{v_j\in\mathcal{W}}\subset[0,\infty)$. For the RSS aggregator (9.66),

$$\begin{aligned}\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V}',w')^2&=\sum_{v_k\in\mathcal{V}} w_k\,\Delta_\bullet(v_k)^2+\sum_{v_j\in\mathcal{W}} w'_j\,\Delta_\bullet(v_j)^2\\&\ge\sum_{v_k\in\mathcal{V}} w_k\,\Delta_\bullet(v_k)^2\\&=\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)^2,\end{aligned}$$

hence (taking square roots) the required inequality follows:

$$\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)\ \le\ \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V}',w').$$

The same argument applies to any admissible aggregator in Definition 9.133 that is coordinatewise nondecreasing on $\mathbb{R}_{\ge 0}^{|\mathcal{V}|}$ and nondecreasing under appending nonnegative coordinates; these properties are part of the aggregation hygiene adopted in Definition 9.133. This proves monotonicity for both $\bullet\in\{\mathrm{law},\mathrm{state}\}$.

Continuity under band retunings within the stability radius. Consider a retuning $(\lambda_{\mathrm{UV}},\ell)\mapsto(\lambda'_{\mathrm{UV}},\ell')$ that lies inside the stability radius of item (P7) in Definition 9.116. Then (i) the typed projector $\Pi^{[\chi]}$ varies continuously in operator norm (Riesz projector stability: Proposition 9.119), (ii) the UV/IR taggers vary continuously in operator norm within the band class (Definition 9.96; IR monotonicity in Lemma 9.105), and (iii) the cone gate and retarded kernels commute with the instrumentation and remain cone-supported (Proposition 9.107 and Definition 9.106). Therefore, for each fixed probe $v\in\mathcal{V}$, the typed operands in (9.64)–(9.65) depend *continuously* on $(\lambda_{\mathrm{UV}},\ell)$ in the operator norm, and applying the bounded linear band functionals $\mathcal{I},\mathcal{I}_\Psi$ (Definition 9.96) yields continuous scalar functions of the retuning parameters. The outer operations (absolute value, positive square root) preserve continuity on $\mathbb{R}_{\ge 0}$, hence each pointwise contrast $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(g;x;v)$ is continuous in $(\lambda_{\mathrm{UV}},\ell)$. Finally, $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)$ is obtained from finitely many continuous nonnegative inputs via a continuous aggregator (e.g. the continuous map (9.66)); thus the aggregate is continuous in $(\lambda_{\mathrm{UV}},\ell)$.

Both claims (monotonicity and continuity) are established for $\bullet\in\{\mathrm{law},\mathrm{state}\}$, completing the proof. □

Definition 9.133 (Typed Σ–visibilities)**.** Let $\mathrm{Vis}(\cdot\,;\cdot)$ denote the visibility normalizer of Definition 9.47 and eqs. (9.21) and (9.22) (monotone-decreasing in its first argument, range $[0,1]$, equals 1 at zero contrast). Define

$$\Lambda_{\bullet}^{\Sigma;[\chi]}(x) := \mathrm{Vis}\Big(\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w) \;;\; \mathcal{N}_{\bullet}^{[\chi]}(x;\mathcal{V},w) \Big) \in [0,1], \quad \bullet \in \{\mathrm{law},\mathrm{state}\}, \tag{9.67}$$

where $\mathcal{N}_{\bullet}^{[\chi]}$ is the sector/typed normalizer specified in Definition 9.47. The *typed law-deficit* is

$$d_{\mathrm{law}}^{\Sigma;[\chi]}(x) := 1 - \Big|\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x)\Big|. \tag{9.68}$$

Proposition 9.134 (Invariance and bounds)**.** *The visibilities* (9.67) *are:*

(a) Gauge/BRST-invariant *by Lemma 9.128 and Proposition 9.97.*

(b) Causally well-posed *(retarded, cone-gated) by Proposition 9.107.*

(c) Normalized *to* $[0,1]$ *with* $\Lambda_{\bullet}^{\Sigma;[\chi]}(x) = 1$ *iff* $\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w) = 0$ *(law/state symmetry baseline, cf. Ch. 8 summary and Definition 9.47).*

Proof of Proposition 9.134. By definition (Definition 9.133), the (typed) visibilities are obtained from the aggregated contrasts via the normalization map encoded in (9.67):

$$\Lambda_{\bullet}^{\Sigma;[\chi]}(x) \;:=\; \mathfrak{n}_{\bullet}\Big(\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)\Big), \qquad \bullet \in \{\mathrm{law},\mathrm{state}\}, \tag{9.69}$$

where $\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}$ is the (nonnegative) aggregate built from the pointwise typed contrasts of Definition 9.127 [(9.58)–(9.59)] and $\mathfrak{n}_{\bullet} : \mathbb{R}_{\geq 0} \to [0,1]$ is the normalization specified in Definitions 9.47 and 9.133 (baseline $\mathfrak{n}_{\bullet}(0) = 1$, monotone nonincreasing).

(a) Gauge/BRST invariance. For each probe v, the pointwise typed contrasts are invariant under band–admissible gauge–parameter variations by Lemma 9.128, using the BRST–annihilation of band functionals (Proposition 9.97) and $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116). Aggregation is performed by a fixed algebraic rule on these scalars (Definition 9.133), hence $\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)$ is gauge/BRST–invariant. Applying the scalar-valued normalization (9.69) preserves invariance. Thus $\Lambda_{\bullet}^{\Sigma;[\chi]}$ is gauge/BRST–invariant.

(b) Causal well-posedness (retarded, cone-gated). All kernels entering the pointwise contrasts are replaced by their retarded, cone-gated versions (Definition 9.106), supported inside $J^{+}\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ by Proposition 9.107. Consequently, the bi-distributional commutators vanish for spacelike separations (Proposition 9.108), and each pointwise contrast is well-defined and real (Lemma 9.129). Aggregation and the pointwise normalization (9.69) do not alter causal support, hence the visibilities are retarded and cone-gated.

(c) Normalization and the $[0,1]$ *range with baseline at* 1. By Lemma 9.129, the aggregate $\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w) \in \mathbb{R}_{\geq 0}$, so the input to $\mathfrak{n}_{\bullet}$ lies in its domain. The normalization axioms of Definitions 9.47 and 9.133 give

$$0 \;\leq\; \Lambda_{\bullet}^{\Sigma;[\chi]}(x) \;=\; \mathfrak{n}_{\bullet}\Big(\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)\Big) \;\leq\; 1, \qquad \mathfrak{n}_{\bullet}(0) = 1.$$

Moreover, the baseline property stipulated in Definition 9.47 ensures that $\mathfrak{n}_\bullet(z) = 1$ iff $z = 0$ (law/state symmetry baseline). Therefore,

$$\Lambda_\bullet^{\Sigma;[\chi]}(x) = 1 \iff \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w) = 0,$$

as claimed.

Combining (a)–(c) proves the proposition. □

Corollary 9.135 (Orthogonal additivity)**.** *For a set of mutually Σ-orthogonal types $\{\chi_j\}$ (Lemma 9.118), the squared aggregated contrasts are additive:*

$$\Big(\Delta_\bullet^{\mathrm{pre},\Sigma;\,[\oplus_j \chi_j]}(x)\Big)^2 = \sum_j \Big(\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi_j]}(x)\Big)^2, \quad \bullet \in \{\mathrm{law},\mathrm{state}\},$$

hence the corresponding visibilities combine monotonically under the normalizer of Definition 9.47.

Proof of Corollary 9.135. Let $\{\Pi^{[\chi_j]}\}_{j=1}^N$ be mutually Σ–orthogonal typed projectors in a fixed block (Lemma 9.118) and set $\Pi_{\mathrm{adm}} := \sum_{j=1}^N \Pi^{[\chi_j]}$ (Proposition 9.124). Write, for a fixed probe v, the Hermitian *law* and *state* pointwise operands (Definition 9.127),

$$A(x;v) := \hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v], \qquad B_\Psi(x;v) := \hat{Q}_x[v] \ \text{ (with band evaluations } \mathcal{I}_\Psi,\ \mathcal{I}_{g\cdot\Psi}),$$

where $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (Definition 9.95).

Step 1: Pointwise additivity of squared contrasts for orthogonal types. Because A and $\hat{Q}_x[v]$ are linear in $\hat{\Sigma}$ and Hermitian (Lemma 9.110), and Π_{adm} is an orthogonal sum, we have the block decomposition

$$\Pi_{\mathrm{adm}}\, A\, \Pi_{\mathrm{adm}} = \sum_j \Pi^{[\chi_j]} A \Pi^{[\chi_j]} \ + \sum_{j\neq j'} \Pi^{[\chi_j]} A \Pi^{[\chi_{j'}]},$$

and the analogous decomposition with A replaced by $\hat{Q}_x[v]$. For v with $k(v) \in \mathcal{C}_x^{\hat{\Sigma},*}$ timelike (Definition 9.104) the Σ–orthogonality lemma (Lemma 9.118) implies that all *off–diagonal* band evaluations vanish:

$$\mathcal{I}\Big[\Pi^{[\chi_j]} A \Pi^{[\chi_{j'}]}\Big] = 0, \qquad \mathcal{I}_\Psi\Big[\Pi^{[\chi_j]} \hat{Q}_x[v] \Pi^{[\chi_{j'}]}\Big] = 0 \qquad (j \neq j').$$

Indeed, each off–diagonal block is a linear combination of terms of the form $\Pi^{[\chi_j]}\hat{Q}_x[v]\Pi^{[\chi_{j'}]}$, and these evaluate to zero by the band Σ–orthogonality (cf. the calculation in Lemma 9.118, Step 2). Therefore

$$\mathcal{I}\Big[(\Pi_{\mathrm{adm}} A \Pi_{\mathrm{adm}})\Big] = \sum_j \mathcal{I}\Big[\Pi^{[\chi_j]} A \Pi^{[\chi_j]}\Big], \tag{9.70}$$

$$\mathcal{I}_\Psi\Big[(\Pi_{\mathrm{adm}} \hat{Q}_x[v] \Pi_{\mathrm{adm}})\Big] = \sum_j \mathcal{I}_\Psi\Big[\Pi^{[\chi_j]} \hat{Q}_x[v] \Pi^{[\chi_j]}\Big]. \tag{9.71}$$

By Definition 9.127, the *squared* pointwise typed contrasts are precisely the right-hand sides of (9.70)–(9.71):

$$\left(\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma;[\oplus_j \chi_j]}(g;x;v)\right)^2 = \sum_j \left(\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma;[\chi_j]}(g;x;v)\right)^2,$$
$$\left(\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma;[\oplus_j \chi_j]}(g;x;v)\right)^2 = \sum_j \left(\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma;[\chi_j]}(g;x;v)\right)^2.$$

Step 2: Aggregated additivity under RSS (and norm-like) aggregation. Aggregating over a probe set $\mathcal{V}$ with nonnegative weights w using the root-sum-square (RSS) aggregator (Definition 9.133, eq. (9.66)), the pointwise additivity lifts to the *aggregated* level by linearity of finite sums:

$$\begin{aligned}\left(\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\oplus_j \chi_j]}(x)\right)^2 &= \sum_{v\in\mathcal{V}} w_v \left(\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\oplus_j \chi_j]}(g;x;v)\right)^2 \\ &= \sum_j \sum_{v\in\mathcal{V}} w_v \left(\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\chi_j]}(g;x;v)\right)^2 \\ &= \sum_j \left(\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\chi_j]}(x)\right)^2,\end{aligned}$$

for $\bullet \in \{\mathrm{law}, \mathrm{state}\}$. (The same conclusion holds for any norm-like, coordinatewise-monotone aggregator from Definition 9.133 that coincides with the ℓ^2-norm on orthogonal collections.)

Step 3: Monotonicity for visibilities. Visibilities are obtained by a nonincreasing normalizer $\mathfrak{n}_\bullet : \mathbb{R}_{\geq 0} \to [0,1]$ (Definitions 9.47 and 9.133; see also Proposition 9.134). Since $\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\oplus_j \chi_j]}(x) = \left(\sum_j \Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\chi_j]}(x)^2\right)^{1/2} \geq \max_j \Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\chi_j]}(x)$, it follows that

$$\Lambda_{\bullet}^{\Sigma;\,[\oplus_j \chi_j]}(x) = \mathfrak{n}_\bullet\!\left(\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\oplus_j \chi_j]}(x)\right) \;\leq\; \mathfrak{n}_\bullet\!\left(\Delta_{\bullet}^{\mathrm{pre},\Sigma;\,[\chi_j]}(x)\right) = \Lambda_{\bullet}^{\Sigma;\,[\chi_j]}(x) \qquad \forall j,$$

i.e. the direct-sum visibility combines *monotonically* under the prescribed normalizer.

Combining Steps 1–3 proves the asserted orthogonal additivity of squared aggregated contrasts and the monotone combination of the corresponding visibilities. □

Lemma 9.136 (Cone-shrink monotonicity for visibilities)**.** *If the IR window is tightened as in Lemma 9.105, then for any fixed $(\mathcal{V}, w)$ one has*

$$\Lambda_{\bullet}^{\Sigma;[\chi]}(x)\Big|_{\ell'} \;\geq\; \Lambda_{\bullet}^{\Sigma;[\chi]}(x)\Big|_{\ell}, \qquad \ell' \leq \ell,$$

i.e. reducing admissible support cannot increase *the measured breaking (monotonicity of* Vis *and of* (9.63)*).*

Proof of Lemma 9.136. Fix x, a permitted type χ, and an admissible probe set $(\mathcal{V}, w)$ (with nonnegative weights) as in Definition 9.133. Let the IR window be tightened from ℓ to ℓ'

with $\ell' \le \ell$. By Lemma 9.105 the Σ–covector cone contracts, $\mathcal{C}_x^{\hat{\Sigma},*}[\ell'] \subseteq \mathcal{C}_x^{\hat{\Sigma},*}[\ell]$, and, at the level of kernels, the *cone gate* (retarded projector) satisfies the Löwner-order relation

$$0 \;\le\; \Gamma_{\ell'} \;\le\; \Gamma_{\ell} \;\le\; \mathbf{1}, \qquad \Gamma_\bullet \text{ as in Definition 9.106, supported in } J^+\Big(\mathcal{C}^{\hat{\Sigma},*}[\bullet]\Big), \tag{9.72}$$

with retardedness preserved by Proposition 9.107.

Step 1: Pointwise contraction of typed operands under the cone gate. For any probe v and typed restriction by $\Pi^{[\chi]}$ (Definition 9.116), the pointwise law/state operands of Definition 9.127 are (schematically)

$$\mathcal{A}_\ell(v) := \Pi^{[\chi]}\,\Gamma_\ell\Big(\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big)\Gamma_\ell\,\Pi^{[\chi]}, \qquad \mathcal{B}_{\Psi,\ell}(v) := \Pi^{[\chi]}\,\Gamma_\ell\,\hat{Q}_x[v]\,\Gamma_\ell\,\Pi^{[\chi]},$$

with $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (Definition 9.95). The replacement $\ell \mapsto \ell'$ inserts the smaller gate $\Gamma_{\ell'}$ in place of Γ_ℓ.

Step 2: Monotonicity of pointwise contrasts under gate shrinking. By (9.72) and the positivity/Hermiticity properties (Lemmas 9.110 and 9.129), the band readouts used in the pointwise contrasts,

$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{law}}(g;x;v) = \Big(\mathcal{I}\big[\mathcal{A}_\ell(v)\big]\Big)^{1/2},$$
$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\mathrm{state}}(g;x;v) = \Big|\mathcal{I}_\Psi\big[\mathcal{B}_{\Psi,\ell}(v)\big] - \mathcal{I}_{g\cdot\Psi}\big[\mathcal{B}_{g\cdot\Psi,\ell}(v)\big]\Big|^{1/2} \quad \text{(Definition 9.127)},$$

are evaluated by positive, ghost-number-0 band functionals (Definitions 9.45 and 9.96). Because the cone gate enters *bilinearly* and as a positive contraction (Löwner order (9.72)), each scalar inside the square roots is *monotone nonincreasing* under $\Gamma_\ell \mapsto \Gamma_{\ell'}$.[2] Therefore, for every fixed probe v,

$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(g;x;v)\Big|_{\ell'} \;\le\; \Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(g;x;v)\Big|_{\ell}, \qquad \bullet \in \{\mathrm{law},\mathrm{state}\}. \tag{9.73}$$

Step 3: Aggregation preserves the inequality. Aggregating over $(\mathcal{V}, w)$ with any admissible (coordinatewise nondecreasing) rule (e.g. weighted RSS, Definition 9.133, eq. (9.66)) and using (9.73) pointwise yields

$$\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(x;\mathcal{V},w)\Big|_{\ell'} \;\le\; \Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(x;\mathcal{V},w)\Big|_{\ell}, \qquad \bullet \in \{\mathrm{law},\mathrm{state}\}. \tag{9.74}$$

Step 4: Normalization flips the inequality for visibilities. Visibilities are obtained by the nonincreasing normalizer $\mathfrak{n}_\bullet : \mathbb{R}_{\ge 0} \to [0,1]$ (Definitions 9.47 and 9.133),

$$\Lambda^{\Sigma;[\chi]}_{\bullet}(x) \;=\; \mathfrak{n}_\bullet\Big(\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(x;\mathcal{V},w)\Big) \quad \text{(eq. (9.67))}.$$

[2] This is the standard C*-algebraic monotonicity: if $0 \le P' \le P \le \mathbf{1}$ and H is Hermitian, then for any positive linear functional φ, $\varphi\big[(P'^{1/2} H P'^{1/2})_\pm\big] \le \varphi\big[(P^{1/2} H P^{1/2})_\pm\big]$, and in particular for the positive inputs used here (cf. Definition 9.45 and Lemma 9.129) the scalar readouts decrease when the gate shrinks.

Applying $\mathfrak{n}_\bullet$ to (9.74) gives

$$\Lambda_\bullet^{\Sigma;[\chi]}(x)\Big|_{\ell'} \;\geq\; \Lambda_\bullet^{\Sigma;[\chi]}(x)\Big|_{\ell}, \qquad \bullet \in \{\text{law}, \text{state}\}.$$

Thus tightening the IR window (shrinking the cone) cannot *increase* the measured breaking; equivalently, the visibilities are monotone *nondecreasing* under $\ell \downarrow$, as stated. □

3.3 Typed pre-physical Quadrant predicate

Definition 9.137 (Typed pre-physical Quadrant predicate)**.** With the visibilities of Definition 9.133, define the quadrant assignment

$$\mathrm{Quad}^{[\chi]}(x) := \mathrm{Quad}\Big(\Lambda_{\text{law}}^{\Sigma;[\chi]}(x),\ \Lambda_{\text{state}}^{\Sigma;[\chi]}(x)\Big) \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}, \tag{9.75}$$

using the canonical decision rule of Definition 7.685. Optional triadic attribution (corr/-vac/spec) is read via the decomposition of Definition 5.54, restricted by $\Pi^{[\chi]}$.

Proposition 9.138 (Typed ⇒ sector/untyped consistency)**.** *If $\Pi^{[\chi]}$ is chosen as the identity on a block ($\Phi\Phi$ or $\Theta\Theta$), then the typed constructions reduce to the sector-level ones of Definitions 9.28, 9.45 and 9.47 and the quadrant rule (9.75) coincides with Definition 7.685.*

Proof of Proposition 9.138. Fix a block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and take the typed projector to be the block identity $\Pi^{[\chi]} = E_{\bullet\bullet} \in \mathrm{End}(\bullet)$ (item (P1) of Definition 9.116; cf. Definition 9.94).

Step 1: Typed restriction collapses to the sector operand. For any band operator A supported in the block $\bullet$,

$$A\Big|_{\Pi^{[\chi]}} = \Pi^{[\chi]} A \Pi^{[\chi]} = E_{\bullet\bullet}\, A\, E_{\bullet\bullet} = A,$$

hence the typed Σ–probe coincides with its sector version: $\hat{Q}_x^{[\chi]}[v] = \Pi^{[\chi]} \hat{Q}_x[v] \Pi^{[\chi]} = \hat{Q}_x[v]$ (Definitions 9.95 and 9.109).

Step 2: Pointwise contrasts coincide with the sector definitions. Using (9.58)–(9.59) (Definition 9.127) and the collapse in Step 1,

$$\begin{aligned}
\Delta_{\text{law}}^{\text{pre},\Sigma;[\chi]}(g;x;v) &= \Big(\mathcal{I}\big[(\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\, \hat{Q}_x[v])\big]\Big)^{1/2} \\
&= \Delta_{\text{law}}^{\text{pre},\Sigma}(g;x;v) \quad \text{(sector version in Definition 9.45)},
\end{aligned}$$

$$\begin{aligned}
\Delta_{\text{state}}^{\text{pre},\Sigma;[\chi]}(g;x;v) &= \Big|\mathcal{I}_\Psi[\hat{Q}_x[v]] - \mathcal{I}_{g\cdot\Psi}[\hat{Q}_x[v]]\Big|^{1/2} \\
&= \Delta_{\text{state}}^{\text{pre},\Sigma}(g;x;v) \quad \text{(sector version in Definition 9.45)}.
\end{aligned}$$

Step 3: Aggregation and normalization agree. Aggregating over $(\mathcal{V}, w)$ via the admissible rules of Definition 9.133 (e.g. weighted RSS (9.66)) gives

$$\Delta_\bullet^{\text{pre},\Sigma;[\chi]}(x;\mathcal{V},w) = \Delta_\bullet^{\text{pre},\Sigma}(x;\mathcal{V},w), \qquad \bullet \in \{\text{law}, \text{state}\}.$$

Applying the visibility normalizer $\mathfrak{n}_\bullet$ (Definitions 9.47 and 9.133) yields

$$\Lambda_\bullet^{\Sigma;[\chi]}(x) = \mathfrak{n}_\bullet\Big(\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)\Big) = \mathfrak{n}_\bullet\Big(\Delta_\bullet^{\mathrm{pre},\Sigma}(x;\mathcal{V},w)\Big) = \Lambda_\bullet^{\Sigma}(x),$$

i.e. the typed visibilities coincide with the sector/untyped visibilities of Definition 9.47.

Step 4: Quadrant rule coincides. The typed quadrant predicate is

$$\mathrm{Quad}^{[\chi]}(x) = \mathrm{Quad}\Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x),\, \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x)\Big) \quad \text{(eq. (9.75), Definition 9.137)}.$$

By Step 3, $\Lambda_\bullet^{\Sigma;[\chi]}(x) = \Lambda_\bullet^{\Sigma}(x)$, so $\mathrm{Quad}^{[\chi]}(x) = \mathrm{Quad}\big(\Lambda_{\mathrm{law}}^{\Sigma}(x), \Lambda_{\mathrm{state}}^{\Sigma}(x)\big)$, which is exactly the canonical sector-level quadrant decision of Definitions 7.685 and 9.28.

Step 5: Causal/BRST properties persist. Retarded cone-gating (Definition 9.106 and Proposition 9.107) and BRST/Nielsen safety (Proposition 9.97 and Lemma 9.128) do not depend on the choice $\Pi^{[\chi]} = E_{\bullet\bullet}$; hence all causal and gauge properties match those of the sector/untyped constructions in Definitions 9.28, 9.45 and 9.47.

Combining Steps 1–4 establishes that choosing the typed projector as the block identity reduces all typed objects (contrasts, aggregation, visibilities, and quadrant predicate) to their sector-level counterparts, proving the proposition. □

Corollary 9.139 (Plateau stability of the quadrant)**.** *Within the retuning-stability radius of Definition 9.116 and under IR tightening (Lemma 9.105), the map $x \mapsto \mathrm{Quad}^{[\chi]}(x)$ is locally constant except at tolerance thresholds specified by the normalizer (Definition 9.47). In particular, quadrant membership is robust on certified plateaux (cf. Chapter 8 certification items and Proposition 9.134).*

Proof of Corollary 9.139. Fix a permitted type χ and define the visibility vector by

$$\vec{\Lambda}^{[\chi]}(x) := \big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x), \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x)\big) \in [0,1]^2,$$

so that the typed quadrant is the decision map

$$\mathrm{Quad}^{[\chi]}(x) = \mathrm{Quad}\big(\vec{\Lambda}^{[\chi]}(x)\big),$$

with decision surfaces given by the tolerance thresholds of $\mathfrak{n}_\bullet$ and the canonical rule (Definition 9.137, eq. (9.75), Definitions 7.685 and 9.47).

(i) Local constancy under retunings within the stability radius. By item (P7) of Definition 9.116 and the Riesz–projector continuity (Proposition 9.119), the typed projector $\Pi^{[\chi]}$ depends continuously on band retunings $(\lambda_{\mathrm{UV}}, \ell)$ inside its stability radius. Consequently, for each fixed x and probe set $(\mathcal{V}, w)$, the aggregated contrasts $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)$ vary *continuously* with the retuning parameters (Lemma 9.132, continuity part), and so do the visibilities $\Lambda_\bullet^{\Sigma;[\chi]}(x)$ after the continuous normalization (Definition 9.133). Therefore $\vec{\Lambda}^{[\chi]}(x)$ moves continuously in $[0,1]^2$ as $(\lambda_{\mathrm{UV}}, \ell)$ vary in that neighborhood. Since $\mathrm{Quad}^{[\chi]}$ is a piecewise-constant decision on the partition of $[0,1]^2$ by the tolerance thresholds (Definitions 7.685 and 9.47), it is *locally constant* so long as $\vec{\Lambda}^{[\chi]}(x)$ does not cross a decision surface. Thus quadrant changes can occur only at those thresholds.

(ii) Monotone robustness under IR tightening. If the IR window is tightened $\ell' \le \ell$, then for any fixed $(\mathcal{V}, w)$ the aggregated contrasts are monotone nonincreasing (Lemma 9.136, Eq. (9.74)), hence the visibilities are monotone nondecreasing:

$$\Lambda_{\bullet}^{\Sigma;[\chi]}(x)\Big|_{\ell'} \;\ge\; \Lambda_{\bullet}^{\Sigma;[\chi]}(x)\Big|_{\ell}, \qquad \bullet \in \{\mathrm{law}, \mathrm{state}\}.$$

Therefore the path $\ell \downarrow$ moves $\vec{\Lambda}^{[\chi]}(x)$ monotonically in $[0,1]^2$; the quadrant $\mathrm{Quad}^{[\chi]}(x)$ can change only if this monotone path intersects a tolerance boundary of the normalizer (Definition 9.47). Absent such an intersection (the certified *plateau* regime), quadrant membership is unchanged.

(iii) Causal and gauge well-posedness along the plateau. Throughout these deformations the pointwise/aggregated quantities remain retarded and cone-gated (Proposition 9.107), real and well-defined (Lemma 9.129), and gauge/BRST-invariant (Lemma 9.128 and Propositions 9.97 and 9.134). Hence no spurious quadrant flips arise from gauge or causal artifacts.

Combining (i)–(iii) proves that within the retuning-stability radius and under IR tightening, $x \mapsto \mathrm{Quad}^{[\chi]}(x)$ is locally constant except when $\vec{\Lambda}^{[\chi]}(x)$ meets a tolerance threshold prescribed by the normalizer (Definition 9.47). This is precisely the plateau stability asserted (cf. the certification semantics summarized in Chapter 8 and Proposition 9.134). □

Remark 9.140 (Operational interface to Parasymmetric meters)**.** Given $\mathrm{Quad}^{[\chi]}$ and the visibilities in Definition 9.133, band-restricted Parasymmetric meters (Section 8.6) provide the valuations $v_{\mathrm{Synthesis}}^{(a);[\chi]}$ and $v_{\mathrm{Synthesis}}^{(LS);[\chi]}$, supplying **T–L–O** (Type–Location–Onset). The onset scales/times are then defined as in §4.2 with $d_{\mathrm{law}}^{\Sigma;[\chi]}$ from (9.68), and inherit the causal and BRST properties of Lemma 9.129 and Proposition 9.134.

9.12 Parasymmetric Meters on the Band (Typed)

We port the Parasymmetric diagnostics of §8.6 to *band-reduced*, *typed* objects by restricting all constructions with the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.96) and the typed projector $\Pi^{[\chi]}$ (Definition 9.116). All kernels are retarded and cone-gated (Definition 9.106 and Proposition 9.107), and all taggers are BRST-closed with ghost number 0 (Definition 9.96 and Proposition 9.97).

4.1 Local and relational meters (typed)

Definition 9.141 (Band-reduced typed meter state)**.** Fix an anchor $a \in \{L, S\}$ and a permitted type $\chi \in \mathcal{C}_{\mathrm{admissible}}^{[\cdot]}$ (Definition 9.122). Let $\mathcal{M}^{(a)[\chi]}$ denote the meter channel obtained by the band restriction and typed compression,

$$\mathcal{M}^{(a)[\chi]} : \; \mathfrak{A}_{\mathrm{band}} \xrightarrow{\Pi^{[\chi]}\,(\cdot)\,\Pi^{[\chi]}} \mathfrak{A}_{\mathrm{band}}^{[\chi]} \xrightarrow{\text{anchor } a} \mathrm{M}_2(\mathbb{C}),$$

where $\mathfrak{A}_{\mathrm{band}}$ is the band-admissible operator algebra. The *band meter state* is the 2×2 density operator

$$\rho_{\mathrm{band}}^{(a)[\chi]} \;:=\; \mathcal{M}^{(a)[\chi]}(\mathbf{1}), \qquad \rho_{\mathrm{band}}^{(a)[\chi]} \succeq 0, \quad \mathrm{Tr}\,\rho_{\mathrm{band}}^{(a)[\chi]} = 1,$$

with local parasymmetric projectors $P_{\mathrm{para}}^{(a)}$, $P_{\mathrm{antipara}}^{(a)}$ as in §8.6.

Definition 9.142 (Parasymmetric anchor basis and projectors)**.** For each anchor $a \in \{L, S\}$, fix an orthonormal basis

$$\mathcal{B}_a = \{\ |\mathrm{Sym}\rangle_a,\ |\mathrm{Break}\rangle_a\ \}$$

in the meter space of §8.6. Define the local parasymmetric projectors by

$$P^{(a)}_{\mathrm{para}} = |\mathrm{Sym}\rangle_{a\,a}\langle\mathrm{Sym}|, \qquad P^{(a)}_{\mathrm{antipara}} = |\mathrm{Break}\rangle_{a\,a}\langle\mathrm{Break}|.$$

When the band-reduced, typed meter state $\rho^{(a)[\chi]}_{\mathrm{band}}$ (Definition 9.141) is expressed in the ordered basis $\mathcal{B}_a$, its matrix elements are $\rho^{(a)[\chi]}_{ij} = {}_a\langle b_i|\,\rho^{(a)[\chi]}_{\mathrm{band}}\,|b_j\rangle_a$ with $|b_1\rangle_a = |\mathrm{Sym}\rangle_a$ and $|b_2\rangle_a = |\mathrm{Break}\rangle_a$.

Definition 9.143 (Local typed Synthesis valuation)**.** For $a \in \{L, S\}$ and a permitted type χ,

$$v^{(a);[\chi]}_{\mathrm{Synthesis}} := \mathrm{Tr}\Big(P^{(a)}_{\mathrm{para}}\,\rho^{(a)[\chi]}_{\mathrm{band}}\Big) = {}_a\langle\mathrm{Sym}|\,\rho^{(a)[\chi]}_{\mathrm{band}}\,|\mathrm{Sym}\rangle_a = \tfrac{1}{2} + \mathrm{Re}\Big(\rho^{(a)[\chi]}_{12}\Big) \in [0,1], \quad (9.76)$$

where $\rho^{(a)[\chi]}_{12} = {}_a\langle\mathrm{Sym}|\,\rho^{(a)[\chi]}_{\mathrm{band}}\,|\mathrm{Break}\rangle_a$ is the off-diagonal entry in the ordered basis $\{|\mathrm{Sym}\rangle_a, |\mathrm{Break}\rangle_a\}$.

Definition 9.144 (Relational typed meters on LS)**.** Let $\rho^{(LS)[\chi]}_{\mathrm{band}}$ be the band-reduced, typed state on the two-anchor space. Define the *relational* valuations

$$v^{(LS);[\chi]}_{\mathrm{Synthesis}} := \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\,\rho^{(LS)[\chi]}_{\mathrm{band}}\Big), \qquad v^{(LS);[\chi]}_{\mathrm{Agreement}} := \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{agree}}\,\rho^{(LS)[\chi]}_{\mathrm{band}}\Big),$$

with projectors $P^{(LS)}_{\mathrm{para}}$, $P^{(LS)}_{\mathrm{agree}}$ defined in §8.6.

Lemma 9.145 (Meter well-posedness, bounds, and BRST invariance)**.** *For any typed χ and anchor choice:*

(a) $0 \le v^{(a);[\chi]}_{\mathrm{Synthesis}} \le 1$ *and* $0 \le v^{(LS);[\chi]}_{\mathrm{Synthesis}}, v^{(LS);[\chi]}_{\mathrm{Agreement}} \le 1$ *(positivity of meter states).*

(b) *Under gauge-parameter variations that are BRST-exact, all valuations are invariant, by Proposition 9.97 and* $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ *(Definition 9.116).*

(c) *Retardedness and cone-gating of inputs imply causal support within* $J^+(\mathcal{C}^{\hat{\Sigma},*})$ *(Propositions 9.107 and 9.108).*

Proof of Lemma 9.145. Fix a permitted type χ and work with the band-reduced, typed meters of Definitions 9.141, 9.143 and 9.144. We prove (a)–(c) in order.

(a) Bounds $0 \le v \le 1$. By Definitions 9.141, 9.143 and 9.144, the local meter is $v^{(a);[\chi]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(a)}_{\mathrm{para}}\,\rho^{(a)[\chi]}_{\mathrm{band}}\Big)$, where $P^{(a)}_{\mathrm{para}}$ is a projector (hence $0 \le P^{(a)}_{\mathrm{para}} \le \mathbf{1}$) and $\rho^{(a)[\chi]}_{\mathrm{band}}$ is a positive, unit-trace density operator on the (two-level) para-anchor space obtained from the typed, band-reduced state. Therefore

$$0 \ \le\ \mathrm{Tr}\Big(P^{(a)}_{\mathrm{para}}\,\rho^{(a)[\chi]}_{\mathrm{band}}\Big) \ \le\ \mathrm{Tr}\Big(\mathbf{1}\,\rho^{(a)[\chi]}_{\mathrm{band}}\Big) = 1.$$

The relational meters are of the same form with positive effects $0 \le P^{(LS)}_{\bullet} \le \mathbf{1}$ acting on the LS para-space (cf. Definitions 9.141, 9.143 and 9.144), so the same argument yields

$0 \le v^{(LS);[\chi]}_{\text{Synthesis}},\, v^{(LS);[\chi]}_{\text{Agreement}} \le 1$. (Equivalently, the explicit two-level expression shown inDefinitions 9.141, 9.143 and 9.144 immediately gives the same bounds.)

(b) BRST/Nielsen invariance. All ingredients that feed the meters—typed projector $\Pi^{[\chi]}$, band taggers $P_x(\lambda_{\text{UV}}), K^{(\ell)}_{\text{IR}}$, and the cone-gated kernels—are BRST-closed of ghost number 0 (Definitions 9.96, 9.106 and 9.116). Hence a gauge-parameter shift acts as a BRST-exact variation on the band algebra: $\delta_\theta(\cdot) = [\,\hat{Q}_{\text{BRST}}, X_\theta]$. Writing the valuation as a band functional $\mathcal{J}^{(a)}(A) := \mathrm{Tr}\Big(P^{(a)}_{\text{para}}\, A\Big)$ (ghost number 0), BRST-closedness of $P^{(a)}_{\text{para}}$ and the Nielsen safety on the band (Proposition 9.97) give

$$\partial_\theta v^{(a);[\chi]}_{\text{Synthesis}} = \mathcal{J}^{(a)}\Big(\delta_\theta \rho^{(a)[\chi]}_{\text{band}}\Big) = \mathcal{J}^{(a)}\Big([\,\hat{Q}_{\text{BRST}}, X_\theta]\Big) = 0.$$

The same argument applies to $v^{(LS);[\chi]}_{\text{Synthesis}}$ and $v^{(LS);[\chi]}_{\text{Agreement}}$, and uses in addition that $[\,\hat{Q}_{\text{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116) so that any typed restriction entering the construction produces only BRST-exact variations annihilated by band functionals (cf. also Lemmas 9.121 and 9.128).

(c) Retardedness and cone support. By construction all inputs to the meters (the correlators used to form $\rho^{(\cdot)[\chi]}_{\text{band}}$ and the typed restrictions effected by $\Pi^{[\chi]}$) use retarded, cone-gated kernels (Definition 9.106). These are supported in $J^+\Big(\mathcal{C}^{\hat{\Sigma},*}\Big)$ (Proposition 9.107), and microcausality holds for spacelike separated supports (Proposition 9.108). Since the meters are algebraic combinations (traces with positive effects) of these retarded, cone-supported inputs, their valuations inherit the same causal support.

Combining (a)–(c) proves the lemma. □

Proposition 9.146 (Monotonicity under cone shrink and band retuning)**.** *If the IR window tightens as in Lemma 9.105, then for fixed typed inputs* $v^{(\cdot);[\chi]}_{\text{Synthesis}}$ *is nondecreasing towards* $1/2$ *(loss of accessible coherence cannot raise asymmetry beyond the available support). Moreover, within the stability radius of Definition 9.116,* $v^{(\cdot);[\chi]}_{\text{Synthesis}}$ *depends continuously on* $(\lambda_{\text{UV}}, \ell)$.

Proof of Proposition 9.146. Fix a permitted type χ and an anchor $a \in \{L, S, LS\}$. The typed, band-reduced meters are defined in Definitions 9.141, 9.143 and 9.144; for the local anchors one has $v^{(a);[\chi]}_{\text{Synthesis}} = \frac{1}{2} + \mathrm{Re}\Big(\rho^{(a)[\chi]}_{12}\Big)$, with $\rho^{(a)[\chi]}$ the 2×2 para-density obtained from the typed, cone-gated band data. All kernels entering $\rho^{(a)[\chi]}$ are retarded and cone-gated (Definition 9.106 and Proposition 9.107), and the projector $\Pi^{[\chi]}$ is BRST-closed (Definition 9.116).

(A) Cone shrink $\ell' \le \ell$ contracts accessible coherence. Tightening the IR window from ℓ to ℓ' (with $\ell' \le \ell$) *shrinks* the Σ–cone (Lemma 9.105) and thus replaces the retarded cone gate by a smaller positive contraction in the Löwner order:

$$0 \;\le\; \Gamma_{\ell'} \;\le\; \Gamma_\ell \;\le\; \mathbf{1}, \qquad \Gamma_\bullet \text{ as in Definition 9.106.} \tag{9.77}$$

In the para-anchor two-level reduction, the matrix elements $\rho^{(a)[\chi]}_{ij}$ are band functionals (ghost number 0) of typed, cone-gated correlators; concretely, there exist positive linear functionals $\{\mathcal{J}^{(a)}_{ij}\}$ on the band algebra such that

$$\rho^{(a)[\chi]}_{ij}(\ell) = \frac{\mathcal{J}^{(a)}_{ij}\Big(\Gamma_\ell \cdot \Gamma_\ell\Big)}{\mathcal{J}^{(a)}_{11}\Big(\Gamma_\ell \cdot \Gamma_\ell\Big) + \mathcal{J}^{(a)}_{22}\Big(\Gamma_\ell \cdot \Gamma_\ell\Big)},$$

where the dot denotes the (fixed) typed operator input determined by $\Pi^{[\chi]}$ and the anchor a (cf. the construction in Definitions 9.141, 9.143 and 9.144). Introduce the Γ–weighted sesquilinear form on the anchor space $\langle u, v\rangle_\Gamma := \mathcal{J}^{(a)}\big(u^\dagger\,\Gamma\,(\cdot)\,\Gamma\,v\big)$; then Cauchy–Schwarz in the seminorm $\|u\|_\Gamma^2 = \langle u, u\rangle_\Gamma$ gives

$$\left|\rho_{12}^{(a)[\chi]}(\ell)\right| \;\le\; \sqrt{\rho_{11}^{(a)[\chi]}(\ell)\;\rho_{22}^{(a)[\chi]}(\ell)}\,. \tag{9.78}$$

By (9.77) and positivity of the band functionals (Definition 9.96), the diagonals are monotone nonincreasing under $\Gamma_\ell \mapsto \Gamma_{\ell'}$:

$$\rho_{ii}^{(a)[\chi]}(\ell') \;\le\; \rho_{ii}^{(a)[\chi]}(\ell) \qquad (i = 1, 2). \tag{9.79}$$

Applying (9.78) at level ℓ' and using (9.79) yields the *contraction of the coherence deviation*:

$$\begin{aligned}\left|\, v_{\text{Synthesis}}^{(a);[\chi]}(\ell') - \tfrac{1}{2}\,\right| &= \left|\,\mathrm{Re}\;\rho_{12}^{(a)[\chi]}(\ell')\right| \le \left|\rho_{12}^{(a)[\chi]}(\ell')\right| \\ &\le \sqrt{\rho_{11}^{(a)[\chi]}(\ell')\,\rho_{22}^{(a)[\chi]}(\ell')} \le \sqrt{\rho_{11}^{(a)[\chi]}(\ell)\,\rho_{22}^{(a)[\chi]}(\ell)}\,.\end{aligned} \tag{9.80}$$

In particular, the *distance to the baseline* $1/2$ cannot increase when the cone shrinks. Under the standard anchor phase convention used in §8.6 (the off-diagonal is taken real and nonnegative in the fixed $\{|\mathrm{Sym}\rangle_a, |\mathrm{Break}\rangle_a\}$ basis; cf. Definitions 9.141, 9.143 and 9.144), (9.80) reads $v_{\text{Synthesis}}^{(a);[\chi]}(\ell') \;\le\; v_{\text{Synthesis}}^{(a);[\chi]}(\ell)$, i.e. $v_{\text{Synthesis}}^{(a);[\chi]}$ moves *monotonically toward* $1/2$ as $\ell \downarrow$. For a general phase, the statement holds as monotone contraction of $\left|v_{\text{Synthesis}}^{(a);[\chi]} - \frac{1}{2}\right|$, which is the operational asymmetry magnitude. The same argument applies verbatim to the relational meter $v_{\text{Synthesis}}^{(LS);[\chi]}$ (and thus to its deviation from $1/2$), since its construction is again a trace against a positive effect on a typed, cone-gated band state (Definitions 9.141, 9.143 and 9.144).

(B) Continuity under band retunings within the stability radius. Let $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\lambda'_{\mathrm{UV}}, \ell')$ be a retuning inside the stability radius of item (P7) in Definition 9.116. Then the typed Riesz projector $\Pi^{[\chi]}$ depends continuously on the parameters (Proposition 9.119), the UV/IR taggers and cone gates vary continuously in operator norm within the band class (Definitions 9.96 and 9.106 and Proposition 9.107), and the band functionals are bounded linear maps (Definition 9.96). Therefore each matrix element $\rho_{ij}^{(a)[\chi]}$ depends continuously on $(\lambda_{\mathrm{UV}}, \ell)$, and so do $v_{\text{Synthesis}}^{(a);[\chi]} = \frac{1}{2} + \mathrm{Re}(\rho_{12}^{(a)[\chi]})$ and $v_{\text{Synthesis}}^{(LS);[\chi]}$. Hence $v_{\text{Synthesis}}^{(\cdot);[\chi]}$ is continuous in $(\lambda_{\mathrm{UV}}, \ell)$ within the stability radius.

Combining (A) and (B) proves that tightening the IR window cannot increase the measured asymmetry: the synthesis meters move (in magnitude) monotonically toward the baseline $\frac{1}{2}$, and they vary continuously under band retunings inside the certified stability neighborhood. □

4.2 Typed T–L–O readouts

Definition 9.147 (Typed T–L–O map)**.** For each permitted type χ at spacetime point x and scale parameter r (e.g. window size or dilation), define the T–L–O triple

$$\mathrm{TLO}^{[\chi]}(x; r) \;:=\; \Big(\underbrace{\text{Type}}_{=\,\mathrm{Quad}^{[\chi]}(x)}\;,\;\underbrace{\text{Location}}_{\text{arena/sector/position/cone sheet}}\;,\;\underbrace{\text{Onset}}_{(r^\star[\chi],\,t^\star[\chi])}\Big),$$

with components:

(i) **Type:** $\mathrm{Quad}^{[\chi]}(x) \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$ from Definition 9.137.

(ii) **Location:** $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$, sector $\Phi\Phi$ or $\Theta\Theta$, spatial tag $P_x(\lambda_{\mathrm{UV}})$, and cone sheet (future/past, null/interior) determined by $\mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104).

(iii) **Onset (scale/time):** with tolerances $(\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}})$ and law-deficit $d_{\mathrm{law}}^{\Sigma;[\chi]}$ from (9.68), set

$$\begin{aligned} r^\star_{\mathrm{SSB}}[\chi] &:= \inf\Big\{ r :\ v^{(S);[\chi]}_{\mathrm{Synthesis}}(r) > \tfrac{1}{2} + \varepsilon_{\mathrm{state}} \\ &\qquad\qquad \wedge\ v^{(LS);[\chi]}_{\mathrm{Synthesis}}(r) \downarrow \tfrac{1}{2} \Big\}, \\ r^\star_{\mathrm{QIV}}[\chi] &:= \inf\Big\{ r :\ d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \geq \delta_\star \Big\}, \\ r^\star_{\mathrm{QIII}}[\chi] &:= \inf\Big\{ r :\ d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \leq C\, r^{-\beta} \Big\}, \end{aligned} \tag{9.81}$$

and define temporal onsets $t^\star[\chi]$ analogously from the time traces $t \mapsto v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}(t; r)$.

Lemma 9.148 (Existence of onsets under mild regularity)**.** *If $r \mapsto v^{(S);[\chi]}_{\mathrm{Synthesis}}(r)$ and $r \mapsto v^{(LS);[\chi]}_{\mathrm{Synthesis}}(r)$ are piecewise monotone with one-sided limits at infinity, and $r \mapsto d^{\Sigma;[\chi]}_{\mathrm{law}}(r)$ admits a regularly varying envelope (as in the large-window law test of Definition 7.685), then the infima in (9.81) are finite or $+\infty$ according to whether the corresponding threshold is eventually met or not; in both cases the onsets are well-defined.*

Proof of Lemma 9.148. Recall the onset rules from Definition 9.147 (eq. (9.81)):

$$r^\star_{\mathrm{SSB}}[\chi] := \inf\Big\{r :\ v^{(S);[\chi]}_{\mathrm{Synthesis}}(r) > \tfrac{1}{2} \ \wedge\ v^{(LS);[\chi]}_{\mathrm{Synthesis}}(r) \downarrow \tfrac{1}{2}\Big\},$$
$$r^\star_{\mathrm{QIV}}[\chi] := \inf\Big\{r :\ d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \geq \delta_\star\Big\}, \qquad r^\star_{\mathrm{QIII}}[\chi] := \inf\Big\{r :\ d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \leq C\, r^{-\beta}\Big\},$$

with the understanding that tolerances $(\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}})$ may be inserted as in Definition 9.147, and where the *typed law–deficit* $d^{\Sigma;[\chi]}_{\mathrm{law}}$ is induced from the typed law–contrast of Definition 9.127. By Lemma 9.145(a) all meters take values in $[0, 1]$, so the threshold statements are meaningful.

(1) SSB onset $r^\star_{\mathrm{SSB}}[\chi]$. Assume $r \mapsto v^{(S);[\chi]}_{\mathrm{Synthesis}}(r)$ and $r \mapsto v^{(LS);[\chi]}_{\mathrm{Synthesis}}(r)$ are piecewise monotone on $[R_0, \infty)$ and admit one–sided limits at $+\infty$ (hypothesis of the lemma; the construction of the meters is in Definitions 9.141, 9.143 and 9.144). Set

$$A := \Big\{r \geq R_0 :\ v^{(S);[\chi]}_{\mathrm{Synthesis}}(r) > \tfrac{1}{2} \ \wedge\ v^{(LS);[\chi]}_{\mathrm{Synthesis}}(r) \downarrow \tfrac{1}{2}\Big\},$$

where "$\downarrow \frac{1}{2}$" abbreviates the monotone approach to $\frac{1}{2}$ from above within the current monotonicity interval (cf. the tolerance semantics in Definition 9.147). Because each meter is piecewise monotone and has a one–sided limit at $+\infty$, either (i) the joint condition in the definition of A is *eventually* satisfied (then A contains a tail interval (R, ∞) for some R), or (ii) it is *eventually* not satisfied (then A is empty beyond some scale). In case (i) $\inf A \in [R_0, \infty)$ is finite; in case (ii) $A = \varnothing$ or A is bounded, and by the convention of Definition 9.147 the infimum is $+\infty$. Thus $r^\star_{\mathrm{SSB}}[\chi] = \inf A \in [0, \infty]$ is well-defined.

(2) QIV onset $r^{\star}_{\mathrm{QIV}}[\chi]$. Let $B := \{r \ge R_1 : \ d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \ge \delta_\star\}$ and assume that $d^{\Sigma;[\chi]}_{\mathrm{law}}$ admits a *regularly varying envelope* as in the large-window law test of Definition 7.685: there exists an eventually monotone function $e(r)$ with $|d^{\Sigma;[\chi]}_{\mathrm{law}}(r)| \le e(r)$ for all $r \ge R_1$ and $e(r) \sim r^{-\alpha}L(r)$ (with slowly varying L) or is asymptotically constant.[3] Then either $e(r) \ge \delta_\star$ eventually, in which case $d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \ge \delta_\star$ eventually and B contains a tail (R, ∞), giving $\inf B < \infty$; or else $e(r) < \delta_\star$ eventually, and then B is empty beyond some scale, giving $\inf B = +\infty$. Hence $r^{\star}_{\mathrm{QIV}}[\chi] = \inf B$ is well-defined and equals a finite scale if and only if the threshold is eventually met.

(3) QIII onset $r^{\star}_{\mathrm{QIII}}[\chi]$. Let $C := \{r \ge R_2 : \ d^{\Sigma;[\chi]}_{\mathrm{law}}(r) \le C_0\, r^{-\beta}\}$. With the same envelope $e(r)$ as above and using $|d^{\Sigma;[\chi]}_{\mathrm{law}}(r)| \le e(r)$ for $r \ge R_2$, either $e(r) \le C_0\, r^{-\beta}$ eventually (then C contains a tail and $\inf C < \infty$), or $e(r) > C_0\, r^{-\beta}$ eventually (then C is empty on a tail and $\inf C = +\infty$). Thus $r^{\star}_{\mathrm{QIII}}[\chi] = \inf C$ is well-defined and is finite exactly when the decay threshold is eventually attained.

In each case the onset is the infimum of a (possibly empty) subset of $[0, \infty)$ determined by eventually monotone data; therefore it exists as an extended nonnegative real number and equals $+\infty$ precisely when the corresponding threshold is not eventually satisfied. This establishes the lemma. □

Proposition 9.149 (Typed Type–Location–Onset is BRST/causally robust)**.** *The T–L–O assignment* $\mathrm{TLO}^{[\chi]}(x; r)$ *is (a) gauge-parameter independent (by Lemma 9.145 and Proposition 9.97); (b) causally supported within* $J^+(\mathcal{C}^{\hat{\Sigma},*})$ *(by Proposition 9.107); and (c) stable under band retunings within the radius of Definition 9.116 (continuity of meters and of* $\Lambda^{\Sigma;[\chi]}$ *in Proposition 9.134).*

Proof of Proposition 9.149. Fix a permitted type χ and a space–scale pair $(x; r)$. By Definition 9.147, the typed Type–Location–Onset assignment is

$$\mathrm{TLO}^{[\chi]}(x; r) := \Big(\underbrace{\mathrm{Quad}^{[\chi]}(x)}_{\text{Type, Definition 9.137}}, \ \underbrace{\mathrm{Loc}^{[\chi]}(x)}_{\text{arena/sector/position/cone sheet, Definition 9.147}}, \ \underbrace{\mathrm{Onset}^{[\chi]}(r)}_{\text{rules (9.81) in Definition 9.147}} \Big),$$

where $\mathrm{Quad}^{[\chi]}$ is computed from the typed visibilities $\vec{\Lambda}^{[\chi]}(x) = (\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x), \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x))$ (Definition 9.133), the location tags are read from the band instrumentation and cone sheet (Definitions 9.96 and 9.106), and the onset entries use the synthesis meters and typed law–deficit (Definitions 9.127, 9.141, 9.143, 9.144 and 9.147).

(a) Gauge/BRST independence. Pointwise typed contrasts are BRST/Nielsen-safe by Lemma 9.128 together with the band Nielsen property Proposition 9.97 and $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$

[3] The only properties used here are eventual monotonicity of e and that e bounds $|d_{\mathrm{law}}|$ from above on a tail.

(Definition 9.116). Hence the aggregated contrasts and visibilities are gauge-invariant (Proposition 9.134(a)), and the quadrant decision $\mathrm{Quad}^{[\chi]}(x)$ is therefore gauge-independent (Definition 9.137). The location tags are built from BRST-closed band taggers $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}$ (Definition 9.96) and cone-sheet labels (from $\mathcal{C}^{\hat{\Sigma},*}$, Definition 9.104), so they are invariant as well. For the onset rules (9.81), the valuations entering the thresholds are gauge-invariant: the synthesis meters are BRST/Nielsen-safe by Lemma 9.145(b), while the typed law–deficit is built from the typed contrasts (already gauge-invariant). Hence the infima defining all onset components are unchanged under gauge-parameter variations.

(b) Causal support within $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$. All kernels used to form the typed contrasts/visibilities and the meter states are *retarded and cone-gated* (Definition 9.106), with support in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ by Proposition 9.107; the commutators vanish at spacelike separation by Proposition 9.108. Consequently the visibilities (hence the quadrant) are causally well-posed (Proposition 9.134(b)), and the meter valuations inherit the same causal support (Lemma 9.145(c)). Therefore every component of $\mathrm{TLO}^{[\chi]}(x;r)$ is produced from retarded, cone-supported inputs, proving causal robustness.

(c) Stability under band retunings within the certified radius. Inside the stability radius of item (P7) in Definition 9.116, the typed Riesz projector $\Pi^{[\chi]}$ varies continuously (Proposition 9.119); the band taggers and cone gates vary continuously in operator norm within the band class (Definitions 9.96 and 9.106), and the band functionals are bounded linear (Definition 9.96). Hence the pointwise typed contrasts vary continuously, and so do the aggregates by Lemma 9.132; applying the continuous normalizer yields continuity of $\vec{\Lambda}^{[\chi]}$ (cf. Definition 9.133 and Proposition 9.134). For the meters, continuity under retuning is stated in Proposition 9.146(B). Therefore the data entering the onset rules (9.81)—the synthesis meters and the typed law–deficit—vary continuously under retunings, and the resulting onsets are stable (changes can only occur at the declared tolerance thresholds; see also the plateau stability discussion in Corollary 9.139). Altogether, the triple $\mathrm{TLO}^{[\chi]}(x;r)$ depends continuously on $(\lambda_{\mathrm{UV}}, \ell)$ within the certified neighborhood.

Combining (a)–(c) proves that the typed T–L–O assignment is gauge/BRST-independent, causally supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$, and stable under admissible band retunings. □

Corollary 9.150 (Consistency with typed quadrants and sector rules)**.** *If $\Pi^{[\chi]} = \mathbb{I}$ on a block, then the T–L–O map reduces to the sector/untyped construction of Definitions 9.28 and 9.47, and the onset criteria* (9.81) *coincide with the large-window (QIII vs. QIV) decision rule in Definition 7.685.*

Proof of Corollary 9.150. Fix a block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and take the typed projector to be the identity on that block, $\Pi^{[\chi]} = \mathbb{I} = E_{\bullet\bullet}$ (item (P1) of Definition 9.116).

(1) Typed ⇒ sector reduction for contrasts, visibilities, quadrants. By Proposition 9.138, the typed restriction becomes a no-op: $\hat{Q}_x^{[\chi]}[v] = \hat{Q}_x[v]$ and the pointwise/aggregated contrasts (Definitions 9.127 and 9.133) match their sector counterparts in Definition 9.45. Applying the same proposition, the normalized visibilities coincide with the sector/untyped visibilities of Definition 9.47, and the typed quadrant rule $\mathrm{Quad}^{[\chi]}$ (Definition 9.137) equals the canonical sector decision Definition 7.685. Thus the *Type* component of $\mathrm{TLO}^{[\chi]}$ reduces to that of Definitions 9.28 and 9.47.

(2) Reduction of meter valuations and location tags. The band-reduced, typed parasymmetric meters (Definitions 9.141, 9.143 and 9.144) are traces against positive effects built from the same band data; with $\Pi^{[\chi]} = \mathbb{I}$ the typed restriction is trivial, so the local and relational valuations $v^{(a);[\chi]}_{\mathrm{Synthesis}}$, $v^{(LS);[\chi]}_{\mathrm{Synthesis}}$ and $v^{(LS);[\chi]}_{\mathrm{Agreement}}$ coincide with their sector/untyped versions used in §8.6. Likewise, the *Location* entry of $\mathrm{TLO}^{[\chi]}$ (arena/sector/position/cone sheet in Definition 9.147) is unchanged, since it depends only on the band taggers and the Σ–cone (Definitions 9.96 and 9.106), not on the typed restriction.

(3) Onset rules coincide with the large-window sector rule. The onset components in $\mathrm{TLO}^{[\chi]}$ are defined by the infima in (9.81) of Definition 9.147, using (i) the synthesis meters from Definitions 9.141, 9.143 and 9.144 and (ii) the typed law–deficit $d^{\Sigma;[\chi]}_{\mathrm{law}}$ induced by the typed law–contrast (Definition 9.127). With $\Pi^{[\chi]} = \mathbb{I}$, item (i) reduces to the sector/untyped meters (Step 2) and item (ii) reduces to the sector law–deficit from Definition 9.45. Therefore the scale thresholds $r^{\star}_{\mathrm{QIII}}[\chi]$ and $r^{\star}_{\mathrm{QIV}}[\chi]$ in (9.81) are *exactly* the large-window (QIII vs. QIV) decision thresholds stated at sector level in Definition 7.685 (decay to $Cr^{-\beta}$ versus exceeding $\delta_{\star}$), and $r^{\star}_{\mathrm{SSB}}[\chi]$ matches the sector SSB criterion since it is formulated purely in terms of the (now sector) synthesis meters.

Combining (1)–(3) establishes that, for $\Pi^{[\chi]} = \mathbb{I}$, the full T–L–O map reduces to the sector/untyped construction of Definitions 9.28 and 9.47, and the onset criteria (9.81) coincide with the large-window decision rule of Definition 7.685, as claimed. □

Remark 9.151 (Boundary arenas and cone-sheet annotations)**.** Repeating the definitions in Definition 9.141–Definition 9.147 on the boundary plateau $\mathfrak{P}_{\partial}$ involves replacing the IR window $K^{(\ell)}_{\mathrm{IR}}$ with its tangential version and using the boundary cone $\mathcal{C}^{\hat{\Sigma},*}_{x;\partial}$ (inherited from Definition 9.104). The "cone sheet" tag in Location records if the readout is on a null sheet or in the timelike interior; this in turn controls admissible χ via typed hyperbolicity (Definition 9.111).

Remark 9.152 (Operational pipeline)**.** Given a permitted χ: (1) compute $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}$ (Definition 9.133); (2) assign $\mathrm{Quad}^{[\chi]}$ (Definition 9.137); (3) evaluate $v^{(a);[\chi]}_{\mathrm{Synthesis}}$, $v^{(LS);[\chi]}_{\mathrm{Synthesis}}$ (Definitions 9.143 and 9.144); (4) report $\mathrm{TLO}^{[\chi]}$ using (9.81). Each step is retarded, cone-gated, and BRST-clean by Propositions 9.97 and 9.107 and Lemma 9.145.

9.13 Per Sector Execution Outline

We formalize the sector-wise execution as a compositional pipeline that takes $(\hat{\Sigma}, \hat{\mathbf{G}}_{\Lambda}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell})$ together with a probe family $(\mathcal{V}, w)$ and produces the typed Type–Location–Onset (T–L–O) artefacts for each χ permitted in the chosen sector. All objects and operations below are band-admissible, retarded, cone-gated, and BRST/Nielsen-safe by Definitions 9.96 and 9.106 and Propositions 9.97 and 9.107.

5.1 Sector execution functor

Definition 9.153 (Sector execution functor)**.** Fix a sector label $\bullet \in \{\Phi\Phi, \Theta\Theta\}$. The *sector execution functor*

$$\mathscr{E}_\bullet : \left(\hat{\Sigma}, \hat{\mathbf{G}}_\Lambda, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell};\ \mathcal{V}, w\right) \longmapsto \left(\mathcal{C}^{[\bullet]}_{\text{admissible}},\ \{\Lambda^{\Sigma;[\chi]}_{\text{law/state}}\}_\chi,\ \{v^{(\cdot);[\chi]}_{\text{Synthesis}}\}_\chi,\ \{\mathrm{TLO}^{[\chi]}\}_\chi\right)$$

is the composition of the following typed, band-level stages:

(E1) **Permit ledger construction:** build $\mathcal{C}^{[\bullet]}_{\text{admissible}}$ by producing typed projectors $\Pi^{[\chi]}$ that satisfy (P1)–(P7) in Definition 9.116 and the typed hyperbolicity test (9.53) (Definition 9.111), using the Σ-weighted spectral construction of Proposition 9.119. This realizes Definition 9.122.

(E2) **Typed visibilities:** for each $\chi \in \mathcal{C}^{[\bullet]}_{\text{admissible}}$, compute the aggregated contrasts $\Delta^{\mathrm{pre},\Sigma;[\chi]}_\bullet(x;\mathcal{V},w)$ (Definition 9.131) and normalize to visibilities $\Lambda^{\Sigma;[\chi]}_{\text{law/state}}(x) \in [0,1]$ by Definition 9.133.

(E3) **Parasymmetric meters & T–L–O:** evaluate the typed meters $v^{(a);[\chi]}_{\text{Synthesis}}$ and $v^{(LS);[\chi]}_{\text{Synthesis}}$ (Definitions 9.143 and 9.144) and return the T–L–O readouts $\mathrm{TLO}^{[\chi]}(x;r)$ using Definition 9.147, with Type $= \mathrm{Quad}^{[\chi]}(x)$ from Definition 9.137.

(E4) **Boundary pass (optional):** repeat (E1)–(E3) on the boundary arena $\mathfrak{P}_\partial$ using the induced boundary cone (Remark in §9.147) and record bulk/edge differences.

Lemma 9.154 (Well-posedness and termination of $\mathscr{E}_\bullet$)**.** *Under band-finiteness and compactness hypotheses of Proposition 9.119, the spectral construction in (E1) yields a locally finite family of isolated clusters, each producing a finite-rank projector $\Pi^{[\chi]}$. Hence (E1) terminates at any fixed spectral resolution and bandwidth, and (E2)–(E3) are well-posed by Lemmas 9.129 and 9.145 and Proposition 9.134.*

Proof of Lemma 9.154. We unpack the three stages of the execution pipeline $\mathscr{E}_\bullet$: **(E1)** spectral selection and typed Riesz projectors inside a chosen block ($\Phi\Phi$ or $\Theta\Theta$); **(E2)** construction of typed contrasts/aggregates/visibilities (Definitions 9.127 and 9.133); **(E3)** construction of typed parasymmetric meters and the ensuing T–L–O (Definitions 9.141, 9.143, 9.144 and 9.147).

(E1) Local finiteness, isolated clusters, finite rank, termination. By Proposition 9.119 the Σ–weighted channel operator $K_\bullet$ (constructed as in Proposition 9.36 and (9.16) within a fixed block) is positive and compact on the band-reduced Hilbert space. Hence its nonzero spectrum consists of at most countably many eigenvalues with finite multiplicities, accumulating only at 0. In particular, on any compact spectral window bounded away from 0 there are *finitely many* eigenvalues, thus only finitely many *isolated clusters*. Each such cluster admits a Riesz projector $\Pi^{[\chi]} = \frac{1}{2\pi i}\oint_\Gamma (z\mathbf{1} - K_\bullet)^{-1}\,dz$ of *finite rank*, and, by Proposition 9.119, these projectors are band-finite, BRST-closed, graded-covariant, and stable under small retunings (items (P1)–(P7) of Definition 9.116). Consequently, for any fixed spectral resolution (i.e. a finite partition of the chosen window into disjoint contours Γ) and any fixed bandwidth, only finitely many clusters are selected and only finitely many $\Pi^{[\chi]}$ are produced. Hence **(E1)** terminates at the chosen resolution/bandwidth.

(E2) Well-posed typed contrasts/visibilities. Given $\Pi^{[\chi]}$, the pointwise typed operands in Definition 9.127 are Hermitian and cone-gated; for timelike covectors k one has reality and nonnegativity of the band evaluations by Lemmas 9.110 and 9.129. Retardedness and cone support are ensured by Definition 9.106 and Proposition 9.107, while microcausality at spacelike separation holds by Proposition 9.108. Aggregation and normalization (Definition 9.133) then produce visibilities in $[0,1]$ that are gauge/BRST-invariant (Proposition 9.134(a)), causal (Proposition 9.134(b)), and properly normalized (Proposition 9.134(c)). Thus **(E2)** is well-posed.

(E3) Well-posed typed meters and T–L–O. The band-reduced, typed meters of Definitions 9.141, 9.143 and 9.144 are traces of positive effects against positive band states; therefore their valuations lie in $[0,1]$ and are gauge/BRST-invariant by Lemma 9.145(a,b). Their inputs are retarded and cone-gated, so causal support is inside $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ (Lemma 9.145(c) together with Proposition 9.107). The T–L–O assignment then inherits gauge/causal robustness and stability under certified retunings by Proposition 9.149. Hence **(E3)** is well-posed.

Combining the compact spectral structure of $K_\bullet$ (local finiteness and finite rank of Riesz spectral projectors; Proposition 9.119) with the positivity/causality/gauge properties of the typed contrasts and meters (Lemmas 9.129 and 9.145 and Proposition 9.134) establishes both the termination of **(E1)** at fixed resolution/bandwidth and the well-posedness of **(E2)**–**(E3)**. □

Proposition 9.155 (Soundness (BRST/causal correctness))**.** *Every numerical output of $\mathscr{E}_\bullet$ (namely, $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}$, $v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}$, and $\mathrm{TLO}^{[\chi]}$) satisfies two key properties. First, it is gauge-parameter independent (BRST/Nielsen-safe), as shown in Proposition 9.97 and Lemmas 9.128 and 9.145. Second, it is causally supported within $J^+(\mathcal{C}^{\hat{\Sigma},*})$, as established by Propositions 9.107 and 9.108.*

Proof of Proposition 9.155. Fix a permitted type χ and a spacetime point x (and, for onsets, a scale r). The numerical outputs of $\mathscr{E}_\bullet$ are: (i) the typed visibilities $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}(x)$ (Definition 9.133, built from the typed contrasts of Definition 9.127); (ii) the typed parasymmetric valuations $v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}$ (Definitions 9.141, 9.143 and 9.144); and (iii) the typed Type–Location–Onset triple $\mathrm{TLO}^{[\chi]}(x;r)$ (Definition 9.147).

(A) Gauge-parameter independence (BRST/Nielsen safety). For each probe v, the *pointwise* typed contrasts are invariant under BRST-exact gauge variations by Lemma 9.128, using in particular the band Nielsen property Proposition 9.97 and the BRST-closedness $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ of Definition 9.116. Aggregation and normalization then preserve invariance, yielding gauge-invariant visibilities; this is summarized in Proposition 9.134(a). For the meters, BRST/Nielsen safety of all valuations is stated in Lemma 9.145(b). Finally, $\mathrm{TLO}^{[\chi]}$ is composed of the (gauge-invariant) quadrant extracted from the visibilities, gauge-invariant location tags (built from BRST-closed band taggers, Definition 9.96), and onsets defined via gauge-invariant meters and law-deficits; its gauge/BRST independence is recorded in Proposition 9.149(a). Therefore, every output listed in the proposition is BRST/Nielsen-safe (Proposition 9.97 and Lemmas 9.128 and 9.145).

(B) Causal support inside $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$. All kernels used in $\mathscr{E}_\bullet$ are replaced by their retarded, cone-gated versions (Definition 9.106), which are supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ by Proposition 9.107. Micro-

causality at spacelike separation then holds for the unified fields (Proposition 9.108), ensuring the pointwise operands that feed the contrasts are well-defined and real (Lemma 9.129). Consequently, the visibilities inherit retarded, cone-gated support (Proposition 9.134(b)). For the meters, causal support of the inputs implies causal support of the valuations (Lemma 9.145(c)). The $\mathrm{TLO}^{[\chi]}$ assignment aggregates only these retarded, cone-supported ingredients (visibilities, meters, and location tags from the cone sheet), and is therefore causally robust by Proposition 9.149(b). Thus every numerical output is supported within $J^{+}\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ (Propositions 9.107 and 9.108).

Combining (A) and (B) proves that all outputs of $\mathscr{E}_{\bullet}$ are both gauge-parameter independent and causally well-posed in the asserted sense. □

Proposition 9.156 (Stability and functoriality)**.** *Within the retuning-stability radius in Definition 9.116, the maps*

$$(\lambda_{\mathrm{UV}},\ell)\ \longmapsto\ \mathcal{C}^{[\bullet]}_{\mathrm{admissible}},\quad (\lambda_{\mathrm{UV}},\ell)\ \longmapsto\ \Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}},\quad (\lambda_{\mathrm{UV}},\ell)\ \longmapsto\ v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}$$

are continuous. Tightening the IR window as in Lemma 9.105 shrinks the ledger (Proposition 9.123) and increases visibilities monotonically towards unity (less apparent breaking) by Lemma 9.136, while meters vary continuously by Proposition 9.146.

Proof of Proposition 9.156. Fix a permitted type χ and consider retunings $(\lambda_{\mathrm{UV}},\ell)$ within the stability radius of item (P7) in Definition 9.116.

(1) Continuity of the ledger map. Inside the certified radius, each typed Riesz projector $\Pi^{[\chi]}$ depends *continuously* on $(\lambda_{\mathrm{UV}},\ell)$ in operator norm by the spectral perturbation stability of Proposition 9.119. The cone/hyperbolicity certificate for χ (Corollary 9.120) supplies a positive spectral gap and an admissible timelike interval; small retunings preserve the positivity margin (9.53), hence the admission test (Proposition 9.102) continues to hold. Therefore the ledger $(\lambda_{\mathrm{UV}},\ell)\mapsto\mathcal{C}^{[\bullet]}_{\mathrm{admissible}}$ is *locally constant* (hence continuous as a set-valued map) in the stability neighborhood.

(2) Continuity of $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}$. For each probe v, the pointwise typed operands in (9.58)–(9.59) (Definition 9.127) depend continuously on $(\lambda_{\mathrm{UV}},\ell)$ because (i) $\Pi^{[\chi]}$ varies continuously (Proposition 9.119), (ii) the band taggers vary continuously within the band class (Definition 9.96), and (iii) the cone gate and retardedness are compatible with instrumentation (Definition 9.106 and Proposition 9.107). The band functionals $\mathcal{I},\mathcal{I}_{\Psi}$ are bounded linear (Definition 9.96), so each pointwise contrast is continuous; the aggregated $\Delta^{\mathrm{pre},\Sigma;[\chi]}_{\bullet}(x;\mathcal{V},w)$ is continuous by the aggregation continuity of Lemma 9.132. Applying the continuous normalizer (visibility map) from Definitions 9.47 and 9.133 yields continuity of $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}}$.

(3) Continuity of $v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}$. Within the same stability neighborhood, the meter valuations vary continuously by Proposition 9.146(B), since they are traces of positive effects against band-reduced states that depend continuously on $\Pi^{[\chi]}$, the taggers, and the cone gate (Definitions 9.96, 9.106, 9.141, 9.143 and 9.144).

(4) Effect of IR tightening $\ell'\le\ell$. By Lemma 9.105, the Σ–cone contracts under IR tightening; the ledger then *shrinks functorially* and cannot gain new types by Proposition 9.123 together

with the exclusion rule (Corollary 9.113). For the visibilities, cone shrink implies

$$\Lambda_{\bullet}^{\Sigma;[\chi]}(x)\Big|_{\ell'} \;\geq\; \Lambda_{\bullet}^{\Sigma;[\chi]}(x)\Big|_{\ell} \qquad (\bullet \in \{\mathrm{law}, \mathrm{state}\}),$$

by Lemma 9.136; thus they increase monotonically (bounded above by 1, Proposition 9.134(c)), i.e. move *towards unity* as the cone tightens. Finally, the meters vary continuously under the same IR change by Proposition 9.146(B).

Combining (1)–(4) gives the asserted continuity of the three maps in the proposition, the functorial ledger shrink under IR tightening, the monotone increase of visibilities toward 1 (less apparent breaking), and the continuity of the meter valuations. □

Corollary 9.157 (Typed quadrant and onset robustness)**.** *On certified plateaux,* $\mathrm{Quad}^{[\chi]}(x)$ *is locally constant up to tolerance thresholds (Corollary 9.139), and onset scales/times* $(r^\star[\chi], t^\star[\chi])$ *of Definition 9.147 exist under mild regularity (Lemma 9.148) and are stable under admissible retunings (Proposition 9.149).*

Proof of Corollary 9.157. Fix a permitted type χ and a certified plateau in the sense of Corollary 9.139, i.e. a neighborhood where the typed visibility pair $\vec{\Lambda}^{[\chi]}(x) := (\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x), \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x))$ stays away from the tolerance decision surfaces of the quadrant normalizer (Definition 9.47).

(i) Local constancy of the typed quadrant. By Corollary 9.139, on any such plateau the map $x \mapsto \mathrm{Quad}^{[\chi]}(x)$ (Definition 9.137) is locally constant, and it can change only at the declared tolerance thresholds of the normalizer (Definition 9.47). This proves the first claim.

(ii) Existence of onset scales/times. The onset components $\mathrm{Onset}^{[\chi]} = (r^\star[\chi], t^\star[\chi])$ are defined by the rules (9.81) in Definition 9.147, using the synthesis meters and the typed law–deficit. Under the mild regularity hypotheses stated in Lemma 9.148—namely, piecewise monotonicity of $r \mapsto v_{\mathrm{Synthesis}}^{(S);[\chi]}(r)$ and $r \mapsto v_{\mathrm{Synthesis}}^{(LS);[\chi]}(r)$ with one–sided limits, and a regularly varying envelope for $r \mapsto d_{\mathrm{law}}^{\Sigma;[\chi]}(r)$—the infima defining $r_{\mathrm{SSB}}^\star[\chi]$, $r_{\mathrm{QIV}}^\star[\chi]$, and $r_{\mathrm{QIII}}^\star[\chi]$ exist as extended nonnegative reals (finite exactly when the corresponding thresholds are eventually met). Hence the onsets are well-defined by Lemma 9.148.

(iii) Stability under admissible retunings. Within the retuning–stability radius of Definition 9.116, the typed visibilities and the meter valuations vary continuously with $(\lambda_{\mathrm{UV}}, \ell)$ by Proposition 9.156 (see also Propositions 9.134 and 9.146). Therefore the data entering (9.81) (the synthesis meters and the typed law–deficit) are continuous in the retuning parameters, and the resulting onsets are stable under these deformations as recorded in Proposition 9.149(c). In particular, on a certified plateau (where the corresponding decision margins are nonzero) small retunings cannot move the system across a tolerance surface, so neither the quadrant nor the onset labels change.

Combining (i)–(iii) gives the asserted robustness: $\mathrm{Quad}^{[\chi]}(x)$ is locally constant on plateaux up to tolerance thresholds (Corollary 9.139), and $(r^\star[\chi], t^\star[\chi])$ exist under the stated regularity (Lemma 9.148) and are stable under admissible retunings (Proposition 9.149). □

5.2 Artefact schema and completeness

Definition 9.158 (Execution artefacts per sector)**.** For each sector $\bullet$ and each point x, the artefacts of $\mathscr{E}_\bullet$ comprise:

$$\begin{aligned}\mathrm{Art}[\bullet](x) := \Big(&\mathcal{C}^{[\bullet]}_{\mathrm{admissible}}(x),\\ &\{\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x), \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x)\}_{\chi\in\mathcal{C}^{[\bullet]}_{\mathrm{admissible}}},\\ &\{v^{(a);[\chi]}_{\mathrm{Synthesis}}(x), v^{(LS);[\chi]}_{\mathrm{Synthesis}}(x)\}_{\chi},\\ &\{\mathrm{TLO}^{[\chi]}(x;r)\}_{\chi,r}\Big).\end{aligned}$$

Proposition 9.159 (Typed completeness w.r.t. ledger)**.** *For every $\chi \in \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}(x)$, the pipeline $\mathscr{E}_\bullet$ computes all quantities needed to evaluate $\mathrm{TLO}^{[\chi]}(x;r)$ (Type via Definition 9.137, Location as in Definition 9.147, and Onset via (9.81)). Conversely, if $\chi \notin \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}$, then by Corollary 9.113 typed hyperbolicity fails and $\mathrm{TLO}^{[\chi]}$ is undefined (and must not be reported).*

Proof of Proposition 9.159. Fix a block $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and a spacetime point x.

(I) Completeness for $\chi \in \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}(x)$. If χ is admitted by the ledger, then by the admission criterion of Proposition 9.102 the associated typed projector $\Pi^{[\chi]}$ is band-finite, graded-covariant, cone-compatible (Definition 9.98) and satisfies typed hyperbolicity (9.42), with stability under retunings (Definition 9.116). Constructing $\Pi^{[\chi]}$ via the Σ-weighted spectral machinery is guaranteed by Proposition 9.119, and the execution stage (E1) of the pipeline $\mathscr{E}_\bullet$ terminates and is well-posed by Lemma 9.154.

Given $\Pi^{[\chi]}$, the pipeline then computes:

- *Type.* Pointwise typed contrasts and their aggregates are computed by Definitions 9.127 and 9.133. The typed quadrant is then

$$\mathrm{Quad}^{[\chi]}(x) = \mathrm{Quad}\Big(\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x),\ \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x)\Big) \quad \text{by Definition 9.137.}$$

  Thus the Type component is obtained canonically from the ledger-admitted χ.
- *Location.* The Location tags (arena $\mathfrak{P}/\mathfrak{P}_\partial$, sector $\bullet$, spatial tag $P_x(\lambda_{\mathrm{UV}})$, cone sheet) are read off as specified in Definition 9.147, using the BRST-closed band instrumentation (Definition 9.96) and the Σ-cone gate (Definitions 9.104 and 9.106). Hence Location is computable for the same χ.
- *Onset.* The band-reduced typed meters $v^{(a);[\chi]}_{\mathrm{Synthesis}}$, $v^{(LS);[\chi]}_{\mathrm{Synthesis}}$ (Definitions 9.141, 9.143 and 9.144) together with the typed law–deficit induced by Definition 9.127 feed the onset rules (9.81) in Definition 9.147, thereby producing $(r^\star[\chi], t^\star[\chi])$. Under the mild regularity hypotheses, existence of these infima is ensured by Lemma 9.148. (Gauge/causal robustness of all ingredients is addressed in Propositions 9.134 and 9.149 and Lemma 9.145.)

Therefore, for every $\chi \in \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}(x)$, the pipeline $\mathscr{E}_\bullet$ computes all quantities needed for $\mathrm{TLO}^{[\chi]}(x;r)$ (Type via Definition 9.137, Location via Definition 9.147, and Onset via (9.81)).

(II) Non-admitted types carry no T–L–O. Conversely, if $\chi \notin \mathcal{C}^{[\bullet]}_{\text{admissible}}(x)$, then by the exclusion rule Corollary 9.113 the typed hyperbolicity condition (9.53) fails for some timelike covector, so the well-posedness implication of Proposition 9.112 does *not* hold for χ. In particular, the typed energy estimate and retarded Green operator required to define the cone-gated, retarded operands of Definition 9.127 are not available. Hence the downstream typed aggregates/visibilities (Definition 9.133), meters (Definitions 9.141, 9.143 and 9.144), and the onset rules (9.81) cannot be soundly instantiated. In this case $\mathrm{TLO}^{[\chi]}$ is *undefined* and, by the ledger discipline of Proposition 9.102, must not be reported.

Combining (I) and (II) proves the stated completeness with respect to the ledger. □

Corollary 9.160 (Bulk/edge relation)**.** *Let* $\mathrm{Art}[\bullet]_{\mathrm{bulk}}$ *and* $\mathrm{Art}[\bullet]_{\partial}$ *denote outputs on* $\mathfrak{P}$ *and* $\mathfrak{P}_{\partial}$*, respectively. Then*

$$\mathcal{C}^{[\bullet]}_{\text{admissible}}(\mathfrak{P}_{\partial}) \;\subseteq\; \mathcal{C}^{[\bullet]}_{\text{admissible}}(\mathfrak{P}), \qquad \Lambda^{\Sigma;[\chi]}_{\bullet'}(x)\Big|_{\mathfrak{P}_{\partial}} \;\geq\; \Lambda^{\Sigma;[\chi]}_{\bullet'}(x)\Big|_{\mathfrak{P}},$$

for $\bullet' \in \{\mathrm{law}, \mathrm{state}\}$*, by cone shrink on the boundary (cf. Lemmas 9.105 and 9.136) and functoriality (Proposition 9.123).*

Proof of Corollary 9.160. Let $\mathfrak{P}$ (bulk) and $\mathfrak{P}_{\partial}$ (edge) be evaluated with their respective band instrumentations (Definition 9.96), writing

$$\mathfrak{B}^{\mathrm{bulk}}_{\lambda_{\mathrm{UV}},\ell} = \Big(P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}}\Big), \qquad \mathfrak{B}^{\partial}_{\lambda_{\mathrm{UV}},\ell'} = \Big(P_x(\lambda_{\mathrm{UV}})P_{\partial},\; K^{(\ell')}_{\mathrm{IR}}\Big),$$

where P_{∂} implements the boundary restriction and $\ell' \leq \ell$ denotes the tighter IR window at the edge. By Lemma 9.105, tightening the IR window yields a *cone shrink*

$$\mathcal{C}^{\hat{\Sigma},*}_{x}[\mathfrak{P}_{\partial}] \;\subseteq\; \mathcal{C}^{\hat{\Sigma},*}_{x}[\mathfrak{P}],$$

and the associated cone gates (retarded projectors of Definition 9.106) satisfy the Löwner order $0 \leq \Gamma_{\partial} \leq \Gamma_{\mathrm{bulk}} \leq \mathbf{1}$ (Proposition 9.107).

(1) Ledger inclusion. Passing from $\mathfrak{P}$ to $\mathfrak{P}_{\partial}$ is a *functorial refinement* of the band tags (additional P_{∂} and smaller ℓ'). By Proposition 9.123, such refinements *shrink* the ledger and cannot add a type that previously failed the typed hyperbolicity test (9.53) (see also the exclusion rule Corollary 9.113). Hence

$$\mathcal{C}^{[\bullet]}_{\text{admissible}}(\mathfrak{P}_{\partial}) \;\subseteq\; \mathcal{C}^{[\bullet]}_{\text{admissible}}(\mathfrak{P}).$$

(2) Visibility monotonicity at the edge. For any admitted type χ and fixed probe set $(\mathcal{V}, w)$, cone shrink implies that the *aggregated* contrasts weakly decrease while the normalized visibilities weakly increase, by Lemma 9.136:

$$\Lambda^{\Sigma;[\chi]}_{\bullet'}(x)\Big|_{\mathfrak{P}_{\partial}} \;\geq\; \Lambda^{\Sigma;[\chi]}_{\bullet'}(x)\Big|_{\mathfrak{P}}, \qquad \bullet' \in \{\mathrm{law}, \mathrm{state}\}.$$

Intuitively, restricting causal support cannot increase measured breaking; algebraically, this is the action of the positive contraction $\Gamma_{\partial} \leq \Gamma_{\mathrm{bulk}}$ inside the band functionals (Definitions 9.127 and 9.133) together with the nonincreasing normalizer (Definition 9.47).

Combining (1) and (2) yields the stated bulk/edge relations for the ledger and the visibilities. □

5.3 Compact execution formula

Theorem 9.161 (Compact execution formula)**.** *For each sector* $\bullet$ *and each permitted* χ*, the output of* $\mathcal{E}_\bullet$ *at* $(x;r)$ *may be written as*

$$\mathrm{TLO}^{[\chi]}(x;r) \;=\; \Big(\; \mathrm{Quad}\Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x), \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x)\Big)\,,\; (\mathcal{A}_\chi, \mathrm{sector}_\chi, P_x, \mathrm{sheet}_\chi)\,,\; (r^\star[\chi], t^\star[\chi])\;\Big),$$

with $\Lambda_\bullet^{\Sigma;[\chi]}$ *given by* (9.67)*,* Quad *by* (9.75)*, and onsets by* (9.81)*. The right-hand side depends only on BRST cohomology classes and on the typed projector* $\Pi^{[\chi]}$ *(gauge covariance Proposition 9.130, BRST invariance Proposition 9.97), and is causally supported inside* $J^+(\mathcal{C}^{\hat\Sigma,*})$ *(Proposition 9.107).*

Proof of Theorem 9.161. Fix a sector $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and a permitted type $\chi \in \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}$ (ledger admission in Proposition 9.102). Let x be a spacetime point and r a scale (band radius).

Step 1 (Representation by definitions; well-posedness). Given $\Pi^{[\chi]}$, the *typed visibilities* are defined by

$$\Lambda_\bullet^{\Sigma;[\chi]}(x) = \mathfrak{n}_\bullet\Big(\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w)\Big), \qquad \bullet \in \{\mathrm{law}, \mathrm{state}\},$$

with $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}$ the aggregated typed contrasts and $\mathfrak{n}_\bullet$ the normalizer (Definitions 9.127 and 9.133; this is Eq. (9.67)). The *typed quadrant* is

$$\mathrm{Quad}^{[\chi]}(x) = \mathrm{Quad}\Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x),\; \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x)\Big) \quad \text{(Definition 9.137, Eq. (9.75))}.$$

The *Location* tuple $(\mathcal{A}_\chi, \mathrm{sector}_\chi, P_x, \mathrm{sheet}_\chi)$ is read from the arena/sector/band tag and cone sheet (Definition 9.147). The *Onset* pair $(r^\star[\chi], t^\star[\chi])$ is defined by the rules (9.81) using the typed meters (Definitions 9.141, 9.143 and 9.144) and the typed law–deficit induced from Definition 9.127. Thus, by *definition*,

$$\mathrm{TLO}^{[\chi]}(x;r) = \Big(\mathrm{Quad}^{[\chi]}(x),\; (\mathcal{A}_\chi, \mathrm{sector}_\chi, P_x, \mathrm{sheet}_\chi),\; (r^\star[\chi], t^\star[\chi])\Big),$$

which is exactly the displayed right-hand side of the theorem with the cited equations. The fact that each ingredient is *well-posed* for admitted χ follows from Propositions 9.112 and 9.134 and Lemmas 9.145 and 9.148 (see also the termination/well-posedness pipeline statement in Lemma 9.154) and the typed completeness Proposition 9.159.

Step 2 (BRST/Nielsen safety ⇒ dependence only on BRST classes). Pointwise typed contrasts are invariant under BRST-exact gauge variations by Lemma 9.128, based on the band Nielsen property Proposition 9.97 and the BRST-closedness $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116). Aggregation/normalization preserve invariance (Proposition 9.134(a)), hence the visibilities—and therefore the quadrant—depend only on BRST cohomology classes of the underlying band operators. The typed meters are likewise BRST/Nielsen-safe (Lemma 9.145(b)), so the onset rules (9.81) are unchanged by BRST-exact variations. In particular, any change $A \mapsto A + [\hat{Q}_{\mathrm{BRST}}, X]$ in the band algebra leaves all numerical outputs unchanged (Proposition 9.97), proving the stated *dependence only on BRST classes.* Gauge

covariance under band-admissible graded frames is recorded in Proposition 9.130 (see also ledger covariance Proposition 9.123).

Step 3 (Causal support inside $J^+(\mathcal{C}^{\hat{\Sigma},*})$). All kernels entering the typed contrasts and the band meters are replaced by their *retarded, cone-gated* versions (Definition 9.106), which are supported inside $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ by Proposition 9.107; microcausality at spacelike separation holds by Proposition 9.108. Consequently, the visibilities are causally well-posed (Proposition 9.134(b)), the meter valuations inherit the same causal support (Lemma 9.145(c)), and the resulting $\mathrm{TLO}^{[\chi]}(x;r)$ is causally robust (Proposition 9.149(b); see also the aggregate soundness statement Proposition 9.155).

Step 4 (Dependence on $\Pi^{[\chi]}$ only, up to conjugation). By construction, the typed restriction is effected solely by $\Pi^{[\chi]}$ (Definition 9.116); hence all typed quantities depend on the chosen projector. Under a graded local frame g, $\Pi^{[\chi]}$ transforms as $g\Pi^{[\chi]}g^\dagger$ and the ledger is invariant up to this equivalence (Proposition 9.123); the numerical outputs remain the same by Proposition 9.130. Therefore the right-hand side in the statement depends only on the typed projector (modulo gauge conjugation) and the BRST classes of the operators it acts upon.

Combining Steps 1–4 yields the compact execution formula and proves that the right-hand side is BRST/gauge correct and causally supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$, as stated. □

Remark 9.162 (Minimal inputs for a runnable instance)**.** To run $\mathscr{E}_\bullet$ one must specify: (i) band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definition 9.96); (ii) a probe family $(\mathcal{V}, w)$ (Definition 9.131); and (iii) a spectral criterion for $\Pi^{[\chi]}$ (e.g. gap thresholds in Proposition 9.119). All subsequent artefacts then follow by Definitions 9.133, 9.143, 9.144 and 9.147.

9.14 Audits & Guardrails

We formalize the audit predicates and their guarantees for the typed, band-level pipeline developed in §1–§5. Throughout, kernels are retarded and cone-gated (Definition 9.106 and Proposition 9.107), band taggers are BRST-closed with ghost number 0 (Definition 9.96 and Proposition 9.97), and typed objects are restricted by $\Pi^{[\chi]}$ (Definition 9.116).

6.1 Audit predicates

Definition 9.163 (BRST/Nielsen audit)**.** We say the *BRST/Nielsen audit* passes for an instrument set $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ if

$$\begin{aligned} [\,\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})\,] = [\,\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}\,] = 0, \quad \mathrm{gh} = 0, \\ \text{and} \quad \mathcal{I}([\,\hat{Q}_{\mathrm{BRST}}, X]) = \mathcal{I}_\Psi([\,\hat{Q}_{\mathrm{BRST}}, X]) = 0. \end{aligned} \tag{9.82}$$

for all band-admissible X (Definitions 9.45 and 9.96 and Proposition 9.97).

Definition 9.164 (Cone/microcausality audit)**.** We say the *cone/microcausality audit* passes for a kernel family $\{\mathcal{K}\}$ if each kernel is restricted to the retarded, cone-gated form $\mathcal{K}^{\mathrm{ret}}$ (Definition 9.106), and for all test functions f, g with spacelike-separated supports w.r.t. $\mathcal{C}^{\hat{\Sigma},*}$,

$$[\,\hat{\mathbf{\Phi}}(f), \hat{\mathbf{\Phi}}(g)\,] = [\,\hat{\mathbf{\Theta}}(f), \hat{\mathbf{\Theta}}(g)\,] = 0 \qquad \text{(Proposition 9.108).} \tag{9.83}$$

Definition 9.165 (Typed hyperbolicity audit)**.** Given a typed projector $\Pi^{[\chi]}$, the *typed hyperbolicity audit* passes at x if

$$\inf_{\Psi\in\mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[\ \hat{Q}_x^{[\chi]}[k]\ \Big] \ >\ 0 \quad \text{for all timelike } k\in \mathcal{C}_x^{\hat{\Sigma},*}, \tag{9.84}$$

i.e. (9.84) coincides with (9.53) (Definition 9.111).

Definition 9.166 (Band-stability audit)**.** The *band-stability audit* passes for $(\Pi^{[\chi]}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell})$ if there exists $\delta>0$ such that for all $(\lambda'_{\mathrm{UV}},\ell')$ with $|\lambda'_{\mathrm{UV}}-\lambda_{\mathrm{UV}}|+|\ell'-\ell|<\delta$,

$$\|\Pi^{[\chi]}(\lambda'_{\mathrm{UV}},\ell')-\Pi^{[\chi]}(\lambda_{\mathrm{UV}},\ell)\|\to 0 \quad\text{and}\quad \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}(x;\mathcal{V},w),\ v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}(x) \text{ vary continuously,}$$

as in (P7) of Definition 9.116 and Lemma 9.132 and Propositions 9.134 and 9.146.

Definition 9.167 (Functoriality audit)**.** Write $(P',K')\preccurlyeq(P,K)$ if $P'=P_x(\lambda'_{\mathrm{UV}})$ with $\lambda'_{\mathrm{UV}}\le\lambda_{\mathrm{UV}}$ and $K'=K_{\mathrm{IR}}^{(\ell')}$ with $\ell'\le\ell$. The *functoriality audit* passes if for every such refinement:

$$\begin{aligned} \mathcal{C}_x^{\hat{\Sigma},*}\big|_{(P',K')} &\subseteq \mathcal{C}_x^{\hat{\Sigma},*}\big|_{(P,K)} \quad \text{(Lemma 9.105)},\\ \Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}\downarrow,\quad \Lambda_\bullet^{\Sigma;[\chi]}\uparrow,&\quad \mathrm{Quad}^{[\chi]} \text{ unchanged except at tolerances,} \end{aligned} \tag{9.85}$$

with "unchanged" interpreted via Corollary 9.139.

6.2 Effective visibilities and uncertainty bands

Definition 9.168 (Effective visibility and uncertainty band)**.** Fix a neighborhood $\mathcal{U}_\delta := \{(\lambda'_{\mathrm{UV}},\ell'):\ |\lambda'_{\mathrm{UV}}-\lambda_{\mathrm{UV}}|+|\ell'-\ell|<\delta\}$. For any typed χ define the *effective visibility* and its *band* by

$$\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta):=\inf_{(\lambda'_{\mathrm{UV}},\ell')\in\mathcal{U}_\delta}\Lambda_\bullet^{\Sigma;[\chi]}(x)\Big|_{(\lambda'_{\mathrm{UV}},\ell')},\qquad \mathcal{B}_\bullet^{[\chi]}(x;\delta):=\Big[\ \Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta),\ \sup_{(\lambda'_{\mathrm{UV}},\ell')\in\mathcal{U}_\delta}\Lambda_\bullet^{\Sigma;[\chi]}(x)\Big], \tag{9.86}$$

for $\bullet\in\{\mathrm{law},\mathrm{state}\}$ (Definition 9.133).

Lemma 9.169 (Bounds and monotonicity of Λ_{eff})**.** *For each x,χ and $\delta'>\delta\ge 0$,*

$$\begin{aligned} 0\le\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta')&\le\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta)\\ &\le\Lambda_\bullet^{\Sigma;[\chi]}(x)\le 1,\\ \mathcal{B}_\bullet^{[\chi]}(x;\delta')&\supseteq\mathcal{B}_\bullet^{[\chi]}(x;\delta), \end{aligned}$$

and $\delta\mapsto\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta)$ is right-continuous by Proposition 9.134 and Definition 9.166.

Proof of Lemma 9.169. Fix x and an admitted type χ. By the audit/stability convention (Definition 9.166), for each tolerance $\delta\ge 0$ we have a nonempty, compact, nested family of admissible retunings $\mathcal{B}_\bullet^{[\chi]}(x;\delta)$ in the band-parameter space (it contains the nominal point,

and $\delta' > \delta \;\Rightarrow\; \mathcal{B}_\bullet^{[\chi]}(x;\delta') \supseteq \mathcal{B}_\bullet^{[\chi]}(x;\delta)$). The *effective* visibility is the worst-case (infimum) of the typed visibility over the audit set:

$$\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta) \;:=\; \inf_{b\in\mathcal{B}_\bullet^{[\chi]}(x;\delta)} \Lambda_\bullet^{\Sigma;[\chi]}(x;b), \qquad \bullet\in\{\mathrm{law},\mathrm{state}\}, \tag{9.87}$$

where b denotes the band retuning parameters and $\Lambda_\bullet^{\Sigma;[\chi]}(x;b)$ is the typed visibility computed at b (Definition 9.133, Eq. (9.67)).

Bounds $0 \le \Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]} \le \Lambda_\bullet^{\Sigma;[\chi]} \le 1$. By normalization, for any fixed band point b, $0 \le \Lambda_\bullet^{\Sigma;[\chi]}(x;b) \le 1$ (Proposition 9.134(c)); taking an infimum preserves these bounds, hence $0 \le \Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta) \le 1$. Since the nominal band point b_0 (no retuning) lies in every $\mathcal{B}_\bullet^{[\chi]}(x;\delta)$ (Definition 9.166),

$$\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta) = \inf_{b\in\mathcal{B}_\bullet^{[\chi]}(x;\delta)} \Lambda_\bullet^{\Sigma;[\chi]}(x;b) \;\le\; \Lambda_\bullet^{\Sigma;[\chi]}(x;b_0) = \Lambda_\bullet^{\Sigma;[\chi]}(x),$$

which yields the middle inequality.

Monotonicity in δ and set inclusion. If $\delta' > \delta$, then by Definition 9.166 the audit sets are nested: $\mathcal{B}_\bullet^{[\chi]}(x;\delta') \supseteq \mathcal{B}_\bullet^{[\chi]}(x;\delta)$. Taking infima over a larger set can only decrease (or leave unchanged) the value, whence

$$\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta') \;\le\; \Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta), \qquad \mathcal{B}_\bullet^{[\chi]}(x;\delta') \supseteq \mathcal{B}_\bullet^{[\chi]}(x;\delta).$$

Right-continuity in δ. By Proposition 9.156 (see also Proposition 9.134), $b \mapsto \Lambda_\bullet^{\Sigma;[\chi]}(x;b)$ is continuous on the band-parameter space; by Definition 9.166, for each δ the set $\mathcal{B}_\bullet^{[\chi]}(x;\delta)$ is compact and the family is increasing in δ. Define $F(\delta) := \Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta)$. Fix $\delta_0 \ge 0$. Since F is monotone nonincreasing, $\lim_{\delta\downarrow\delta_0^+} F(\delta)$ exists. To show $F(\delta_0^+) = F(\delta_0)$, let $\varepsilon > 0$ and pick $b_\varepsilon \in \mathcal{B}_\bullet^{[\chi]}(x;\delta_0)$ with $\Lambda_\bullet^{\Sigma;[\chi]}(x;b_\varepsilon) \le F(\delta_0) + \varepsilon$ (attainment holds by compactness; otherwise approximate). By continuity there is a neighborhood U of b_ε on which $\Lambda_\bullet^{\Sigma;[\chi]}(x;\cdot) \le F(\delta_0) + 2\varepsilon$. Since $\{\mathcal{B}(\delta)\}_{\delta>\delta_0}$ increases to a neighborhood of $\mathcal{B}(\delta_0)$, for all $\delta > \delta_0$ sufficiently close we have $U \subseteq \mathcal{B}_\bullet^{[\chi]}(x;\delta)$; hence

$$F(\delta) \;=\; \inf_{b\in\mathcal{B}(\delta)} \Lambda_\bullet^{\Sigma;[\chi]}(x;b) \;\le\; \Lambda_\bullet^{\Sigma;[\chi]}(x;b_\varepsilon) \;+\; 2\varepsilon \;\le\; F(\delta_0) \;+\; 3\varepsilon.$$

Letting $\varepsilon \downarrow 0$ gives $\limsup_{\delta\downarrow\delta_0^+} F(\delta) \le F(\delta_0)$, while monotonicity yields the reverse inequality $F(\delta) \ge F(\delta_0)$ for $\delta > \delta_0$. Hence F is right-continuous at δ_0. This proves the stated right-continuity, relying on the bounds/normalization of Proposition 9.134 and the audit-band properties of Definition 9.166.

Combining the three parts yields the displayed chain of inequalities and the inclusion of audit sets, as well as the right-continuity of $\delta \mapsto \Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}(x;\delta)$. □

Proposition 9.170 (Quadrant robustness under uncertainty)**.** *Let* $\mathrm{Quad}^{[\chi]}(x)$ *be assigned by* (9.75)*. If there exists* $\delta > 0$ *such that the rectangle* $\mathcal{R}(x;\delta) := \mathcal{B}_{\mathrm{law}}^{[\chi]}(x;\delta) \times \mathcal{B}_{\mathrm{state}}^{[\chi]}(x;\delta)$ *lies entirely within a single quadrant of the decision rule (Definition 7.685), then* $\mathrm{Quad}^{[\chi]}(x)$ *is invariant under all retunings in* $\mathcal{U}_\delta$*.*

Proof of Proposition 9.170. Fix an admitted type χ at x. By the audit/stability convention (Definition 9.166) there is, for each $\delta > 0$, an admissible retuning set $\mathcal{U}_\delta$ in band-parameter space and the associated *visibility bands*

$$\mathcal{B}_\bullet^{[\chi]}(x;\delta) \;:=\; \Big\{\, \Lambda_\bullet^{\Sigma;[\chi]}(x;b) \;:\; b \in \mathcal{U}_\delta \,\Big\} \subset [0,1], \qquad \bullet \in \{\mathrm{law}, \mathrm{state}\},$$

with $\Lambda_\bullet^{\Sigma;[\chi]}$ the typed visibilities of Definition 9.133 (cf. normalization and invariance in Proposition 9.134). Define the *audit rectangle* $\mathcal{R}(x;\delta) := \mathcal{B}_{\mathrm{law}}^{[\chi]}(x;\delta) \times \mathcal{B}_{\mathrm{state}}^{[\chi]}(x;\delta) \subset [0,1]^2$.

By hypothesis, there exists $\delta > 0$ such that the rectangle $\mathcal{R}(x;\delta)$ lies entirely within a single quadrant of the canonical decision rule (Definition 7.685). For any retuning $b \in \mathcal{U}_\delta$ we have

$$\Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x;b),\; \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x;b)\Big) \;\in\; \mathcal{R}(x;\delta),$$

hence this pair belongs to the *same* quadrant region. By the typed quadrant predicate (Definition 9.137, Eq. (9.75)),

$$\mathrm{Quad}^{[\chi]}(x;b) = \mathrm{Quad}\Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x;b),\; \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x;b)\Big)$$

is therefore constant for all $b \in \mathcal{U}_\delta$, i.e. invariant under all admissible retunings in $\mathcal{U}_\delta$.

Finally, note that the visibilities are continuous in the retuning parameters (Proposition 9.156) and remain in $[0,1]$ (Proposition 9.134(c)), so no crossing of quadrant decision surfaces can occur as long as the image stays in $\mathcal{R}(x;\delta)$; this is the same robustness mechanism underlying the plateau stability of Corollary 9.139. The proposition follows. □

6.3 Global guardrail theorem

Theorem 9.171 (Global guardrails for the typed band pipeline)**.** *Suppose the audits of Definitions 9.163 to 9.167 pass for a sector $\bullet$ and a permitted type χ. Then:*

(i) BRST/Nielsen safety
Every scalar diagnostic among $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}$, $\Lambda_\bullet^{\Sigma;[\chi]}$, $v_{\mathrm{Synthesis}}^{(\cdot);[\chi]}$, and $\mathrm{TLO}^{[\chi]}$ is gauge-parameter independent (Proposition 9.97 and Lemmas 9.128 and 9.145).

(ii) Causal correctness
All commutators vanish for spacelike separation and all kernels are supported in $J^+(\mathcal{C}^{\hat{\Sigma},*})$ (Propositions 9.107 and 9.108).

(iii) Typed well-posedness
The principal form is strictly positive on timelike covectors after restriction by $\Pi^{[\chi]}$ (Definition 9.165); hence the typed sector is hyperbolic and admits retarded Green operators (Proposition 9.112).

(iv) Band stability with uncertainty bands
Outputs vary continuously under small retunings and admit certified intervals $\mathcal{B}_\bullet^{[\chi]}$ (Definition 9.168 and Lemma 9.169).

(iv) Functorial sharpening
Refining $(P_x, K_{\mathrm{IR}}^{(\ell)})$ decreases $\Delta_\bullet^{\mathrm{pre},\Sigma;[\chi]}$, increases $\Lambda_\bullet^{\Sigma;[\chi]}$, and preserves quadrant membership off tolerance boundaries (Definition 9.167 and Corollary 9.139).

Proof of Theorem 9.171. Fix a sector $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and a type χ admitted by the ledger. Assume the audits of Definitions 9.163 to 9.167 all pass.

(a) BRST/Nielsen safety. By the BRST audit Definition 9.163, the band taggers, typed projectors, and kernels are ghost-number 0 and BRST-closed. Pointwise typed contrasts are invariant under BRST-exact gauge variations by Lemma 9.128, using the band Nielsen property Proposition 9.97 and $[\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ (Definition 9.116). Aggregation/normalization preserves invariance, yielding gauge-invariant visibilities (Proposition 9.134(a)). Typed meter valuations are likewise BRST/Nielsen-safe by Lemma 9.145(b). The T–L–O assignment inherits gauge/BRST independence by Proposition 9.149(a). Hence every listed scalar diagnostic is gauge-parameter independent.

(b) Causal correctness. By the cone/causality audit Definition 9.164, all kernels are replaced by their retarded, cone-gated versions (Definition 9.106), which are supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ (Proposition 9.107), and microcausality holds at spacelike separation (Proposition 9.108). Consequently, typed contrasts are real and well-defined (Lemma 9.129), visibilities are causally well-posed (Proposition 9.134(b)), meters inherit the same causal support (Lemma 9.145(c)), and T–L–O is causally robust (Proposition 9.149(b)).

(c) Typed well-posedness. The hyperbolicity audit Definition 9.165 asserts positivity of the typed principal form on cone-timelike covectors (condition (9.53)); therefore the typed sector is hyperbolic and admits a retarded Green operator supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ by Proposition 9.112. (If positivity fails, the exclusion rule Corollary 9.113 removes χ from the ledger, ensuring soundness of the pipeline.)

(d) Band stability with uncertainty bands. Within the retuning-stability radius (audit Definition 9.166), the ledger is locally constant and the typed visibilities are continuous in $(\lambda_{\mathrm{UV}}, \ell)$ (Proposition 9.156; see also Proposition 9.134); typed meters depend continuously as well (Proposition 9.146(B)). The effective (audited) visibilities $\Lambda_{\bullet,\mathrm{eff}}^{\Sigma;[\chi]}$ and the band families $\mathcal{B}_{\bullet}^{[\chi]}$ are defined in Definition 9.168, and satisfy bounds, monotonicity, and right-continuity by Lemma 9.169. Therefore outputs admit certified uncertainty intervals and vary continuously under small retunings.

(e) Functorial sharpening. Refining $(P_x, K_{\mathrm{IR}}^{(\ell)})$ as stipulated by the functoriality audit Definition 9.167 *shrinks* the Σ–cone by Lemma 9.105. Hence aggregated typed contrasts weakly decrease while visibilities weakly increase by Lemma 9.136 (cf. normalization in Proposition 9.134(c)). Plateau stability Corollary 9.139 then guarantees that quadrant membership is preserved away from tolerance boundaries; equivalently, audit rectangles entirely within a quadrant ensure robustness by Proposition 9.170. Ledger functoriality (no new types appear under refinement) is ensured by Proposition 9.123 together with Corollary 9.113.

Combining (a)–(e) yields the stated global guardrails for the typed band pipeline. □

6.4 Certificates and reporting

Definition 9.172 (Audit certificate for a typed sector)**.** For each (x, χ) we define the *audit certificate*

$$\mathfrak{C}^{[\chi]}(x) := \Big(\underbrace{\text{BRST/Nielsen}}_{(9.82)}, \underbrace{\text{Cone/Micro}}_{(9.83)}, \underbrace{\text{Hyperbolicity}}_{(9.84)}, \underbrace{\text{Stability}}_{\delta \text{ of Definition 9.166}}, \underbrace{\text{Functoriality}}_{(9.85)}, \underbrace{\mathcal{B}^{[\chi]}_{\text{law}}(x;\delta) \times \mathcal{B}^{[\chi]}_{\text{state}}(x;\delta)}_{\text{uncertainty rectangle}} \Big),$$

together with the decision $\mathrm{Quad}^{[\chi]}(x)$ (Definition 9.137).

Corollary 9.173 (Minimal certificate for publication)**.** *A minimal, publishable report for (x, χ) consists of: (i) the cone/hyperbolicity certificate triple (admissible timelike interval, spectral gap, stability radius) from Corollary 9.120; (ii) the uncertainty rectangles of Definition 9.172; and (iii) the quadrant and T–L–O outputs (Definition 9.147). By Theorem 9.171, these are sufficient to verify BRST safety, causal correctness, and stability.*

Proof of Corollary 9.173. Fix (x, χ) with $\chi \in \mathcal{C}^{[\bullet]}_{\text{admissible}}(x)$ (Proposition 9.102). The proposed certificate consists of:

(C1) the cone/hyperbolicity *certificate triple* (admissible timelike interval in $\mathcal{C}_x^{\hat{\Sigma},*}$, spectral gap for the Σ–weighted channel, stability radius) from Corollary 9.120;

(C2) the *uncertainty rectangles* (audit bands) of Definition 9.172 for the visibility pair $\vec{\Lambda}^{[\chi]}(x)$;

(C3) the *quadrant* and full *T–L–O* outputs as in Definition 9.147.

We show that (C1)–(C3) suffice to verify the three global properties stated in Theorem 9.171.

Typed well-posedness and admission. By Corollary 9.120, (C1) guarantees a *positive* typed principal form on the admissible timelike interval together with a *nonzero spectral gap* for the Σ–weighted channel operator and a *retuning-stability radius*. Hence the typed sector χ is *hyperbolic* and admits a retarded Green operator supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$ by Proposition 9.112. This ensures the typed constructions (contrasts $\to$ visibilities $\to$ quadrant, meters $\to$ onsets) are well-posed, as required in (c) of Theorem 9.171. Moreover, because the projectors are produced by the Σ–spectral construction (Proposition 9.119), they are BRST-closed; this feeds into the BRST audit below.

Band stability and functorial behavior. Item (C2) is precisely the uncertainty data of Definition 9.172, encoding the audit sets $\mathcal{U}_\delta$ and the visibility rectangles $\mathcal{R}(x;\delta) = \mathcal{B}^{[\chi]}_{\mathrm{law}}(x;\delta) \times \mathcal{B}^{[\chi]}_{\mathrm{state}}(x;\delta)$. By Proposition 9.156 the visibilities and meters vary continuously under certified retunings, and by Lemma 9.169 the effective visibilities satisfy the displayed bounds, monotonicity, and right-continuity. If, in addition, $\mathcal{R}(x;\delta)$ lies in a single decision quadrant, the quadrant is robust under all admissible retunings by Proposition 9.170; equivalently, plateau robustness holds by Corollary 9.139. This delivers (d) and (e) of Theorem 9.171 (stability and functorial sharpening; cf. Lemma 9.136 and Proposition 9.123).

Causal correctness and BRST/Nielsen safety. The reported T–L–O in (C3) is computed via the typed, retarded, cone-gated pipeline: retardedness and cone support follow from Proposition 9.107 and microcausality from Proposition 9.108, yielding causal correctness (item (b) of Theorem 9.171; see also Propositions 9.149 and 9.155(b)). BRST/Nielsen safety follows because the typed Riesz projector is BRST-closed (Proposition 9.119 and Lemma 9.121), pointwise typed contrasts are invariant (Lemma 9.128 using Proposition 9.97), the visibilities preserve invariance (Proposition 9.134(a)), and the meter valuations are BRST-safe (Lemma 9.145(b)); therefore T–L–O is BRST/gauge independent by Proposition 9.149(a). This is item (a) of Theorem 9.171.

Conclusion. Thus (C1) furnishes typed hyperbolicity and stability margins; (C2) furnishes certified uncertainty regions guaranteeing stability/robustness; and (C3) supplies the causally correct, BRST-safe outputs. By Theorem 9.171, these three pieces are *sufficient* to verify BRST safety, causal correctness, and stability for (x, χ), completing the proof. □

9.15 Pre-Physical Artefacts

We formalize the artefacts produced by the typed, band-level pipeline (§1–§5) for each sector $\bullet \in \{\Phi\Phi, \Theta\Theta\}$. All deliverables are computed with retarded, cone-gated kernels (Definition 9.106 and Proposition 9.107), BRST-closed taggers (Definition 9.96 and Proposition 9.97), and typed restrictions $\Pi^{[\chi]}$ from the permit ledgers (Definitions 9.116 and 9.122).

7.1 Deliverable schema

Definition 9.174 (Deliverable bundle per sector)**.** For sector $\bullet$ at point x, the *deliverable bundle* is

$$\mathrm{Del}[\bullet](x) \;:=\; \Big(\underbrace{\mathrm{PL}[\bullet](x)}_{\text{permit ledger}}, \underbrace{\mathrm{TM}[\bullet](x)}_{\text{typed }\Sigma\text{–maps}}, \underbrace{\mathrm{PD}[\bullet](x)}_{\text{parasymmetric dashboards}}, \underbrace{\mathrm{QC}[\bullet](x)}_{\text{quadrant certificates}} \Big),$$

whose components are defined in Definitions 9.175 to 9.178 below.

Definition 9.175 (Permit ledger deliverable)**.** The *permit ledger* is the finite (locally) set

$$\mathrm{PL}[\bullet](x) \;:=\; \mathcal{C}^{[\bullet]}_{\mathrm{admissible}}(x) \;\subset\; \mathrm{End}(\bullet),$$

as in Definition 9.122, where each entry χ is packaged with:

(a) a Σ-*construction recipe* for $\Pi^{[\chi]}$ (spectral/Riesz projector from Σ-weighted mode operators; cf. Propositions 9.36 and 9.119 and eq. (9.16));

(b) a *cone/hyperbolicity certificate* consisting of: (i) the admissible timelike interval in $\mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104); (ii) the typed positivity margin for $\hat{Q}_x^{[\chi]}[k]$ (Definition 9.111); (iii) the retuning-stability radius from Definition 9.116 (see also Corollary 9.120).

Definition 9.176 (Typed Σ–map deliverable)**.** For each permitted $\chi \in \mathrm{PL}[\bullet](x)$, the *typed* Σ*–map* is the function

$$\mathrm{TM}^{[\chi]}(x) := \Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x),\ \Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x)\Big) \in [0,1]^2, \tag{9.88}$$

computed as in Definition 9.133 from aggregated typed contrasts (9.63). Optionally, an *uncertainty rectangle*

$$\mathcal{R}^{[\chi]}(x;\delta) := \mathcal{B}_{\mathrm{law}}^{[\chi]}(x;\delta) \times \mathcal{B}_{\mathrm{state}}^{[\chi]}(x;\delta)$$

is included (effective visibilities of Definition 9.168).

Definition 9.177 (Parasymmetric dashboard deliverable)**.** For each χ and scale parameter r, the *parasymmetric dashboard* is the pair of typed meter curves

$$\mathrm{PD}^{[\chi]}(r) := \Big(\upsilon_{\mathrm{Synthesis}}^{(a);[\chi]}(r)\Big|_{a\in\{L,S\}},\ \ \upsilon_{\mathrm{Synthesis}}^{(LS);[\chi]}(r)\Big), \tag{9.89}$$

defined from the band meter states (Definition 9.141) via Definitions 9.143 and 9.144. The *onset scales/times* are reported as

$$(r^\star[\chi], t^\star[\chi]) \ \text{ from } \ (9.81), \quad \text{with law-deficit } d_{\mathrm{law}}^{\Sigma;[\chi]} = 1 - \Lambda_{\mathrm{law}}^{\Sigma;[\chi]} \ (\text{eq. } (9.68)). \tag{9.90}$$

Definition 9.178 (Quadrant certificate deliverable)**.** The *quadrant certificate* for χ at x is the tuple

$$\mathrm{QC}^{[\chi]}(x) := \Big(\underbrace{\mathrm{Quad}^{[\chi]}(x)}_{\text{Definition 9.137}},\ \underbrace{\mathrm{Loc}^{[\chi]}(x)}_{\text{arena/sector/position/sheet}},\ \underbrace{\mathfrak{C}^{[\chi]}(x)}_{\text{audit certificate of Definition 9.172}} \Big),$$

where $\mathrm{Loc}^{[\chi]}(x)$ records: arena $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$, sector $\bullet \in \{\Phi\Phi, \Theta\Theta\}$, spatial tag $P_x(\lambda_{\mathrm{UV}})$ (Definition 9.96), and the cone sheet (future/past, null/interior) from $\mathcal{C}_x^{\hat{\Sigma},*}$ (Definition 9.104).

7.2 Completeness, invariances, and functoriality

Proposition 9.179 (Deliverable completeness)**.** *For each sector* $\bullet$ *and permitted* χ*, the bundle* $\mathrm{Del}[\bullet](x)$ *determines the T–L–O output* $\mathrm{TLO}^{[\chi]}(x;r)$ *uniquely for all* r *by* (9.88), (9.89), (9.90)*, and Definition 9.147; conversely,* $\mathrm{TLO}^{[\chi]}$ *together with* $\mathrm{PL}[\bullet]$ *reconstructs* $\mathrm{TM}^{[\chi]}$ *and* $\mathrm{PD}^{[\chi]}$*. Hence* $\mathrm{Del}[\bullet]$ *is equivalent to the output of the execution functor* $\mathscr{E}_\bullet$ *(Definition 9.153, Theorem 9.161).*

Proof of Proposition 9.179. Fix a sector $\bullet \in \{\Phi\Phi, \Theta\Theta\}$ and an admitted type $\chi \in \mathcal{C}^{[\bullet]}_{\text{admissible}}$ (ledger admission in Proposition 9.102). Recall that the deliverable bundle at x is

$$\mathrm{Del}[\bullet](x) \;:=\; \Big(\mathrm{PL}[\bullet],\ \{\mathrm{TM}^{[\chi]}(x)\}_{\chi},\ \{\mathrm{PD}^{[\chi]}\}_{\chi},\ \text{certificates}\Big),$$

where (i) $\mathrm{PL}[\bullet]$ is the permit ledger (typed projectors with certificates), (ii) $\mathrm{TM}^{[\chi]}(x)$ is the *typed* Σ*–map* at x,

$$\mathrm{TM}^{[\chi]}(x) \equiv \Big(\Lambda^{\Sigma;[\chi]}_{\text{law}}(x),\ \Lambda^{\Sigma;[\chi]}_{\text{state}}(x)\Big), \qquad \text{(eq. (9.88) and Definition 9.133)},$$

and (iii) $\mathrm{PD}^{[\chi]}$ is the typed *parasymmetric dashboard*,

$$\mathrm{PD}^{[\chi]} : r \longmapsto \Big(v^{(L);[\chi]}_{\text{Synthesis}}(r),\ v^{(S);[\chi]}_{\text{Synthesis}}(r),\ v^{(LS);[\chi]}_{\text{Synthesis}}(r)\Big),$$

(eq. (9.89) and Definitions 9.141, 9.143 and 9.144)

(A) Forward direction: $\mathrm{Del}[\bullet](x) \;\Rightarrow\; \mathrm{TLO}^{[\chi]}(x;r)$ *uniquely.* Given $\mathrm{TM}^{[\chi]}(x)$, the *Type* component is the typed quadrant

$$\mathrm{Quad}^{[\chi]}(x) = \mathrm{Quad}\Big(\Lambda^{\Sigma;[\chi]}_{\text{law}}(x),\ \Lambda^{\Sigma;[\chi]}_{\text{state}}(x)\Big),$$

by Definition 9.137 (cf. eq. (9.75)). The *Location* component $(\mathcal{A}_\chi, \mathrm{sector}_\chi, P_x, \mathrm{sheet}_\chi)$ is read directly from the ledger tags and band instrumentation (arena/sector/spatial tag/cone sheet; see Definition 9.147). The *Onset* pair $(r^\star[\chi], t^\star[\chi])$ is determined *uniquely* from $\mathrm{PD}^{[\chi]}$ and the typed law–deficit via the rules (9.90)–(9.81) (Definition 9.147; existence/uniqueness of the infima follows under the mild regularity of Lemma 9.148). Hence, for each r, the triple

$$\mathrm{TLO}^{[\chi]}(x;r) = \Big(\mathrm{Quad}^{[\chi]}(x),\ (\mathcal{A}_\chi, \mathrm{sector}_\chi, P_x, \mathrm{sheet}_\chi),\ (r^\star[\chi], t^\star[\chi])\Big)$$

is fixed by (9.88), (9.89), (9.90) and Definition 9.147. Uniqueness is immediate from the determinism of the normalizer (Definitions 9.47 and 9.133) and of the onset rules.

(B) Converse: $\mathrm{TLO}^{[\chi]} + \mathrm{PL}[\bullet] \;\Rightarrow\; \mathrm{TM}^{[\chi]},\ \mathrm{PD}^{[\chi]}$. By the *compact execution formula* (Theorem 9.161), $\mathrm{TLO}^{[\chi]}(x;r)$ is produced from and only from $\big(\Lambda^{\Sigma;[\chi]}_{\text{law}}(x), \Lambda^{\Sigma;[\chi]}_{\text{state}}(x)\big)$, the location tags, and the onset pair computed from the dashboard curves. Conversely, the deliverable relations provide the *reconstruction maps*:

- Eq. (9.88) inverts the quadrant reporting by associating to $\mathrm{TLO}^{[\chi]}$ the *numerical* typed visibility pair $\mathrm{TM}^{[\chi]}(x) = (\Lambda^{\Sigma;[\chi]}_{\text{law}}(x), \Lambda^{\Sigma;[\chi]}_{\text{state}}(x))$.[4]

[4]This uses the ledger's typed projector $\Pi^{[\chi]}$ and the fixed normalizer in Definitions 9.47 and 9.133; gauge/BRST independence guarantees well-definedness, Proposition 9.134(a), Proposition 9.97.

- Eq. (9.89) reconstructs $\mathrm{PD}^{[\chi]}$ from the meter valuations implicit in $\mathrm{TLO}^{[\chi]}$ (via Definitions 9.141, 9.143 and 9.144) together with the onset calibration (9.90). Precisely, the onset pair pins the threshold levels on the curves, and the functorial/continuity properties (Proposition 9.146, Proposition 9.149(c)) fix the dashboard family on the certified band neighborhood.

Thus $\mathrm{TLO}^{[\chi]}$ plus the ledger $\mathrm{PL}[\bullet]$ suffices to recover both $\mathrm{TM}^{[\chi]}$ and $\mathrm{PD}^{[\chi]}$.

(C) Equivalence with the execution functor. By Definition 9.153 the execution functor $\mathscr{E}_\bullet$ produces exactly the (typed) visibilities, the meters/dashboards, and the T–L–O. The compact execution formula (Theorem 9.161) identifies the TLO constructed from $\mathrm{TM}^{[\chi]}$ and $\mathrm{PD}^{[\chi]}$, while Proposition 9.159 ensures that for each admitted χ the functor computes all quantities needed to evaluate $\mathrm{TLO}^{[\chi]}$ and, conversely, no $\mathrm{TLO}^{[\chi]}$ exists for excluded types (ledger discipline via Corollary 9.113). Parts (A) and (B) above therefore show that $\mathrm{Del}[\bullet]$ and the output of $\mathscr{E}_\bullet$ determine each other, i.e. they are *equivalent data*.

Combining (A)–(C) yields the claim: $\mathrm{Del}[\bullet](x)$ determines $\mathrm{TLO}^{[\chi]}(x;r)$ uniquely for all r, and $\mathrm{TLO}^{[\chi]}$ together with $\mathrm{PL}[\bullet]$ reconstructs $\mathrm{TM}^{[\chi]}$ and $\mathrm{PD}^{[\chi]}$; hence $\mathrm{Del}[\bullet]$ is equivalent to the output of $\mathscr{E}_\bullet$. □

Lemma 9.180 (BRST/causal invariance of deliverables)**.** *All scalar entries in* $\mathrm{Del}[\bullet]$ *are gauge-parameter independent (BRST/Nielsen-safe) by Proposition 9.97 and Lemmas 9.128 and 9.145 and causally supported within* $J^+(\mathcal{C}^{\hat{\Sigma},*})$ *by Propositions 9.107 and 9.108.*

Proof of Lemma 9.180. Recall the deliverable bundle at x:

$$\mathrm{Del}[\bullet](x) = \Big(\mathrm{PL}[\bullet],\ \{\mathrm{TM}^{[\chi]}(x)\}_\chi,\ \{\mathrm{PD}^{[\chi]}\}_\chi,\ \text{certificates}\Big).$$

The *scalar* entries are:

(i) the typed visibility pair $\mathrm{TM}^{[\chi]}(x) = \Big(\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x), \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x)\Big)$ (eq. (9.88), Definition 9.133);

(ii) the typed meter valuations encoded by the dashboard curves $\mathrm{PD}^{[\chi]}$ (eq. (9.89), Definitions 9.141, 9.143 and 9.144);

(iii) the numerical items of the certificate triple (admissible timelike interval, spectral gap, stability radius; Corollary 9.120).

Gauge-parameter independence (BRST/Nielsen safety). For the visibilities, pointwise typed contrasts are BRST/Nielsen-safe by Lemma 9.128 (using Proposition 9.97 and $[\,\hat{Q}_{\mathrm{BRST}}, \Pi^{[\chi]}] = 0$ from Definition 9.116); aggregation/normalization preserves invariance, hence $\Lambda^{\Sigma;[\chi]}_\bullet$ is gauge-invariant (Proposition 9.134(a)). For the meters, BRST/Nielsen safety of all valuations is stated in Lemma 9.145(b). For the certificate scalars, the underlying typed projectors are BRST-closed (constructed as Riesz projectors; Proposition 9.119) and are gauge-stable under conjugation (Proposition 9.123); the gap/interval/radius therefore depend only on BRST classes (see also Lemma 9.121). Thus every scalar entry in $\mathrm{Del}[\bullet]$ is gauge-parameter independent.

Causal support within $J^+(\mathcal{C}^{\hat{\Sigma},*})$. All kernels entering the evaluation of typed contrasts and meter states are replaced by their retarded, cone-gated versions (Definition 9.106), supported in $J^+\Big(\mathcal{C}^{\hat{\Sigma},*}\Big)$ by Proposition 9.107; microcausality holds at spacelike separation

by Proposition 9.108. Hence the visibilities are causally well-posed (Proposition 9.134(b)), and the meter valuations inherit the same causal support (Lemma 9.145(c)). The certificate numbers themselves do not arise from spacetime kernels (they are spectral/positivity data on the band), so no causal propagation issue arises; they are trivially compatible with the cone gate used elsewhere.

Combining the BRST/Nielsen safety cited above with retarded cone-gating and microcausality establishes that every scalar entry reported in Del[•] is gauge-parameter independent and causally supported as claimed. □

Proposition 9.181 (Functorial refinement of deliverables)**.** *For any refinement* $(P', K') \preccurlyeq (P, K)$ *(per Definition 9.167), the following properties hold:*

$$\begin{gathered}\mathrm{PL}[\bullet]_{(P',K')}(x) \subseteq \mathrm{PL}[\bullet]_{(P,K)}(x),\\ \mathrm{TM}^{[\chi]}(x) \ \uparrow,\\ v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}(r) \xrightarrow{\text{cont.}} \textit{(towards } 1/2\textit{)}.\end{gathered}$$

Furthermore, quadrant membership in $\mathrm{QC}^{[\chi]}(x)$ *remains unchanged off tolerance boundaries (Lemma 9.136, Proposition 9.146, and Corollary 9.139).*

Proof of Proposition 9.181. Let $(P', K') \preccurlyeq (P, K)$ be a refinement in the sense of Definition 9.167; in particular, the IR window tightens and the cone gate contracts (cf. Lemma 9.105).

(i) Ledger inclusion. Refining the band taggers $(P, K) \mapsto (P', K')$ is a functorial operation on the pipeline: by Proposition 9.123 the permit ledger can only *shrink* under such refinements, and by the exclusion rule Corollary 9.113 no new type that failed the typed hyperbolicity test (9.53) can be added. Hence

$$\mathrm{PL}[\bullet]_{(P',K')}(x) \ \subseteq \ \mathrm{PL}[\bullet]_{(P,K)}(x).$$

(ii) Typed Σ*–map monotonicity.* Fix a type χ admitted at both tag levels.[5] Cone shrink (IR tightening) implies that aggregated typed contrasts weakly *decrease* while the normalized visibilities weakly *increase* (Lemma 9.136, using normalization in Proposition 9.134(c)). Since $\mathrm{TM}^{[\chi]}(x) = (\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x), \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x))$ (Definition 9.133), this yields the componentwise monotonicity

$$\mathrm{TM}^{[\chi]}(x)\Big|_{(P',K')} \ \geq \ \mathrm{TM}^{[\chi]}(x)\Big|_{(P,K)}.$$

(iii) Meter continuity and drift toward symmetry. Under IR tightening, the typed synthesis meters satisfy the monotonicity and continuity properties of Proposition 9.146: for fixed typed inputs, $v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}(r)$ is nondecreasing *towards* $1/2$ (loss of accessible coherence cannot raise asymmetry beyond the available support) and varies continuously with the tag parameters in the certified stability radius (Definition 9.116). Therefore

$$v^{(\cdot);[\chi]}_{\mathrm{Synthesis}}(r)\Big|_{(P',K')} \xrightarrow{\text{cont.}} \text{towards } \tfrac{1}{2}.$$

[5] If χ is removed by refinement, the statement is vacuous for that χ at (P', K').

(iv) Quadrant robustness off tolerance boundaries. Because $\mathrm{TM}^{[\chi]}(x)$ increases componentwise under refinement (Step (ii)) and the meters vary continuously (Step (iii)), the typed quadrant $\mathrm{Quad}^{[\chi]}(x)$ (Definition 9.137) is unchanged as long as the visibility pair does not cross a tolerance surface of the decision rule. This is precisely the plateau robustness statement of Corollary 9.139; equivalently, it follows from Lemma 9.136 together with the continuity in Proposition 9.146.

Combining (i)–(iv) proves the asserted functorial refinement properties for the deliverables. □

Corollary 9.182 (Bulk/edge comparison)**.** *On the boundary arena* $\mathfrak{P}_\partial$, $\mathrm{PL}[\bullet]_\partial(x) \subseteq \mathrm{PL}[\bullet]_{\mathrm{bulk}}(x)$ *and* $\mathrm{TM}^{[\chi]}_\partial(x) \geq \mathrm{TM}^{[\chi]}_{\mathrm{bulk}}(x)$ *componentwise, with differences reported in* $\mathrm{QC}^{[\chi]}(x)$*; cf. Corollary 9.160.*

Proof of Corollary 9.182. Let the bulk and boundary band instrumentations be $\mathfrak{B}^{\mathrm{bulk}}_{\lambda_{\mathrm{UV}},\ell} = \left(P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}}\right)$ and $\mathfrak{B}^{\partial}_{\lambda_{\mathrm{UV}},\ell'} = \left(P_x(\lambda_{\mathrm{UV}})P_\partial, K^{(\ell')}_{\mathrm{IR}}\right)$ with $\ell' \leq \ell$. Then $(P_xP_\partial, K^{(\ell')}_{\mathrm{IR}}) \preccurlyeq (P_x, K^{(\ell)}_{\mathrm{IR}})$ is a functorial refinement in the sense of Definition 9.167; equivalently, the boundary cone *shrinks* by Lemma 9.105.

Ledger inclusion. Applying Proposition 9.181(i) to this refinement yields $\mathrm{PL}[\bullet]_\partial(x) \subseteq \mathrm{PL}[\bullet]_{\mathrm{bulk}}(x)$, which also recovers the ledger inclusion proved directly in Corollary 9.160.

Typed Σ–map monotonicity. For any type χ admitted at the boundary, Proposition 9.181(ii) gives the componentwise increase

$$\mathrm{TM}^{[\chi]}_\partial(x) = \left(\Lambda^{\Sigma;[\chi]}_{\mathrm{law},\partial}(x),\, \Lambda^{\Sigma;[\chi]}_{\mathrm{state},\partial}(x)\right) \;\geq\; \left(\Lambda^{\Sigma;[\chi]}_{\mathrm{law,bulk}}(x),\, \Lambda^{\Sigma;[\chi]}_{\mathrm{state,bulk}}(x)\right) = \mathrm{TM}^{[\chi]}_{\mathrm{bulk}}(x),$$

where $\mathrm{TM}^{[\chi]}$ is the typed Σ–map (Definition 9.133). This is the deliverable-level restatement of the visibility monotonicity proved in Corollary 9.160 (via Lemma 9.136 and Proposition 9.134(c)).

Reporting differences in $\mathrm{QC}^{[\chi]}(x)$. The quadrant certificate $\mathrm{QC}^{[\chi]}(x)$ records the typed quadrant and the location tags (arena/sector/position/cone sheet) used by T–L–O (Definition 9.147). Since boundary refinement is functorial (Proposition 9.181) and the cone sheet/arena change from $\mathfrak{P}$ to $\mathfrak{P}_\partial$, any bulk/edge discrepancy in the typed Σ–map is reflected and reported in $\mathrm{QC}^{[\chi]}(x)$ together with the boundary location tag; cf. the bulk/edge discussion in Corollary 9.160.

These three assertions establish the stated bulk/edge comparison. □

7.3 Minimal publishing package and verification

Definition 9.183 (Minimal publishing package)**.** A *minimal package* for (x, χ) consists of:

(i) the ledger entry with recipe and certificate ($\Pi^{[\chi]}$, cone/hyperbolicity/stability) (Definition 9.175);

(ii) the typed Σ–map with uncertainty rectangle $\mathcal{R}^{[\chi]}(x;\delta)$ (Definitions 9.168 and 9.176);

(iii) the dashboard curves and onsets $(r^\star[\chi], t^\star[\chi])$ (Definition 9.177);

(iv) the quadrant certificate $\mathrm{QC}^{[\chi]}(x)$ including the audit certificate $\mathfrak{C}^{[\chi]}(x)$ (Definitions 9.172 and 9.178).

Corollary 9.184 (Sufficiency for independent verification)**.** *Providing the minimal package of Definition 9.183 is sufficient for an independent reconstruction and verification of* $\mathrm{TLO}^{[\chi]}(x;r)$ *for all* r*, and for re-running the audits of §6. In particular, the uncertainty rectangle criterion of Proposition 9.170 certifies quadrant robustness without access to internal gauge choices.*

Proof. By Corollary 9.173, the minimal package (certificate triple + uncertainty rectangles + quadrant/T–L–O outputs) suffices to verify BRST safety, causal correctness, and stability. Independent *reconstruction* of $\mathrm{TLO}^{[\chi]}(x;r)$ follows from deliverable completeness (Proposition 9.179) together with the compact execution formula (Theorem 9.161), which shows that the T–L–O triple is determined by the typed visibilities, location tags, and onset rules.

Re-running the audits of §6 uses only the data included in the minimal package: the cone/hyperbolicity certificate triple supports the hyperbolicity audit (Definition 9.165, cf. Corollary 9.120); the uncertainty rectangles provide the band-stability/audit sets (Definition 9.166) and certify quadrant robustness via Proposition 9.170; BRST/Nielsen safety and causal correctness follow from Theorem 9.171 (items (a)–(b)), which rely only on BRST-closed instrumentation and cone-gated retarded kernels (Propositions 9.97, 9.107 and 9.108 and Lemmas 9.128 and 9.145).

Therefore the minimal package of Definition 9.183 is sufficient both to reconstruct/verify $\mathrm{TLO}^{[\chi]}(x;r)$ for all r and to re-run the audits of §6 without access to internal gauge choices, completing the proof. □

9.15.1 Typed Pre-Physics: Ledger, Visibilities, TLO

The sequence of constructions in Sections 9.8 to 9.15 turns the operator chronogeometry $\hat{\Sigma}$ and the unified block fields into a *typed, testable* pipeline whose outputs are the parasymmetric *Type–Location–Onset* assignments $\mathrm{TLO}^{[\chi]}(x;r)$ for the two pre-physical quanta—*apeiron* ($\Phi\Phi$; Gaiamiti) and *kymon* ($\Theta\Theta$; Tantrakyma).

(1) Causality and order from $\hat{\Sigma}$. The Σ–pre-physical cone $\mathcal{C}^{\hat{\Sigma},*}$ is *derived* from the probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ and band functionals; all kernels are retarded and cone-gated in $J^+(\mathcal{C}^{\hat{\Sigma},*})$, and spacelike commutators vanish (Section 9.9). This makes "chronogeometric order" an *operational* feature of $\hat{\Sigma}$, not an assumption imported from an expectation layer.

(2) Kinematics discovered, not posited. Within each block ($\Phi\Phi$ for apeiron, $\Theta\Theta$ for kymon), the *kinematic permit census* uses band-finite, graded-covariant, cone-compatible projectors $\Pi^{[\chi]}$ and a typed hyperbolicity test to *admit* or *exclude* labels χ (see the ledger statement and typed certificates in Proposition 9.102 and Corollary 9.120). Thus, allowed "spins/helicities/polarizations" at pre-physics are *outputs with certificates*, not inputs.

(3) Mechanisms measured by typed visibilities. Typed Σ–contrasts separate *explicit law effects* from *state response* and normalize to visibilities $\Lambda^{\Sigma;[\chi]}_{\mathrm{law/state}} \in [0,1]$ (Section 9.11), feeding

the canonical quadrant map $\mathrm{Quad}^{[\chi]}$ (typed mechanism). This provides a sector-conditioned witness pair for each admitted χ under the same causal gate.

An algorithm, not an analogy. Section 9.13 makes the pipeline a *procedure*: (1) build the permit ledger; (2) compute visibilities; (3) evaluate meters and report T–L–O; (4) compare bulk/edge when applicable. Soundness (BRST safety and causal support) and completeness (no reports for excluded types) are established by the execution results.

Guardrails that make numbers trustworthy. The audit suite in Section 9.14 comprises five items: BRST/Nielsen; cone/causality; typed hyperbolicity; band stability; and functoriality. By the global guardrails theorem, every scalar output is (i) cohomologically invariant, (ii) causally supported in $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$, (iii) typed well posed, and (iv) stable under certified retunings (monotone under cone shrink). Hence the pipeline's numbers are *meaningful* and *robust*—not artifacts of gauge choice or regulator quirks.

Deliverables and reproducibility. Section 9.15 packages the outputs into *publishable artefacts*: a permit ledger with certificates (cone interval, spectral gap, stability radius), typed Σ–maps, dashboards, and quadrant certificates. A minimal certificate suffices for independent reconstruction and re-audit of $\mathrm{TLO}^{[\chi]}(x;r)$.

Implications for the two quanta. *Apeiron (Gaiamiti; ΦΦ).* The census admits precisely those chronogeometric modes that pass typed hyperbolicity after Σ–restriction—e.g., Σ–trace/trace-free and TT-like subspaces, with helicity refinement where a Σ–spatial direction exists (Section 9.10). For each admitted χ, the typed visibilities quantify whether the *law* or the *state* is driving deviations, and the parasymmetric meters certify *onset scales/times* for symmetry breaking or healing. In effect, the apeiron's admissible content becomes a *measured property* of $\hat{\Sigma}$—chronogeometric excitations are certified by cone/hyperbolicity data rather than assumed. Bulk/edge comparisons then show that boundaries *shrink* the ledger and *increase* visibilities (more symmetric appearance), making edge diagnostics a controlled refinement of bulk behavior (cf. functorial/boundary results and Corollary 9.160).

Kymon (Tantrakyma; ΘΘ). The same typed pipeline admits Σ–transverse/longitudinal channels and helicity $\lambda = \pm$, and—crucially—the *Chrono–Kymon* torsional/temporal channel is treated on equal footing: when its Σ–weighted torsional operator has an isolated nonzero band, the corresponding Riesz projector defines a permitted type with a positive certificate margin (Corollary 9.125). Typed visibilities now disentangle explicit torsional law effects from state-induced responses, and the meters supply *onset scales* for torsional dynamics, with the location metadata specifying whether such activity is bulk or boundary, which cone sheet it occupies, and how it coexists with other kymon types. In short, kymonic excitations are *admitted, diagnosed, and localized* by the same causal/BRST-clean yardstick, making torsion a quantifiable pre-physical feature rather than an interpretive add-on.

Bottom line. The parasymmetric application at pre-physics does three things at once: (i) it *derives* causal order from $\hat{\Sigma}$, (ii) it *discovers* the admissible kinematics of apeiron/kymon via typed hyperbolicity, and (iii) it *diagnoses* mechanisms and their *where/when* through typed

visibilities and meters. For both Gaiamiti and Tantrakyma, what counts as a legitimate mode, what drives its behavior, and where/when it turns on are no longer assumptions—they are *certified outcomes* of a BRST-clean, cone-gated, band-stable pipeline, ready to be published and independently verified.

9.15.2 Permitted Kinematics for the Gaiamiti (Apeiron, ΦΦ) Field

No a priori spin: admission by certificate. In the apeiron block ΦΦ, kinematic labels ("spin/helicity/polarization" in the pre-physical sense) are *not* postulated; they are *admitted* if and only if their typed projectors $\Pi^{[\chi]}$ satisfy the band-level criteria of Definition 9.116 and pass the cone/hyperbolicity/stability audits that define the ledger (Proposition 9.102). Concretely, $\chi \in \mathcal{C}^{[\text{apeiron}]}_{\text{admissible}} \subset \text{End}(\Phi\Phi)$ iff

(a) $\Pi^{[\chi]}$ is band-finite, graded-covariant, BRST-closed, and cone-compatible (Definition 9.116); and

(b) the *typed hyperbolicity* condition holds on cone-timelike covectors,

$$\inf_{\Psi} \mathcal{I}_{\Psi}\Big[\hat{Q}_x[k]\Big|_{\Pi^{[\chi]}}\Big] > 0, \qquad k \in \operatorname{int} \mathcal{C}_x^{\hat{\Sigma},*},$$

with continuity under small retunings (Definition 9.111 and Proposition 9.112).

Each admitted χ carries its cone/hyperbolicity certificate (admissible timelike interval, spectral gap, stability radius; Corollary 9.120).

Canonical typed subspaces considered in ΦΦ. Within the symmetric apeiron sector, the *constructive* Σ-weighted spectral/Riesz procedure (Proposition 9.119) yields the following natural classes, each to be kept *only if* it passes the typed hyperbolicity test above:

(i) Σ–trace (scalar-like) $\Pi^{[\Sigma\text{-tr}]}$ projects to the Σ–trace channel of the symmetric tensor. Interpretable as a scalar-like polarization of the chronogeometric block; helicity refinement is trivial (isotropic).

(ii) Σ–trace-free symmetric, TT-like $\Pi^{[\text{TT}_\Sigma]}$ onto the trace-free subspace; where a Σ–spatial direction $\hat{\mathbf{k}}$ is meaningful (away from null degeneracies), introduce *helicity-refined* projectors $\Pi^{[\text{TT}_\Sigma;\lambda]}$ with $\lambda = \pm$ that resolve the two circular polarizations on the Σ–spatial slice (helicity labels at pre-physics; no particle/graviton mapping).

(iii) Σ–divergence decomposition $\Pi^{[\text{T}_\Sigma]}$ (Σ–transverse) and $\Pi^{[\text{L}_\Sigma]}$ (Σ–longitudinal) channels of the symmetric field (defined by the Σ–divergence). Where applicable, one may further refine $\Pi^{[\text{T}_\Sigma]}$ by helicity $\lambda = \pm$ along $\hat{\mathbf{k}}$.

These are the *candidate* polarizations one typically tests in the apeiron ledger; admission is granted *only* when the typed principal form is positive and stable (Proposition 9.112 and Corollary 9.120). Any candidate failing (9.53) is *excluded* by Corollary 9.113.

What the ledger actually permits (and how to read it). The permit ledger for Gaiamiti at a point x is the set

$$\mathcal{C}^{[\text{apeiron}]}_{\text{admissible}}(x) = \Big\{\ \chi \in \{\Sigma\text{-tr},\ \mathrm{TT}_\Sigma,\ \mathrm{T}_\Sigma,\ \mathrm{L}_\Sigma,\ \text{helicity refinements (constructed as above)}\} \ \Big|\ \chi \text{ passes (9.53)}\ \Big\}.$$

For each admitted χ, the *typed* witness pair $\left(\Lambda^{\Sigma;[\chi]}_{\text{law}}(x), \Lambda^{\Sigma;[\chi]}_{\text{state}}(x)\right)$ (Definition 9.133) and the parasymmetric meters determine the *Type* (quadrant), *Location* (arena/sector/position/cone sheet), and *Onset* scales/times (Definition 9.147). Helicity-refined entries carry separate rows in the ledger (each with its own certificate triple), so, e.g., $\mathrm{TT}_\Sigma;+$ and $\mathrm{TT}_\Sigma;-$ may in principle have distinct admission windows or onsets.

Edge/boundary behavior and functoriality. Under IR tightening or passage to the boundary arena $\mathfrak{P}_\partial$, the cone *shrinks* (Lemma 9.105), so the apeiron ledger can only *lose* entries, never gain them (Proposition 9.123); correspondingly, the typed visibilities weakly *increase* (monotone toward symmetry) and meters drift continuously toward 1/2 (Lemma 9.136, Proposition 9.146, and Corollary 9.160). Quadrant membership remains stable off tolerance boundaries (Corollary 9.139 and Proposition 9.170).

Summary. For the Gaiamiti field, the *permitted* spins/helicities/polarizations are precisely those Σ–structured subspaces—*Σ–trace*, *Σ–trace-free (TT-like)*, and *Σ–transverse/longitudinal* (with helicity refinements where a Σ–spatial direction exists)—whose typed projectors are band-finite, BRST-closed, cone-compatible, and satisfy *typed hyperbolicity* with a nonzero certificate margin. No other kinematic labels are admitted at pre-physics; and no mapping to particles/gravitons is made below Planckian. The exact list at a given x is your apeiron permit ledger $\mathrm{PL}[\Phi\Phi](x)$, carrying the cone interval, spectral gap, and stability radius for each χ.

9.15.3 Permitted Kinematics for the Tantrakyma (Kymon, $\Theta\Theta$) Field

Admission, not assumption. As in the apeiron case, kinematic labels in the kymon block $\Theta\Theta$ ("spin, helicity, polarization" in the pre-physical sense) are *admitted* if and only if their typed projectors $\Pi^{[\chi]}$ satisfy the band-level criteria of Definition 9.116 and pass the cone/hyperbolicity/stability audits that define the permit ledger (Proposition 9.102). Concretely, $\chi \in \mathcal{C}^{[\text{kymon}]}_{\text{admissible}} \subset \mathrm{End}(\Theta\Theta)$ iff $\Pi^{[\chi]}$ is band-finite, graded-covariant, BRST-closed, cone-compatible, and the typed principal form is strictly positive on cone-timelike covectors with stability under small retunings (Definition 9.111 and Proposition 9.112). Each admitted χ carries its cone/hyperbolicity *certificate triple* (admissible timelike interval, spectral gap, stability radius; Corollary 9.120).

Canonical typed subspaces considered in $\Theta\Theta$. Using the constructive Σ-weighted spectral/Riesz procedure (Proposition 9.119), the natural *candidate* channels in the kymon sector include:

(i) Σ–transverse vs. Σ–longitudinal Projectors $\Pi^{[\mathrm{T}_\Sigma]}$ and $\Pi^{[\mathrm{L}_\Sigma]}$ defined by the Σ–divergence in the ΘΘ block. Where a Σ–spatial direction $\hat{\mathbf{k}}$ is meaningful (timelike k), refine $\Pi^{[\mathrm{T}_\Sigma]}$ by helicity $\lambda = \pm$ to resolve circular polarizations on the Σ–spatial slice.

(ii) Helicity-refined transverse modes $\Pi^{[\mathrm{T}_\Sigma;\lambda]}$ with $\lambda = \pm$ obtained by commuting the spectral projector with the little-group stabilizer on the Σ–spatial hyperplane determined by a timelike k (same mechanism as in the apeiron case; cf. Definition 9.116).

(iii) Chrono–Kymon (torsional/temporal) channel Let $T := \hat{t}^{(\Theta)}_{\mu\nu}\hat{\Sigma}^{(\Theta)\,\mu\nu}$ be the Σ–weighted torsional operator in the ΘΘ block. If T has a nonzero isolated spectral band, the Riesz projector $\Pi^{[\mathrm{CK}]}$ defines a typed channel; if the band is separated from 0, the typed hyperbolicity condition holds and CK is admitted by Corollary 9.125.

Each candidate is retained *only if* it passes typed hyperbolicity with a nonzero margin (Proposition 9.112 and Corollary 9.120); otherwise it is excluded by Corollary 9.113.

What the ledger actually permits (and how to read it). At a point x the kymon permit ledger is

$$\mathcal{C}^{[\mathrm{kymon}]}_{\mathrm{admissible}}(x) = \Big\{ \chi \in \{\mathrm{T}_\Sigma,\ \mathrm{L}_\Sigma,\ (\mathrm{T}_\Sigma;\ \lambda = \pm),\ \mathrm{CK},\ \Sigma\text{-structured refinements}\} \ \Big|\ \chi \text{ passes (9.53)} \Big\}.$$

For each admitted χ, the typed visibility pair $\left(\Lambda^{\Sigma;[\chi]}_{\mathrm{law}}(x), \Lambda^{\Sigma;[\chi]}_{\mathrm{state}}(x)\right)$ (Definition 9.133) diagnoses mechanism type via the quadrant rule, while the parasymmetric meters determine onset scales/times and supply the *Location* tags (arena/sector/position/cone sheet) (Definition 9.147). Helicity-refined entries ($\lambda = \pm$) appear as separate rows, each with its own certificate triple, so distinct helicities may have different admission windows or onsets.

Edge/boundary behavior and functoriality. Under IR tightening or passage to the boundary arena $\mathfrak{P}_\partial$, cone shrink (Lemma 9.105) implies the kymon ledger can only *lose* entries (Proposition 9.123); visibilities weakly *increase* (monotone toward symmetry) and meters drift continuously toward 1/2 (Lemma 9.136, Proposition 9.146, and Corollary 9.160). Quadrant membership remains stable off tolerance boundaries (Corollary 9.139 and Proposition 9.170).

Summary. For Tantrakyma, the *permitted* pre-physical kinematics are precisely the Σ–structured ΘΘ channels—Σ–transverse/longitudinal (with helicity $\lambda = \pm$ where defined) and the torsional/temporal *Chrono–Kymon* mode—whose typed projectors are band-finite, BRST-closed, cone-compatible, and satisfy *typed hyperbolicity* with a positive certificate margin. No other kinematic labels are admitted at pre-physics, and no particle/graviton mapping is made below Planckian. The concrete, location- and onset-annotated list at x is your kymon permit ledger $\mathrm{PL}[\Theta\Theta](x)$.

9.15.4 Pre-Physics Parasymmetric Admission, Mechanism, Onset

Pre-physical kinematics as admission, not assumption. Kinematics at the pre-physical level is defined operationally and uniformly for both fundamental sectors—apeiron (ΦΦ; Gaiamiti) and kymon (ΘΘ; Tantrakyma)—without invoking expectation values or particle language. A typed label χ is *permitted* exactly when the Σ–induced principal quadratic form, restricted by the typed projector $\Pi^{[\chi]}$, is strictly positive on all cone-timelike covectors of the Σ–pre-physical cone:

$$\inf_{\Psi\in\mathcal{S}_{\mathrm{band}}} \mathcal{I}_\Psi\Big[\hat{Q}_x[k]\Big|_{\Pi^{[\chi]}}\Big] \;>\; 0 \qquad \text{for all } k\in \operatorname{int}\mathcal{C}_x^{\hat{\Sigma},*},$$

with cone-compatibility and band-finiteness as structural requirements (Section 9.10, Definitions 9.111 and 9.116, and Proposition 9.112). This yields a certified *permit ledger* for each sector.

Causal order from operator chronogeometry. Chronogeometric order is extracted from $\hat{\Sigma}$ alone. The covector cone $\mathcal{C}_x^{\hat{\Sigma},*}$ is defined by the band-admissible Σ–probe $\hat{Q}_x[v]=v^\mu v^\nu\hat{\Sigma}_{\mu\nu}(x)$; all kernels are retarded and cone-gated within $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$, and spacelike commutators vanish by construction (Section 9.9). Thus future/past structure, causal support, and microcausality arise as *operator-level* features rather than consequences of an expectation-level metric.

Typed witnesses that separate law from state. For each permitted χ, the visibility vector

$$\vec{\Lambda}^{[\chi]}(x) := \Big(\Lambda_{\mathrm{law}}^{\Sigma;[\chi]}(x),\Lambda_{\mathrm{state}}^{\Sigma;[\chi]}(x)\Big)\in[0,1]^2$$

quantifies explicit-law effects and state-dependent response under the same causal gate (Section 9.11 and Definition 9.133). Applying the canonical quadrant decision to $\vec{\Lambda}^{[\chi]}$ yields the typed mechanism $\mathrm{Quad}^{[\chi]}(x)\in\{\mathrm{QI},\mathrm{QII},\mathrm{QIII},\mathrm{QIV}\}$ (Definitions 7.685, 9.47 and 9.137).

Parasymmetric readouts and T–L–O. Band-level parasymmetric meters, restricted to the typed subspace, provide operational valuations at local anchors and on the relational pair. Their scale/time dependence defines onset thresholds and location metadata, producing the full typed *Type–Location–Onset* assignment $\mathrm{TLO}^{[\chi]}(x;r)$ (Section 9.12 and Definition 9.147).

Meaning for the two fundamental quanta. *Apeiron (ΦΦ; Gaiamiti).* Typical admitted subspaces (per the admission criterion above) include Σ–trace, Σ–trace-free symmetric (TT-like), and helicity refinements when a Σ–spatial direction is meaningful (Section 9.10).
Kymon (ΘΘ; Tantrakyma). The same typed structure applies—Σ–transverse and Σ–longitudinal (with helicities $\lambda=\pm$) together with the torsional/temporal *Chrono–Kymon* channel—each treated within the same admission/witness/readout pipeline (Corollary 9.125).

Uniform guardrails and reproducibility. A unified audit suite—BRST/Nielsen safety, cone/-causality, typed hyperbolicity, band stability, and functoriality—applies to every stage (Section 9.14). Consequently all scalar outputs (visibilities, meters, T–L–O) are cohomologically invariant, causally supported within $J^+\big(\mathcal{C}^{\hat{\Sigma},*}\big)$, well-posed for admitted types, and

stable under certified retunings with monotone behavior under cone shrink. Deliverables are packaged for reconstruction and independent verification (Section 9.15).

Bridge from pre-physical breaking to physical realization. The PQS/QHS operator chronogeometry supplies certified pre-physical structures—admitted types (permit ledgers), mechanisms ($\mathrm{Quad}^{[\chi]}$), and onsets/locations ($\mathrm{TLO}^{[\chi]}$)—which can flow, under appropriate coarse-graining, into physical realizations without invoking particle language or expectation-level geometry in the sub-Planckian regime.

9.16 Typed Parasymmetric Quadrants of the Gaiamiti and Tantrakyma Fields

We *fix the realized regime* (plateau certified; evaluation on the BRST-physical sector) and formalize the typed, sector-resolved *parasymmetric* diagnostics from Chapter 9 so that the *Typed Quadrant Ledger* is populated *before* any particle naming. All readouts use the canonical decision rule of §8.6 on the *same diagnostic realized reference configuration*. Throughout, $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ denotes the triadic channels (Chapter 7), and $S \in \{\Phi\Phi, \Theta\Theta\}$ indexes the (gaiamiti, tantrakyma) sectors. Band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ and the band functor $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ follow Chapter 8.

Definition 9.185 (Diagnostic realized reference configuration)**.** Fix a certified plateau $\mathfrak{P}$ (bulk) or $\mathfrak{P}_\partial$ (boundary) per Chapter 8, with band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ (cf. use in Section 9.16.2 and location/onset semantics in Definition 9.190). Let $\mathsf{P}_{\mathrm{phys}}$ denote the BRST projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (see gauge/Nielsen safety in Proposition 9.191).

The *diagnostic realized reference configuration* is

$$\Big(\mathcal{H}_{\mathrm{phys}},\ \ \mathfrak{P} \text{ or } \mathfrak{P}_\partial;\ P_x(\lambda_{\mathrm{UV}}),\ K_{\mathrm{IR}}^{(\ell)};\ \{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}\Big),$$

with all expectations on $\mathcal{H}_{\mathrm{phys}}$ and all limits taken *within* $\mathfrak{P}$ (or $\mathfrak{P}_\partial$) under Chapter 8 tolerances. This configuration underlies the typed subspaces (Section 9.16.1), the typed witnesses (Definition 9.187), and the typed quadrant predicate (Definition 9.189).

Definition 9.186 (Typed projectors and sector selection)**.** For a *sector* $S \in \{\Phi\Phi, \Theta\Theta\}$ and a *type* $[\chi]$ (e.g. TT spin-2, trace spin-0, T/L, helicity $\lambda = \pm$, Chrono-Kymon), a BRST-closed *typed projector* $\Pi_S^{[\chi]}$ on $\mathcal{H}_{\mathrm{phys}}$ is defined *on the diagnostic realized reference configuration* of Definition 9.185 and with types chosen from the menus in Definitions 9.195 and 9.196. It satisfies:

(i) Triadic compatibility

$\Pi_\alpha\, \Pi_S^{[\chi]} = \Pi_S^{[\chi]}\, \Pi_\alpha$ for all $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (triadic channels as fixed in Definition 9.185); this ensures channel-wise, unambiguous typed readouts used in Section 9.16.2.

(ii) Sector purity
$\Pi_S^{[\chi]}$ annihilates the complement of S and restricts to the standard spin/helicity/polarization subspaces determined by the realized geometry $\bar{\Sigma}$ on the plateau (cf. the explicit constructions in Definitions 9.200 and 9.201).

(iii) Cone preservation
Principal symbols remain inside the $\bar{\Sigma}$-cones fixed at the plateau (no cross-cone leakage), as required for orthogonality/completeness in Proposition 9.202 and for the well-posedness/Nielsen-flatness statements of Proposition 9.191 and the typed quadrant assignment in Proposition 9.212.

These projectors are the typed filters inserted in the witness $\mathbf{W}_{[\chi]}^{[S]}$ of Definition 9.187 and thereby drive the canonical quadrant predicate in Definition 9.211.

Definition 9.187 (Typed witnesses on H^0 (SynTh))**.** Let the *sector-conditioned witness* be denoted $\mathbf{W}^{[\mathscr{S}]}$ (cf. Definition 8.4). Its typed version is

$$\mathbf{W}_{[\chi]}^{[S]} \equiv \left(v_{\text{Synthesis}}^{(L)},\, v_{\text{Synthesis}}^{(S)},\, v_{\text{Synthesis}}^{(LS)}\right)^{[S,\chi]}.$$

Formally, for fixed $(S,[\chi])$ and a diagnostic realized reference configuration as in Definition 9.185,

$$\left(v_{\text{Synthesis}}^{(L)},\, v_{\text{Synthesis}}^{(S)},\, v_{\text{Synthesis}}^{(LS)}\right)^{[S,\chi]}(\ell;\mathfrak{P})$$

are the SynTh valuations (Law, State, and joint Law⊕State) obtained by inserting the typed filter $\Pi_S^{[\chi]}$ from Definition 9.186 (cf. explicit constructions in Definitions 9.200 and 9.201) and the triadic projectors $\{\Pi_\alpha\}$ from Definition 9.185:

$$\Pi_\alpha\, \Pi_S^{[\chi]}\,(\cdot)\,\Pi_S^{[\chi]}\,\Pi_\alpha, \qquad \alpha \in \{\text{corr}, \text{vac}, \text{spec}\},$$

with evaluation on $\mathcal{H}_{\text{phys}}$ following the procedure of Section 9.16.2. By construction these valuations are Nielsen-flat on $\mathfrak{P}$ (see Proposition 9.191); they are the inputs that drive the typed quadrant predicate in Definition 9.211.

Definition 9.188 (Law/State sources and typed healing)**.** Let $\delta_L^{[S,\chi]}$ (resp. $\delta_S^{[S,\chi]}$) denote the typed *law* (resp. *state*) source derived from the typed witness $\mathbf{W}_{[\chi]}^{[S]}$ on the certified plateau $\mathfrak{P}$ (typed witness as in Definition 9.187, diagnostic realized reference configuration as in Definition 9.185, and typed filters in Definition 9.186). Define the IR *healing indicators*

$$\mathscr{H}_L^{[S,\chi]} := \lim_{\substack{\ell\uparrow\infty \\ (\lambda,\ell)\in\mathfrak{P}}} \delta_L^{[S,\chi]}(\ell), \qquad \mathscr{H}_S^{[S,\chi]} := \lim_{\substack{\ell\uparrow\infty \\ (\lambda,\ell)\in\mathfrak{P}}} \delta_S^{[S,\chi]}(\ell),$$

where '$\uparrow\infty$' denotes the bulk/boundary IR dilation of Chapter 9 (cf. the overlay in Definition 9.214 and the control axis in Definition 9.190). We say *healed* iff $\mathscr{H}_\bullet = 0$ and *persistent* iff $\mathscr{H}_\bullet > 0$; these indicators feed the canonical quadrant predicate of Definition 9.211 and underpin the typed healing/persistence property in Proposition 9.193.

Definition 9.189 (Typed quadrant functional)**.** The *typed quadrant* of a sector/type pair $(S,[\chi])$ (with $S\in\{\Phi\Phi,\Theta\Theta\}$ and $[\chi]$ chosen from Definitions 9.195 and 9.196) is the value

$$\mathrm{Quad}^{[S,\chi]}\in\{\mathrm{QI},\mathrm{QII},\mathrm{QIII},\mathrm{QIV}\},$$

decided by the canonical rule of §8.6, evaluated *on the same diagnostic realized reference configuration* as in Definition 9.185 (same certified $\mathfrak{P}$ or $\mathfrak{P}_\partial$) and with the same typed filter $\Pi_S^{[\chi]}$ of Definition 9.186 inserted in the SynTh witness $\mathbf{W}_{[\chi]}^{[S]}$ from Definition 9.187. The decision uses the diagnostic realized reference configuration SynTh meters of §9.16.2 together with the typed healing indicators of Definition 9.188, and obeys the following invariants:

(i) QI (symmetric)
No law source and no sustained state selection, i.e. $\mathscr{H}_L^{[S,\chi]}=0$ and $\mathscr{H}_S^{[S,\chi]}=0$.

(ii) QII (SSB)
Law symmetric with state selection (finite-volume elevation, asymptotic healing): $\mathscr{H}_L^{[S,\chi]}=0$, $\mathscr{H}_S^{[S,\chi]}=0$, and an NG pole appears in the correlational channel Π_{corr} for the typed mode (cf. Proposition 9.197).

(iii) QIII (explicit, healing)
Nonzero law source at finite scale with IR *healing*, encoded by $\mathscr{H}_L^{[S,\chi]}=0$.

(iv) QIV (explicit, persistent)
Nonzero law source with *persistence* and GMOR slope on $\mathfrak{P}$: $\mathscr{H}_L^{[S,\chi]}>0$, exhibiting pNG behavior where applicable (cf. Proposition 9.197).

Gauge/Nielsen safety of this assignment follows from Proposition 9.191, and the resulting label $\mathrm{Quad}^{[S,\chi]}$ is what is recorded in the ledger of Definition 9.198.

Definition 9.190 (Location and onset (T–L–O data))**.** The *location* $\mathrm{Loc}^{[S,\chi]}$ takes values *bulk* or *boundary* and is determined by the chosen diagnostic realized reference configuration of Definition 9.185: use the bulk plateau $\mathfrak{P}$ for *bulk* and the boundary plateau $\mathfrak{P}_\partial$ for *boundary* (cf. the bulk–boundary overlay in Definition 9.214). The *onset* $\mathrm{On}^{[S,\chi]}$ is the minimal (certified) scale/time along the plateau at which the typed quadrant predicate in Definition 9.189 first holds, i.e.

$$\mathrm{On}^{[S,\chi]}:=\inf\left\{\,\upsilon\in\mathrm{Axis}(\mathfrak{P})\;\middle|\;\mathrm{Quad}^{[S,\chi]}(\upsilon)\text{ is stable under the Chapter 8 tolerances (see Definition 9.210)}\,\right\},$$

where $\mathrm{Axis}(\mathfrak{P})$ denotes the control axis (IR length ℓ, drive time, boundary size, or mixed; Chapter 9; cf. its use in Definition 9.214 and the decision pipeline of Section 9.16.3). The pair $\left(\mathrm{Loc}^{[S,\chi]},\mathrm{On}^{[S,\chi]}\right)$ constitutes the T–L–O data used in the T–L–O stamp of Definition 9.216 and the ledger augmentation of Corollary 9.218.

Proposition 9.191 (Well-posedness and Nielsen flatness)**.** *For every $(S,[\chi])$ and any certified plateau (bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$) as in Definition 9.185, the typed witness $\mathbf{W}_{[\chi]}^{[S]}$ of Definition 9.187 is well-defined on $\mathcal{H}_{\mathrm{phys}}$. Its components $\left(\upsilon^{(L)}_{\mathrm{Synthesis}},\upsilon^{(S)}_{\mathrm{Synthesis}},\upsilon^{(LS)}_{\mathrm{Synthesis}}\right)^{[S,\chi]}$ (cf. §9.16.2) are gauge-parameter independent (Nielsen-flat), and the typed quadrant $\mathrm{Quad}^{[S,\chi]}$ of Definition 9.189 is invariant under all BRST-exact deformations allowed on $\mathfrak{P}$.*

Proof. **Well-posedness.** By Definition 9.187, $\mathbf{W}_{[\chi]}^{[S]}$ is constructed by inserting the typed filter $\Pi_S^{[\chi]}$ (see Definition 9.186) and the triadic projectors $\{\Pi_\alpha\}$ (see Definition 9.185) into the channel-restricted readouts, then evaluating on $\mathcal{H}_{\mathrm{phys}}$. The commutation $\Pi_\alpha \Pi_S^{[\chi]} = \Pi_S^{[\chi]} \Pi_\alpha$ and cone preservation required in Definition 9.186 imply that principal symbols and residues are stable on the plateau, ensuring existence and finiteness of the aggregated diagnostic realized reference configuration meters $\overline{v}_a^{[S,\chi]}$ (cf. Definition 9.210).

Nielsen flatness (gauge independence). The SynTh components are BRST-closed readouts on H^0 (Chapter 7) taken on a certified plateau (Chapter 8). The Nielsen identities imply that the derivative with respect to a gauge-fixing parameter inserts a BRST-exact operator; its expectation on $\mathcal{H}_{\mathrm{phys}}$ vanishes. Hence the meters are gauge independent (see also the channel/type compatibility statement Proposition 9.207 which records Nielsen-flatness for the typed meters).

Quadrant invariance. The canonical predicate in Definition 9.189 depends only on the diagnostic realized reference configuration meters $\overline{v}_a^{[S,\chi]}$ and the typed healing indicators $\mathscr{H}_\bullet^{[S,\chi]}$ of Definition 9.188. Since these are unchanged under BRST-exact deformations and gauge reparametrizations (previous paragraphs), the value $\mathrm{Quad}^{[S,\chi]}$ is invariant. This completes the proof (see also Proposition 9.212 for the assignment's global well-definedness). □

Lemma 9.192 (Typed projector compatibility)**.** *If $\Pi_S^{[\chi]}$ and $\Pi_S^{[\chi']}$ are distinct types for the same sector S, then the corresponding SynTh meters (cf. §9.16.2) decouple at leading order on the certified plateau $\mathfrak{P}$:*

$$\textit{cross-terms} \;=\; \mathcal{O}(\varepsilon_{\mathfrak{P}}),$$

where $\varepsilon_{\mathfrak{P}}$ is the Chapter 8 tolerance scale (Slope/Curv/Osc aggregates).

Proof. By Definition 9.186, the typed filters $\Pi_S^{[\chi]}$ are BRST-closed, commute with the triadic projectors Π_α fixed on the diagnostic realized reference configuration (see Definition 9.185), and preserve the $\bar{\Sigma}$-cones. Orthogonality/completeness of the typed decompositions in each sector (Gaiamiti and Tantrakyma) is recorded in Proposition 9.202, implying a block-diagonal principal symbol for the channel-restricted readouts. The SynTh meters are obtained by inserting these filters into the readouts and aggregating over the plateau window (cf. §9.16.2 and Definition 9.210). Mixed terms then arise only from subleading commutators and boundary-of-window effects; a Duhamel/BCH expansion combined with the Chapter 8 certification tolerances bounds these by $\mathcal{O}(\varepsilon_{\mathfrak{P}})$. Order-of-insertion independence and gauge flatness are consistent with Propositions 9.191 and 9.207. □

Proposition 9.193 (Typed healing vs. persistence)**.** *For each $(S, [\chi])$, the sign of $\mathscr{H}_L^{[S,\chi]}$ in Definition 9.188 is independent of other types $[\chi']$ (for the same sector) and of the complementary sector. Consequently, the QIII/QIV split is meaningful* per type *in the canonical predicate of Definition 9.189.*

Proof. Type-wise independence follows from Lemma 9.192: cross-couplings between $[\chi]$ and $[\chi']$ contribute only at $\mathcal{O}(\varepsilon_{\mathfrak{P}})$, which is below the Chapter 8 significance thresholds entering Definition 9.210. Sector-wise independence is ensured by sector purity in Definition 9.186, which annihilates the complement of S. By Definition 9.188, $\mathscr{H}_L^{[S,\chi]}$ is an IR limit taken along the plateau control axis $\mathrm{Axis}(\mathfrak{P})$ (see Definition 9.190); since the diagnostic realized

reference configuration aggregation and the IR dilation are performed with the same typed filter, the limit depends only on the $[\chi]$-block. Therefore the law-channel dichotomy "healing vs. persistence''—and hence the QIII/QIV branch in Definition 9.189—is a well-defined *typed* property, unaffected by orthogonal types or sectors. Gauge/Nielsen safety of these statements is inherited from Proposition 9.191. □

Corollary 9.194 (Typed Quadrant Ledger is well-defined)**.** *The sextuple*

$$\mathbf{L}^{[S,\chi]} := \Big(\underbrace{S}_{\text{Sector}}, \underbrace{[\chi]}_{\text{Type}}, \underbrace{\mathbf{W}^{[S]}_{[\chi]}}_{\textit{Meters on } H^0}, \underbrace{\mathrm{Quad}^{[S,\chi]}}_{\text{Quadrant}}, \underbrace{\mathrm{Loc}^{[S,\chi]}}_{\text{Location}}, \underbrace{\mathrm{On}^{[S,\chi]}}_{\text{Onset}} \Big)$$

is uniquely determined for every sector/type pair at any certified plateau (bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$).

Proof. Existence. Fix an diagnostic realized reference configuration as in Definition 9.185 and a sector/type $(S,[\chi])$ with $[\chi]$ taken from the menus Definitions 9.195 and 9.196. The typed projector $\Pi_S^{[\chi]}$ is BRST-closed and cone-preserving by Definition 9.186, hence the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ of Definition 9.187 exists and is finite on $\mathcal{H}_{\mathrm{phys}}$ (diagnostic realized reference configuration aggregation in §9.16.2). The typed quadrant value $\mathrm{Quad}^{[S,\chi]}$ exists by the canonical predicate Definition 9.189, which uses the diagnostic realized reference configuration SynTh meters and healing indicators Definition 9.188. Location/onset data $(\mathrm{Loc}^{[S,\chi]}, \mathrm{On}^{[S,\chi]})$ exist by Definition 9.190. Thus all six entries of $\mathbf{L}^{[S,\chi]}$ are defined.

Gauge/Nielsen safety. By Proposition 9.191, the components of $\mathbf{W}^{[S]}_{[\chi]}$ are Nielsen-flat, and $\mathrm{Quad}^{[S,\chi]}$ is invariant under BRST-exact deformations on $\mathfrak{P}$. Since $\mathrm{Loc}^{[S,\chi]}$ and $\mathrm{On}^{[S,\chi]}$ are defined purely from the diagnostic realized reference configuration choice and the certified stability criteria (Chapter 8; cf. Definitions 9.190 and 9.210), they inherit this invariance.

Uniqueness. Sector purity and typed orthogonality/completeness (cf. Proposition 9.202) together with typed decoupling at leading order (Lemma 9.192) imply that the diagnostic realized reference configuration-aggregated meters for $(S,[\chi])$ are independent of other types $[\chi']$ up to $\mathcal{O}(\varepsilon_{\mathfrak{P}})$, which lies below the Chapter 8 tolerances used in Definition 9.210. Hence the canonical predicate Definition 9.189 produces a unique quadrant label for the fixed diagnostic realized reference configuration and type. Likewise, $\mathrm{On}^{[S,\chi]}$ is the infimum over the control axis $\mathrm{Axis}(\mathfrak{P})$ where that predicate stabilizes, which is unique by the same tolerances (see Definition 9.190). Therefore the mapping $(\mathfrak{P}; S, [\chi]) \mapsto \mathbf{L}^{[S,\chi]}$ is a well-defined function for any certified plateau (bulk or boundary).

Collecting the conclusions proves the statement. □

Typed menus for the two sectors. The following menus fix the vocabulary for $[\chi]$, to be used with the typed projectors $\Pi_S^{[\chi]}$ of Definition 9.186 and the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ of Definition 9.187. They are evaluated on the diagnostic realized reference configuration of Definition 9.185 and feed the quadrant assignment of Definition 9.189 (see also the application of meters in §9.16.2 and the per-type decision in §9.16.3). Entries chosen here are the *Type* components that populate the ledger rows of Definition 9.198.

Definition 9.195 (Gaiamiti ($\Phi\Phi$) typed menu)**.** On the realized geometry $\bar{\Sigma}$ (diagnostic realized reference configuration of Definition 9.185) admit:

(i) TT
Spin-2, transverse-traceless w.r.t. $\bar{\Sigma}$.

(ii) Tr
Spin-0 trace.

(iii) Optional vectorial admixtures
Optional vectorial admixtures if a $\bar{\Sigma}$-preferred foliation is fixed (kept orthogonal to TT/Tr at the plateau; cf. the projector constructions in Definition 9.200).

These types are the allowed $[\chi]$ for $S = \Phi\Phi$ in Definition 9.186, are inserted into the witness of Definition 9.187, and determine the typed quadrant via Definition 9.189.

Definition 9.196 (Tantrakyma ($\Theta\Theta$) typed menu)**.** On $\bar{\Sigma}$ admit:

(i) T, L
Transverse/longitudinal.

(ii) Helicities $\lambda = \pm$
Helicities $\lambda = \pm$ where a chiral frame is meaningful.

(iii) Chrono-Kymon channel
The torsional/time-like *Chrono-Kymon* channel (spin-1 precursor) as a distinct type.

These types are the allowed $[\chi]$ for $S = \Theta\Theta$ in Definition 9.186; the corresponding projectors are given in Definition 9.201. They are used to form the typed witness in Definition 9.187, to evaluate the meters in §9.16.2, and to assign $\mathrm{Quad}^{[S,\chi]}$ via Definition 9.189, after which they are recorded in the ledger of Definition 9.198.

Proposition 9.197 (NG/pNG semantics per type)**.** *Let $(S, [\chi])$ be a sector/type pair chosen from Definitions 9.195 and 9.196 and evaluated on the diagnostic realized reference configuration of Definition 9.185 with typed filter $\Pi_S^{[\chi]}$ as in Definition 9.186. If* $\mathrm{Quad}^{[S,\chi]} = \mathrm{QII}$ *(per Definition 9.189), then the correlational channel $\Pi_{\mathrm{corr}}\,\Pi_S^{[\chi]}$ exhibits an* exact *NG pole with positive residue on $\mathcal{H}_{\mathrm{phys}}$. If* $\mathrm{Quad}^{[S,\chi]} = \mathrm{QIV}$*, the same channel exhibits a pseudo–NG band with GMOR slope on the certified plateau $\mathfrak{P}$. (For* QIII *there is no NG/pNG in the IR;* QI *is fully symmetric.)*

Sketch. The canonical quadrant semantics of §8.6 imply: (i) QII ⇒ state selection without law source, producing an NG pole in the *correlational* channel, and (ii) QIV ⇒ explicit (persistent) law source with GMOR scaling, yielding a pseudo–NG band on the plateau. In the typed setting, we insert $\Pi_S^{[\chi]}$ (see Definition 9.186) into the witness construction $\mathbf{W}_{[\chi]}^{[S]}$ (see Definition 9.187) and into the channel restriction Π_{corr} used by the SynTh meters of §9.16.2. Typed decoupling $\mathcal{O}(\varepsilon_{\mathfrak{P}})$ from other modes follows by Lemma 9.192, so the NG/pNG readout is *per type*. Positivity of the residue in QII is inherited from the projected Hessian on H^0 under the plateau tolerances (Chapter 8), while gauge/Nielsen safety of the statement follows from Proposition 9.191. Thus the untyped NG/pNG semantics of Chapter 9 transfer to the typed channel $\Pi_{\mathrm{corr}}\Pi_S^{[\chi]}$ exactly as stated. □

Definition 9.198 (Typed Quadrant Ledger)**.** The *ledger* has one row per $(S, [\chi])$ containing the sextuple $\mathbf{L}^{[S,\chi]}$ of Corollary 9.194. Each row is obtained by evaluating, on the diagnostic realized reference configuration of Definition 9.185, the typed witness $\mathbf{W}_{[\chi]}^{[S]}$ from Definition 9.187

(built with the typed projectors of Definition 9.186 and the meters of §9.16.2), assigning the typed quadrant via Definition 9.189 (decision pipeline in §9.16.3), and stamping the T–L–O data using Definition 9.190 (bulk–boundary overlay in Definition 9.214). We fix the column order

$$\big[S\big] \quad \big[\chi\big] \quad \big(\mathbf{W}^{[S]}_{[\chi]}\big) \quad \big[\mathrm{Quad}\big] \quad \big[\mathrm{Loc}\big] \quad \big[\mathrm{On}\big],$$

and require stability under the Chapter 8 tolerances (cf. Definition 9.210); boundary rows use $\mathfrak{P}_\partial$ with boundary IR dilation as in Definition 9.214.

Corollary 9.199 (Operational fixing of labels)**.** *Once Definition 9.198 is populated, the* spin/helicity/polarization *labels for each typed mode are fixed* operationally *by the chosen* $[\chi]$ *(from the menus Definitions 9.195 and 9.196), independently of any particle names. Only thereafter may SSB nomenclature be used (e.g.* $(\Phi\Phi, \mathrm{TT})$ *in QII* $\to$ *"graviton";* $(\Theta\Theta, \mathrm{L})$ *or Chrono-Kymon in QII/QIV* $\to$ *Higgs/NG/pNG), consistently with the typed NG/pNG semantics of Proposition 9.197.*

Proof. By Definition 9.186, the typed filter $\Pi^{[\chi]}_S$ selects a BRST-closed, cone-preserving subspace whose kinematic content (spin, helicity, polarization) is determined by $[\chi]$ (menus in Definitions 9.195 and 9.196). Evaluating the typed witness on the diagnostic realized reference configuration (Definitions 9.185 and 9.187) produces meters that are Nielsen-flat and gauge-safe (Proposition 9.191); the canonical predicate then yields a unique $\mathrm{Quad}^{[S,\chi]}$ (Definition 9.189 and Proposition 9.212). Typed decoupling (Lemma 9.192) ensures that these determinations are independent of other types and sectors at leading order, which suffices under the Chapter 8 tolerances used in Definition 9.210. Therefore, the operational labels (spin/helicity/polarization) are fixed by $[\chi]$ and recorded in the ledger $\mathbf{L}^{[S,\chi]}$ (Definition 9.198 and Corollary 9.194), while particle names applied afterward follow the quadrant semantics (NG/pNG) of Proposition 9.197. □

9.16.1 Typed Subspaces and Projectors

We now *choose typed subspaces* that pin down the degrees of freedom to be labeled in each sector, using the realized geometry $\bar{\Sigma}_{\mu\nu}$ on the diagnostic realized reference configuration of Definition 9.185. All operators below act on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ and are BRST-closed; Π_α denotes the triadic channel projectors (Chapter 7). When a helicity refinement is invoked, it is understood that a $\bar{\Sigma}$-admissible spatial orientation (e.g. a unit spatial direction $\hat{n}$ from a foliation or a spectral mode direction) has been fixed at the plateau.

Definition 9.200 (Gaiamiti ($\Phi\Phi$) typed subspaces)**.** Let Sym^2 denote the $\bar{\Sigma}$-symmetric rank-2 block of the $\Phi\Phi$ sector on $\mathcal{H}_{\mathrm{phys}}$ (diagnostic realized reference configuration of Definition 9.185; types chosen from the menu Definition 9.195). Define BRST-closed projectors $\Pi^{[\chi]}_{\Phi\Phi} : \mathsf{Sym}^2 \to \mathsf{Sym}^2$ that commute with each triadic channel projector Π_α ($\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, cf. Definition 9.185) and preserve the $\bar{\Sigma}$-cones (as required in Definition 9.186):

(i) Trace (spin-0)

The spin-0 trace is

$$\big(\Pi^{[\mathrm{Tr}]}_{\Phi\Phi} h\big)_{\mu\nu} := \frac{1}{D}\,\bar{\Sigma}_{\mu\nu}\,\big(\bar{\Sigma}^{\rho\sigma} h_{\rho\sigma}\big), \qquad h \in \mathsf{Sym}^2,$$

where $D := \bar{\Sigma}^{\mu\nu}\bar{\Sigma}_{\mu\nu}$ is the $\bar{\Sigma}$-trace of the identity (plateau slice; §9.16.1).

(ii) TT-like (spin-2, trace-free symmetric)

For TT-like spin-2, trace-free symmetric

$$\Pi^{[\mathrm{TT}]}_{\Phi\Phi} := \mathbb{1}_{\mathsf{Sym}^2} - \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}, \qquad \bar{\Sigma}^{\mu\nu}\big(\Pi^{[\mathrm{TT}]}_{\Phi\Phi} h\big)_{\mu\nu} = 0.$$

If a covariant spatial connection is fixed on $\bar{\Sigma}$ at the plateau, one may additionally impose transversality; the projector remains BRST-closed and cone-preserving, consistent with Definition 9.186.

(iii) Helicity refinement (optional)

When a $\bar{\Sigma}$-spatial direction $\hat{n}$ is available on the diagnostic realized reference configuration, let $\mathcal{J}_{\hat{n}}$ be the generator of rotations about $\hat{n}$ restricted to the TT subspace. Define the $\lambda = \pm 2$ helicity projectors by functional calculus on $\mathcal{J}_{\hat{n}}$:

$$\Pi^{[\lambda]}_{\Phi\Phi} := \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\, \mathbf{1}_{\{\mathcal{J}_{\hat{n}}=\lambda\}}\, \Pi^{[\mathrm{TT}]}_{\Phi\Phi}, \qquad \lambda = \pm 2,$$

so that $\Pi^{[\mathrm{TT}]}_{\Phi\Phi} = \Pi^{[+2]}_{\Phi\Phi} + \Pi^{[-2]}_{\Phi\Phi}$ with orthogonality and completeness on $\operatorname{Ran}\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$ (see Proposition 9.202).

These projectors serve as the typed filters for $S = \Phi\Phi$ in Definition 9.186, are inserted into the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ of Definition 9.187, and thereby feed the meters of §9.16.2 and the quadrant predicate Definition 9.189.

Definition 9.201 (Tantrakyma ($\Theta\Theta$) typed subspaces)**.** Let Vec denote the $\bar{\Sigma}$-covector (or vector) block of the $\Theta\Theta$ sector on $\mathcal{H}_{\mathrm{phys}}$ (diagnostic realized reference configuration of Definition 9.185; types chosen from the menu Definition 9.196). Fix a unit timelike field u^μ (realized rest frame) with $\bar{\Sigma}_{\mu\nu}u^\mu u^\nu = -1$, and set $h_{\mu\nu} := \bar{\Sigma}_{\mu\nu} + u_\mu u_\nu$ for the induced spatial metric. Define BRST-closed projectors $\Pi^{[\chi]}_{\Theta\Theta} : \mathsf{Vec} \to \mathsf{Vec}$ that commute with each triadic projector Π_α ($\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, cf. Definition 9.185) and preserve $\bar{\Sigma}$-cones (as required in Definition 9.186):

(i) Chrono-Kymon (temporal/torsional, spin-1 precursor)

Then the chrono-kymon is

$$\big(\Pi^{[\mathrm{CK}]}_{\Theta\Theta}\,\Theta\big)_\mu := -\,u_\mu\,(u^\nu\Theta_\nu), \qquad \Theta \in \mathsf{Vec}.$$

This isolates the time-like (torsional) channel singled out by u^μ (ultimately tied to the temporal piece of $\bar{\Sigma}$; see diagnostic realized reference configuration geometry in Definition 9.185).

(ii) Spatial L/T (Helmholtz) decomposition

And the longitudinal or transverse

$$\Theta^{\mathrm{sp}}_\mu := h_\mu{}^\nu\Theta_\nu, \qquad \Theta^{[L]}_\mu := \bar{\nabla}_\mu\varphi, \quad \Theta^{[T]}_\mu := \Theta^{\mathrm{sp}}_\mu - \bar{\nabla}_\mu\varphi,$$

where $\bar{\nabla}$ is the Levi–Civita connection of h at the plateau and $\varphi := \Delta^{-1}(\bar{\nabla}^\rho\Theta^{\mathrm{sp}}_\rho)$ uses the spatial Laplacian $\Delta := \bar{\nabla}^\rho\bar{\nabla}_\rho$ with plateau boundary conditions. Define projectors $\Pi^{[L]}_{\Theta\Theta}\Theta := \Theta^{[L]}$ and $\Pi^{[T]}_{\Theta\Theta}\Theta := \Theta^{[T]}$. Then $h^{\mu\nu}\bar{\nabla}_\mu\Theta^{[T]}_\nu = 0$, and

$$\Pi^{[\mathrm{CK}]}_{\Theta\Theta} + \Pi^{[T]}_{\Theta\Theta} + \Pi^{[L]}_{\Theta\Theta} = \mathbb{1}_{\mathsf{Vec}}, \qquad \Pi^{[i]}_{\Theta\Theta}\Pi^{[j]}_{\Theta\Theta} = \delta^{ij}\Pi^{[i]}_{\Theta\Theta}\ (i,j \in \{\mathrm{CK}, T, L\}),$$

with orthogonality/completeness summarized in Proposition 9.202.

(iii) Helicity refinement (transverse, $\lambda = \pm$)

When a spatial orientation $\hat{n}$ (or mode direction) is fixed on the diagnostic realized reference configuration, let $\mathcal{J}_{\hat{n}}$ be the generator of rotations about $\hat{n}$ restricted to $\operatorname{Ran}\Pi^{[T]}_{\Theta\Theta}$. Define

$$\Pi^{[\lambda]}_{\Theta\Theta} := \Pi^{[T]}_{\Theta\Theta}\,\mathbf{1}_{\{\mathcal{J}_{\hat{n}}=\lambda\}}\,\Pi^{[T]}_{\Theta\Theta}, \qquad \lambda = \pm 1,$$

so that $\Pi^{[T]}_{\Theta\Theta} = \Pi^{[+]}_{\Theta\Theta} + \Pi^{[-]}_{\Theta\Theta}$ with orthogonality and completeness on the transverse subspace (cf. Proposition 9.202).

These projectors provide the typed filters for $S = \Theta\Theta$ in Definition 9.186, are inserted into the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ of Definition 9.187, and thereby feed the meters of §9.16.2 and the typed quadrant predicate Definition 9.189.

Proposition 9.202 (Orthogonality, completeness, and triadic compatibility)**.** *The projectors of Definitions 9.200 and 9.201 satisfy:*

(i) Gaiamiti

$\Pi^{[\mathrm{Tr}]}_{\Phi\Phi} + \Pi^{[\mathrm{TT}]}_{\Phi\Phi} = \mathbb{1}_{\mathsf{Sym}^2}$ *with* $\Pi^{[\mathrm{Tr}]}\Pi^{[\mathrm{TT}]} = 0$*; any helicity refinement obeys* $\Pi^{[\mathrm{TT}]} = \Pi^{[+2]}_{\Phi\Phi} + \Pi^{[-2]}_{\Phi\Phi}$ *and orthogonality on* $\operatorname{Ran}\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$ *(see construction in Definition 9.200).*

(ii) Tantrakyma

$\Pi^{[\mathrm{CK}]}_{\Theta\Theta} + \Pi^{[T]}_{\Theta\Theta} + \Pi^{[L]}_{\Theta\Theta} = \mathbb{1}_{\mathsf{Vec}}$ *with pairwise orthogonality; any helicity refinement obeys* $\Pi^{[T]}_{\Theta\Theta} = \Pi^{[+]}_{\Theta\Theta} + \Pi^{[-]}_{\Theta\Theta}$ *and orthogonality on* $\operatorname{Ran}\Pi^{[T]}_{\Theta\Theta}$ *(see Definition 9.201).*

(iii) Triadic compatibility

$\Pi_\alpha \Pi^{[\chi]}_S = \Pi^{[\chi]}_S \Pi_\alpha$ *for all* $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ *(triadic channels fixed on the diagnostic realized reference configuration of Definition 9.185); consequently, typed readouts can be taken channel-by-channel without ambiguity (cf. the usage in §9.16.2).*

(iv) Cone preservation

Each $\Pi^{[\chi]}_S$ *preserves the* $\bar{\Sigma}$*-cones as required in Definition 9.186, and thus preserves the principal symbols relevant for the canonical decision rule (§8.6; typed predicate in Definition 9.189).*

Proof. **(1) Gaiamiti block.** Work on the diagnostic realized reference configuration of Definition 9.185 and endow Sym^2 with the $\bar{\Sigma}$-inner product $\langle h, k\rangle_{\bar{\Sigma}} := \bar{\Sigma}^{\mu\alpha}\bar{\Sigma}^{\nu\beta}h_{\mu\nu}k_{\alpha\beta}$. By Definition 9.200, the trace projector is $\left(\Pi^{[\mathrm{Tr}]}_{\Phi\Phi}h\right)_{\mu\nu} = \frac{1}{D}\bar{\Sigma}_{\mu\nu}\,(\bar{\Sigma}^{\rho\sigma}h_{\rho\sigma})$ with $D = \bar{\Sigma}^{\mu\nu}\bar{\Sigma}_{\mu\nu}$. A direct computation shows idempotence and self-adjointness: $(\Pi^{[\mathrm{Tr}]})^2 = \Pi^{[\mathrm{Tr}]}$ and $\langle \Pi^{[\mathrm{Tr}]}h, k\rangle_{\bar{\Sigma}} = \langle h, \Pi^{[\mathrm{Tr}]}k\rangle_{\bar{\Sigma}}$. Define $\Pi^{[\mathrm{TT}]} := \mathbb{1} - \Pi^{[\mathrm{Tr}]}$. Then $(\Pi^{[\mathrm{TT}]})^2 = \Pi^{[\mathrm{TT}]}$, $\Pi^{[\mathrm{Tr}]}\Pi^{[\mathrm{TT}]} = 0$, and $\Pi^{[\mathrm{Tr}]} + \Pi^{[\mathrm{TT}]} = \mathbb{1}_{\mathsf{Sym}^2}$, proving orthogonality and completeness for the TT/Tr split, as stated in item (1). Moreover, $\bar{\Sigma}^{\mu\nu}(\Pi^{[\mathrm{TT}]}h)_{\mu\nu} = 0$, so TT is the $\bar{\Sigma}$-orthogonal complement of Tr.

For the helicity refinement (when a $\bar{\Sigma}$-admissible spatial direction $\hat{n}$ exists on the plateau), Definition 9.200 defines $\mathcal{J}_{\hat{n}}$ on $\operatorname{Ran}\Pi^{[\mathrm{TT}]}$. The generator $\mathcal{J}_{\hat{n}}$ is essentially self-adjoint on the TT subspace with respect to $\langle\cdot,\cdot\rangle_{\bar{\Sigma}}$, hence by the spectral theorem its spectral projectors $\mathbf{1}_{\{\mathcal{J}_{\hat{n}}=\lambda\}}$ are orthogonal idempotents that resolve the identity on that subspace. Setting

$\Pi^{[\lambda]}_{\Phi\Phi} = \Pi^{[\mathrm{TT}]}\mathbf{1}_{\{\mathcal{J}_{\hat{n}}=\lambda\}}\Pi^{[\mathrm{TT}]}$ ($\lambda = \pm 2$) gives $\Pi^{[\mathrm{TT}]} = \Pi^{[+2]} + \Pi^{[-2]}$ with orthogonality on $\operatorname{Ran}\Pi^{[\mathrm{TT}]}$, establishing the helicity clause of item (1).

(2) Tantrakyma block. On Vec (diagnostic realized reference configuration of Definition 9.185) choose the $\bar{\Sigma}$-inner product $\langle A, B\rangle_{\bar{\Sigma}} := \bar{\Sigma}^{\mu\nu}A_\mu B_\nu$. With u^μ and $h_{\mu\nu} = \bar{\Sigma}_{\mu\nu} + u_\mu u_\nu$ from Definition 9.201, the Chrono–Kymon projector is $\left(\Pi^{[\mathrm{CK}]}\Theta\right)_\mu = -u_\mu(u^\nu\Theta_\nu)$. Then $(\Pi^{[\mathrm{CK}]})^2 = \Pi^{[\mathrm{CK}]}$ and $\langle\Pi^{[\mathrm{CK}]}\Theta, \Phi\rangle_{\bar{\Sigma}} = \langle\Theta, \Pi^{[\mathrm{CK}]}\Phi\rangle_{\bar{\Sigma}}$; further, $h_\mu{}^\nu u_\nu = 0$ implies $\langle\Pi^{[\mathrm{CK}]}\Theta, h\Phi\rangle_{\bar{\Sigma}} = 0$, so the temporal CK channel is orthogonal to the spatial block.

For the spatial Helmholtz/Hodge decomposition on the plateau domain (with Chapter 8 boundary conditions), define $\Theta^{\mathrm{sp}}_\mu = h_\mu{}^\nu\Theta_\nu$ and $\varphi := \Delta^{-1}(\bar{\nabla}^\rho\Theta^{\mathrm{sp}}_\rho)$ where $\Delta = \bar{\nabla}^\rho\bar{\nabla}_\rho$. Set $\Theta^{[L]}_\mu := \bar{\nabla}_\mu\varphi$ and $\Theta^{[T]}_\mu := \Theta^{\mathrm{sp}}_\mu - \bar{\nabla}_\mu\varphi$ (Definition 9.201). Standard Hodge theory on the certified plateau then yields $h^{\mu\nu}\bar{\nabla}_\mu\Theta^{[T]}_\nu = 0$, $\langle\Theta^{[L]}, \Theta^{[T]}\rangle_{\bar{\Sigma}} = 0$, and $\Theta^{\mathrm{sp}} = \Theta^{[L]} + \Theta^{[T]}$. Thus the operators $\Pi^{[L]}\Theta = \Theta^{[L]}$, $\Pi^{[T]}\Theta = \Theta^{[T]}$ are orthogonal idempotents that resolve the identity on the spatial block. Combining with CK gives $\Pi^{[\mathrm{CK}]} + \Pi^{[T]} + \Pi^{[L]} = \mathbb{1}_{\mathsf{Vec}}$ and pairwise orthogonality, proving item (2). When a spatial orientation $\hat{n}$ is available, the restricted rotation generator $\mathcal{J}_{\hat{n}}$ on $\operatorname{Ran}\Pi^{[T]}$ is self-adjoint; its spectral projectors $\Pi^{[\pm]} = \Pi^{[T]}\mathbf{1}_{\{\mathcal{J}_{\hat{n}}=\pm 1\}}\Pi^{[T]}$ are orthogonal idempotents with $\Pi^{[T]} = \Pi^{[+]} + \Pi^{[-]}$ (again as in Definition 9.201).

(3) Triadic compatibility. By Definition 9.186, each typed projector $\Pi^{[\chi]}_S$ is defined from $\bar{\Sigma}$, u^μ, $h_{\mu\nu}$, and the plateau connection $\bar{\nabla}$, all fixed by the diagnostic realized reference configuration (Definition 9.185). The triadic channel projectors Π_α act on the correlation/-vacuum/spectral channels (Chapter 7) and commute with these kinematical constructions; hence $\Pi_\alpha\Pi^{[\chi]}_S = \Pi^{[\chi]}_S\Pi_\alpha$ for all α, establishing item (3) and justifying channel-wise typed readouts (cf. §9.16.2).

(4) Cone preservation. The operators $\Pi^{[\chi]}_S$ are $\bar{\Sigma}$-intrinsic algebraic (TT/Tr, CK) or elliptic (L/T via Δ^{-1}) filters with smooth symbols that project onto subbundles invariant under the $\bar{\Sigma}$-lightcone structure. Therefore their principal symbols are the usual momentum-space projectors (e.g. $p_\mu p_\nu/|p|^2$ for L and $h_{\mu\nu} - p_\mu p_\nu/|p|^2$ for T), which preserve $\bar{\Sigma}$-cones and do not induce cross-cone leakage at leading order; this is the cone-preservation clause of Definition 9.186. Consequently, the principal symbols relevant for the Chapter 9 canonical decision rule (§8.6, typed form Definition 9.189) are stable under insertion of $\Pi^{[\chi]}_S$, yielding item (4).

Combining the four parts proves Proposition 9.202. □

Remark 9.203 (Use in witnesses and meters)**.** For any sector/type pair $(S, [\chi])$, the *typed witness* $\mathbf{W}^{[S]}_{[\chi]}$ is defined in Definition 9.187 and is evaluated on the diagnostic realized reference configuration of Definition 9.185. Operationally, one inserts the typed projector $\Pi^{[\chi]}_S$ (see Definition 9.186, with concrete constructions in Definitions 9.200 and 9.201) together with the triadic channel projectors $\{\Pi_\alpha\}$ into the channel-restricted readouts, following the procedure of §9.16.2. Triadic compatibility and cone preservation (Proposition 9.202) ensure that the order of insertion is immaterial and that the resulting SynTh meters are well posed and Nielsen-flat (Proposition 9.191; cf. Proposition 9.207). Helicity refinements are *optional* and are invoked only when a $\bar{\Sigma}$-admissible spatial direction is fixed at the plateau (see the helicity clauses in Definitions 9.200 and 9.201). The typed meters thus obtained feed the typed quadrant predicate of Definition 9.189 and, together with the location/onset data of Definition 9.190 (bulk–boundary overlay in Definition 9.214), populate the corresponding

row in the Typed Quadrant Ledger $\mathbf{L}^{[S,\chi]}$ (Definition 9.198 and Corollary 9.194).

9.16.2 Applying Parasymmetric Meters to Typed Subspaces

We now *evaluate* the Chapter 9 parasymmetric meters on each typed subspace chosen in §9.16.1. All quantities are read on the diagnostic realized reference configuration of Definition 9.185 and on the BRST-physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$. Typed filters $\Pi_S^{[\chi]}$ (from Definitions 9.186, 9.200 and 9.201) and triadic channel projectors Π_α (Chapter 7) are inserted in every readout. We follow the *Simultaneous Synthesis* (SynTh) notation of Chapter 9, using the sector-conditioned witness $\mathbf{W}_{[\chi]}^{[S]}$ with components

$$\Big(v^{(L)}_{\text{Synthesis}},\ v^{(S)}_{\text{Synthesis}},\ v^{(LS)}_{\text{Synthesis}}\Big)^{[S,\chi]}(\ell;\mathfrak{P}),$$

which drive the quadrant decision of §8.6.

Definition 9.204 (Local parasymmetric two–mode reduction)**.** Fix a certified plateau cell (scale/time) on the diagnostic realized reference configuration of Definition 9.185 and a sector/type pair $(S,[\chi])$ (types chosen from Definitions 9.195 and 9.196). Let $\mathcal{H}_{\text{loc}}^{[S,\chi]} \subset \mathcal{H}_{\text{phys}}$ be the two–mode subspace singled out by the typed projector $\Pi_S^{[\chi]}$ of Definition 9.186 and the SynTh channel predicate (Law, State, or Law⊕State) used in §9.16.2:

$$\mathcal{H}_{\text{loc}}^{[S,\chi]} := \operatorname{Ran}\Big(\Pi_S^{[\chi]}\,\Pi_\alpha\Big)\ \restriction_{\text{SynTh channel}}, \qquad \alpha \in \{\text{corr},\text{vac},\text{spec}\}\ \text{(cf. Definition 9.185)}.$$

Choose an orthonormal pair $\{|\psi_1\rangle, |\psi_2\rangle\}$ spanning $\mathcal{H}_{\text{loc}}^{[S,\chi]}$. For each $a \in \{L,S,LS\}$ (Law, State, Law⊕State) define the *reduced density matrix*

$$\rho_{ij}^{(a)\,[S,\chi]}(\ell) \;:=\; \frac{\big\langle \psi_i,\ \Pi_S^{[\chi]}\,\Pi_\alpha\,\mathcal{O}^{(a)}(\ell)\,\Pi_\alpha\,\Pi_S^{[\chi]}\ \psi_j\big\rangle}{\sum_{k=1}^{2}\big\langle \psi_k,\ \Pi_S^{[\chi]}\,\Pi_\alpha\,\mathcal{O}^{(a)}(\ell)\,\Pi_\alpha\,\Pi_S^{[\chi]}\ \psi_k\big\rangle}, \qquad i,j\in\{1,2\},$$

where $\mathcal{O}^{(a)}(\ell)$ is the SynTh channel operator whose expectation yields the valuations in Definition 9.187 (see also the diagnostic realized reference configuration aggregation and significance criteria in §9.16.2 and Definition 9.210). This local two–mode reduction underlies the typed meters $v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell)$ of Definition 9.205 and enjoys the channel/type compatibility properties stated in Proposition 9.207.

Definition 9.205 (Typed parasymmetric meters (local form))**.** For a fixed sector/type pair $(S,[\chi])$ on the diagnostic realized reference configuration of Definition 9.185, let $\rho_{ij}^{(a)\,[S,\chi]}(\ell)$ be the reduced density matrix from the local two–mode construction of Definition 9.204, with $a \in \{L,S,LS\}$ denoting the SynTh channel (Law, State, Law⊕State; cf. §9.16.2). The *local* SynTh valuations are

$$\begin{aligned}&\Big(v^{(L)}_{\text{Synthesis}}, v^{(S)}_{\text{Synthesis}}, v^{(LS)}_{\text{Synthesis}}\Big)^{[S,\chi]}_{\text{loc}}(\ell) :=\\ &\quad\Big(\tfrac{1}{2}+\operatorname{Re}\,\rho_{12}^{(L)\,[S,\chi]}(\ell),\ \tfrac{1}{2}+\operatorname{Re}\,\rho_{12}^{(S)\,[S,\chi]}(\ell),\ \tfrac{1}{2}+\operatorname{Re}\,\rho_{12}^{(LS)\,[S,\chi]}(\ell)\Big),\end{aligned}$$

which obey the bounds and baselines of Lemma 9.206. The *diagnostic realized reference configuration* valuations used by the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ (see Definition 9.187) are obtained by the Chapter 8 aggregation $\mathcal{A}_{\mathfrak{P}}$ across the certification window of the chosen plateau $\mathfrak{P}$ (significance/tolerances in Definition 9.210):

$$\left(v^{(L)}_{\text{Synthesis}},\, v^{(S)}_{\text{Synthesis}},\, v^{(LS)}_{\text{Synthesis}}\right)^{[S,\chi]}(\ell;\mathfrak{P}) \;:=\; \mathcal{A}_{\mathfrak{P}}\Big[\, \left(v^{(L)}_{\text{Synthesis}},\, v^{(S)}_{\text{Synthesis}},\, v^{(LS)}_{\text{Synthesis}}\right)^{[S,\chi]}_{\text{loc}}(\ell') \,\Big]_{\ell'\in\mathfrak{P}}.$$

These meters are Nielsen-flat and compatible with channel/type insertions (Propositions 9.191 and 9.207), and they feed the typed quadrant predicate of Definition 9.189.

Lemma 9.206 (Bounds, baselines, and phase insensitivity)**.** *For each $a \in \{L, S, LS\}$ and $(S, [\chi])$:*

(i) $0 \le v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell) \le 1$ *(and hence the same bounds hold for the diagnostic realized reference configuration–aggregated meters defined in Definition 9.205).*

(ii) $v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell) = \frac{1}{2}$ *iff the two–mode reduction is incoherent, i.e.* $\operatorname{Re}\rho^{(a)[S,\chi]}_{12}(\ell) = 0$ *(see Definitions 9.204 and 9.205).*

(iii) $v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell) = 1$ *iff the two–mode reduction is maximally (Bell–)coherent with* $\operatorname{Re}\rho^{(a)[S,\chi]}_{12}(\ell) = \frac{1}{2}$ *and equal marginals* $\rho_{11} = \rho_{22} = \frac{1}{2}$*;* $v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell) = 0$ *iff* $\operatorname{Re}\rho^{(a)[S,\chi]}_{12}(\ell) = -\frac{1}{2}$ *with the same equal–marginal condition.*

(iv) *The value depends only on the* relative *phase of $|\psi_1\rangle, |\psi_2\rangle$ chosen in Definition 9.204; a common $U(1)$ rephasing leaves $v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell)$ invariant.*

Proof. Work on a fixed plateau cell of the diagnostic realized reference configuration (Definition 9.185) and a fixed sector/type pair $(S, [\chi])$. By Definition 9.204, the (typed, channel–restricted) two–mode reduction produces a 2×2 positive semidefinite density matrix $\rho^{(a)[S,\chi]}(\ell)$ with unit trace, thanks to the normalization in the denominator. The local SynTh meter is $v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell) = \frac{1}{2} + \operatorname{Re}\rho^{(a)[S,\chi]}_{12}(\ell)$ (Definition 9.205).

(1) Bounds. Positivity implies $\det\rho^{(a)} \ge 0$, i.e. $\rho_{11}\rho_{22} - |\rho_{12}|^2 \ge 0$, hence $|\rho_{12}| \le \sqrt{\rho_{11}\rho_{22}}$. Since $\rho_{11} + \rho_{22} = 1$, AM–GM gives $\sqrt{\rho_{11}\rho_{22}} \le \frac{1}{2}$, so $|\rho_{12}| \le \frac{1}{2}$. Therefore $-\frac{1}{2} \le \operatorname{Re}\rho_{12} \le \frac{1}{2}$ and $0 \le v^{(a)[S,\chi]}_{\text{Synthesis,loc}}(\ell) \le 1$. Diagnostic realized reference configuration aggregation over $\mathfrak{P}$ (Chapter 8; Definitions 9.205 and 9.210) preserves these bounds by convexity.

(2) Baseline. By definition $v = \frac{1}{2} + \operatorname{Re}\rho_{12}$; hence $v = \frac{1}{2}$ iff $\operatorname{Re}\rho_{12} = 0$, which is the usual incoherence condition in the selected two–mode subspace (off–diagonal purely imaginary or vanishing).

(3) Extremes and Bell coherence. From $|\rho_{12}| \le \sqrt{\rho_{11}\rho_{22}} \le \frac{1}{2}$, the extremal values $v = 1$ or $v = 0$ require $|\rho_{12}| = \frac{1}{2}$. Equality in Cauchy–Schwarz (or the positivity bound) occurs iff $\rho_{11} = \rho_{22} = \frac{1}{2}$ and ρ_{12} is aligned in phase with the chosen basis so that $\operatorname{Re}\rho_{12} = \pm\frac{1}{2}$. Thus $v = 1$ (resp. $v = 0$) iff $\operatorname{Re}\rho_{12} = +\frac{1}{2}$ (resp. $-\frac{1}{2}$) and $\rho_{11} = \rho_{22} = \frac{1}{2}$, i.e. a maximally coherent (Bell–like) two–mode reduction.

(4) Phase insensitivity (relative vs. common). Under a basis rephasing $|\psi_j\rangle \mapsto e^{i\phi_j}|\psi_j\rangle$ (within the typed, channel–selected subspace of Definition 9.204), one has $\rho_{12} \mapsto e^{i(\phi_1-\phi_2)}\rho_{12}$. Hence $v = \frac{1}{2} + \operatorname{Re}\rho_{12}$ depends only on the *relative* phase $\phi_1 - \phi_2$; in particular, a common $U(1)$ phase $\phi_1 = \phi_2$ leaves v unchanged.

These statements are insensitive to gauge–fixing (Nielsen–flat) because the operators inserted are BRST–closed and evaluated on H^0 (Proposition 9.191); channel/type insertion order does not affect the result by Proposition 9.207. □

Proposition 9.207 (Channel and type compatibility)**.** *Let $(S,[\chi])$ be fixed (with $[\chi]$ taken from Definitions 9.195 and 9.196) and let $a \in \{L,S,LS\}$ denote the SynTh channel. On the diagnostic realized reference configuration of Definition 9.185,*

$$\Pi_\alpha\,\Pi_S^{[\chi]} \;\rightsquigarrow\; \left(v^{(a)}_{\mathrm{Synthesis}}\right)^{[S,\chi]}(\ell;\mathfrak{P}) \quad \textit{is well defined, Nielsen–flat, and independent of the order of insertion of } \Pi_\alpha, \Pi_S^{[\chi]}.$$

Moreover, if $[\chi'] \neq [\chi]$ for the same sector S, then $\left(v^{(a)}_{\mathrm{Synthesis}}\right)^{[S,\chi]}$ and $\left(v^{(a)}_{\mathrm{Synthesis}}\right)^{[S,\chi']}$ decouple at leading order on $\mathfrak{P}$: cross–terms are $\mathcal{O}(\varepsilon_{\mathfrak{P}})$, where $\varepsilon_{\mathfrak{P}}$ is the Chapter 8 tolerance scale (cf. Definition 9.210). The same statements hold on the boundary diagnostic realized reference configuration $\mathfrak{P}_\partial$.

Proof. **Well-definedness and order independence.** By construction of the typed projectors (Definition 9.186) and the diagnostic realized reference configuration (Definition 9.185), we have triadic compatibility $\Pi_\alpha\Pi_S^{[\chi]} = \Pi_S^{[\chi]}\Pi_\alpha$ (see also Proposition 9.202, item 3). Hence the composed insertion $\Pi_\alpha\Pi_S^{[\chi]}$ is an idempotent, self-adjoint filter on $\mathcal{H}_{\mathrm{phys}}$, independent of insertion order. The local two–mode reduction (Definition 9.204) therefore yields a normalized 2×2 density matrix $\rho^{(a)[S,\chi]}(\ell)$, and the local meters $v^{(a)[S,\chi]}_{\mathrm{Synthesis,loc}}(\ell)$ are defined by Definition 9.205. Aggregating across the certified window by $\mathcal{A}_{\mathfrak{P}}$ (Chapter 8; Definitions 9.205 and 9.210) produces the diagnostic realized reference configuration valuations $\left(v^{(a)}_{\mathrm{Synthesis}}\right)^{[S,\chi]}(\ell;\mathfrak{P})$, establishing well-definedness.

Nielsen flatness (gauge independence). The SynTh readouts are BRST-closed on H^0 and evaluated on a certified plateau; therefore their gauge-parameter derivatives insert BRST-exact operators whose expectations vanish on $\mathcal{H}_{\mathrm{phys}}$. This is the content of Proposition 9.191 (see also the discussion around §9.16.2), which directly applies to the typed meters because the only change is the insertion of the commuting, cone-preserving projector $\Pi_S^{[\chi]}$ (Definition 9.186). Hence the valuations are Nielsen-flat.

Typed decoupling. For two distinct types $[\chi] \neq [\chi']$ within the same sector, orthogonality/completeness of the typed decompositions was established in Proposition 9.202 (items 1–2). Consequently, the channel-restricted principal symbols are block-diagonal at the plateau. A Duhamel/BCH control of subleading commutators across the certification window (Chapter 8) yields that mixed contributions fall below tolerance, which is summarized in Lemma 9.192 as $\mathcal{O}(\varepsilon_{\mathfrak{P}})$. Therefore the diagnostic realized reference configuration valuations computed with $\Pi_S^{[\chi]}$ are insensitive, at leading order, to the presence of orthogonal typed filters $\Pi_S^{[\chi']}$, proving the stated decoupling.

All statements carry over verbatim to the boundary diagnostic realized reference configuration by replacing $\mathfrak{P}$ with $\mathfrak{P}_\partial$ and using the edge dilation/overlay (cf. Definition 9.214). □

Definition 9.208 (Quadrant drivers)**.** Fix a sector/type pair $(S,[\chi])$ (types from Definitions 9.195 and 9.196) and an diagnostic realized reference configuration as in Definition 9.185.

Let

$$\mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P}) := \Big(v^{(L)}_{\text{Synthesis}},\ v^{(S)}_{\text{Synthesis}},\ v^{(LS)}_{\text{Synthesis}} \Big)^{[S,\chi]}(\ell;\mathfrak{P})$$

be the typed SynTh meters obtained from the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ (Definition 9.187) via the diagnostic realized reference configuration aggregation of Definition 9.205 (constructed locally by Definition 9.204 and used operationally in §9.16.2). Together with the typed healing indicators $\big(\mathscr{H}_L^{[S,\chi]}, \mathscr{H}_S^{[S,\chi]}\big)$ of Definition 9.188, this triplet $\mathbf{V}^{[S,\chi]}$ *drives* the canonical typed quadrant predicate $\mathrm{Quad}^{[S,\chi]}$ in Definition 9.189, evaluated on the same certified plateau (bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$).

Corollary 9.209 (Typed parasymmetric meters determine the quadrant)**.** *On any certified $\mathfrak{P}$ (or $\mathfrak{P}_\partial$), the data $\big(\mathbf{V}^{[S,\chi]},\ \mathscr{H}_L^{[S,\chi]},\ \mathscr{H}_S^{[S,\chi]}\big)$ are sufficient to evaluate the predicate of Definition 9.189 and thus to assign $\mathrm{Quad}^{[S,\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$. Consequently, these determinations populate the Typed Quadrant Ledger entry $\mathbf{L}^{[S,\chi]}$ (cf. Definition 9.198 and Corollary 9.194).*

Proof. By construction, $\mathbf{V}^{[S,\chi]}$ consists of the diagnostic realized reference configuration SynTh meters defined in Definition 9.205 from the typed witness of Definition 9.187, and $\mathscr{H}_\bullet^{[S,\chi]}$ are the typed healing indicators of Definition 9.188. The canonical predicate in Definition 9.189 depends only on these quantities (together with the fixed Chapter 8 tolerances referenced in Definition 9.210); hence they are *sufficient* to decide the quadrant on the chosen diagnostic realized reference configuration. Well-posedness and gauge/Nielsen safety of the meters and the decision follow from Propositions 9.191 and 9.207, while uniqueness of the resulting label on a certified plateau is ensured by Proposition 9.212. Once $\mathrm{Quad}^{[S,\chi]}$ is fixed, inserting it (along with the already-defined witness and T–L–O data) into the ledger row $\mathbf{L}^{[S,\chi]}$ is exactly the prescription of Definition 9.198, whose existence/uniqueness were established in Corollary 9.194. □

9.16.3 Assigning the Quadrant Per Type (Canonical decision on H^0)

We now *assign the quadrant* for each typed subspace using the Chapter 9 canonical rule, evaluated on the diagnostic realized reference configuration of Definition 9.185. All inputs are the typed SynTh meters and healing indicators introduced in §9.16.2:

$$\mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P}) = \Big(v^{(L)}_{\text{Synthesis}},\ v^{(S)}_{\text{Synthesis}},\ v^{(LS)}_{\text{Synthesis}} \Big)^{[S,\chi]}(\ell;\mathfrak{P}), \qquad \big(\mathscr{H}_L^{[S,\chi]},\ \mathscr{H}_S^{[S,\chi]}\big).$$

Decisions are taken *on the same diagnostic realized reference configuration* and are thus BRST/Nielsen–safe (cf. Proposition 9.191).

Definition 9.210 (Stability and significance on the plateau)**.** Fix a certified plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$). Let $\mathrm{Axis}(\mathfrak{P})$ be its control axis (Chapter 8) and let $\mathcal{A}_{\mathfrak{P}}[\cdot]$ denote the Chapter 8 aggregation over the certification window.

1. (*Diagnostic realized reference configuration meters*) Define the diagnostic realized reference configuration values by aggregation:

$$\overline{v}_a^{[S,\chi]} := \mathcal{A}_{\mathfrak{P}}\Big[v^{(a)\,[S,\chi]}_{\text{Synthesis}}(\ell) \Big], \quad a \in \{L, S, LS\}.$$

2. (*Baselines and deviations*) Use the SynTh baseline 1/2 (§9.16.2) and set $\Delta_S^{[S,\chi]} := \left|\overline{v}_S^{[S,\chi]} - \frac{1}{2}\right|$.
3. (*Significance thresholds*) Let $\tau_L, \tau_S > 0$ be the Chapter 8 detection tolerances (Slope/Curv/Osc encoded) for law–source and state–selection, respectively. We write Law $\mathrm{src}^{[S,\chi]}$ if $\overline{v}_L^{[S,\chi]}$ exceeds its symmetric-band acceptance by $> \tau_L$, and State $\mathrm{sel}^{[S,\chi]}$ if $\Delta_S^{[S,\chi]} > \tau_S$.

Definition 9.211 (Typed canonical quadrant predicate)**.** For a fixed sector/type $(S,[\chi])$ on the diagnostic realized reference configuration, define $\mathrm{Quad}^{[S,\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$ by:

$$\mathrm{QI}: \quad \neg\text{Law src}^{[S,\chi]} \ \wedge\ \neg\text{State sel}^{[S,\chi]} \iff \mathscr{H}_L^{[S,\chi]} = 0,\ \mathscr{H}_S^{[S,\chi]} = 0,\ \Delta_S^{[S,\chi]} \le \tau_S;$$

$$\mathrm{QII}: \quad \neg\text{Law src}^{[S,\chi]} \ \wedge\ \text{State sel}^{[S,\chi]} \ \wedge\ \mathscr{H}_S^{[S,\chi]} = 0 \iff \mathscr{H}_L^{[S,\chi]} = 0,\ \Delta_S^{[S,\chi]} > \tau_S;$$

$$\mathrm{QIII}: \quad \text{Law src}^{[S,\chi]} \ \wedge\ \mathscr{H}_L^{[S,\chi]} = 0 \iff \text{explicit law source at finite scale, } \textit{healing} \text{ in the IR;}$$

$$\mathrm{QIV}: \quad \text{Law src}^{[S,\chi]} \ \wedge\ \mathscr{H}_L^{[S,\chi]} > 0 \iff \text{explicit law source with } \textit{persistence} \text{ (GMOR slope; pNG band when applicable).}$$

All predicates are evaluated using the same $\mathfrak{P}$ and the same typed filter $\Pi_S^{[\chi]}$ (cf. Definition 9.186).

Proposition 9.212 (Typed quadrant assignment is well defined and BRST/Nielsen–safe)**.** *For each $(S,[\chi])$ and certified $\mathfrak{P}$ (or $\mathfrak{P}_\partial$), the value $\mathrm{Quad}^{[S,\chi]}$ given by Definition 9.211 exists, is independent of gauge–fixing parameters, and is invariant under BRST–exact deformations admissible on $\mathfrak{P}$.*

Proof. Existence and invariance follow from Proposition 9.191 (diagnostic realized reference configuration well–posedness, Nielsen flatness) together with typed decoupling at leading order (Lemma 9.192). The predicates use only diagnostic realized reference configuration quantities $\overline{v}_a^{[S,\chi]}$, $\mathscr{H}_\bullet^{[S,\chi]}$ and Chapter 8 tolerances, all defined on the same diagnostic realized reference configuration. □

Corollary 9.213 (Per–type quadrant label)**.** *For every type $[\chi]$ (spin/helicity/polarization/species) in either sector $S \in \{\Phi\Phi, \Theta\Theta\}$ (types chosen from Definitions 9.195 and 9.196 and implemented via Definition 9.186), we obtain a definite label*

$$\mathrm{Quad}^{[S,\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}.$$

These labels are the inputs recorded in the Typed Quadrant Ledger entry $\mathbf{L}^{[S,\chi]}$ (see Definition 9.198) and are to be fixed prior *to any SSB/particle nomenclature (cf. Corollary 9.199).*

Proof. Fix an diagnostic realized reference configuration (bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$) as in Definition 9.185 and a sector/type pair $(S,[\chi])$. The typed witness $\mathbf{W}_{[\chi]}^{[S]}$ exists and is Nielsen–flat by Definition 9.187 and Proposition 9.191; its diagnostic realized reference

configuration meters are constructed in Definition 9.205 and the associated typed healing indicators in Definition 9.188. The canonical predicate that assigns $\mathrm{Quad}^{[S,\chi]}$ is given in Definition 9.189 and, by Proposition 9.212, is well defined and gauge/BRST–safe on any certified plateau.

Uniqueness and per–type definiteness follow from typed orthogonality/triadic compatibility (Proposition 9.202), typed decoupling at leading order (Lemma 9.192), and the Chapter 8 stability tolerances used in Definition 9.210: these ensure that the diagnostic realized reference configuration meters determining the predicate are insensitive to orthogonal types up to errors below certification thresholds. Hence a single, definite quadrant value is produced for each $(S,[\chi])$.

Finally, once $\mathrm{Quad}^{[S,\chi]}$ is fixed, the ledger row $\mathbf{L}^{[S,\chi]}$ is populated per Definition 9.198; existence/uniqueness of the ledger entry was established in Corollary 9.194. The instruction to defer SSB/particle naming until after ledger population is precisely the operational rule stated in Corollary 9.199. □

9.16.4 Recording the Type, Location, and Onset (TLO)

We now *stamp* each typed mode with its Type–Location–Onset (T–L–O) data. We use the same diagnostic realized reference configuration and meters as in §9.16.2, together with the typed quadrant assignment of §9.16.3. Recall the location/onset primitives from Definition 9.190 and write

$$\mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P}) = \left(v^{(L)}_{\mathrm{Synthesis}}, v^{(S)}_{\mathrm{Synthesis}}, v^{(LS)}_{\mathrm{Synthesis}}\right)^{[S,\chi]}(\ell;\mathfrak{P}),$$

with healing indicators $\mathscr{H}^{[S,\chi]}_{\bullet}$ from Definition 9.188.

Definition 9.214 (Bulk and boundary meters (overlay))**.** For each sector/type $(S,[\chi])$ we define the *bulk* and *boundary* SynTh triplets by evaluating the same typed witness on the appropriate diagnostic realized reference configuration:

$$\mathbf{V}^{[S,\chi]}_{\mathrm{bulk}}(\ell) := \mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P}), \qquad \mathbf{V}^{[S,\chi]}_{\partial}(\ell) := \mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P}_{\partial}),$$

together with the corresponding healing indicators $\mathscr{H}^{[S,\chi]}_{\bullet,\mathrm{bulk}}$ and $\mathscr{H}^{[S,\chi]}_{\bullet,\partial}$. The *boundary overlay* is the comparison map

$$\mathcal{O}^{[S,\chi]}_{\partial\leftarrow\mathrm{bulk}} : \left(\mathbf{V}^{[S,\chi]}_{\mathrm{bulk}}, \mathscr{H}^{[S,\chi]}_{\bullet,\mathrm{bulk}}\right) \longrightarrow \left(\mathbf{V}^{[S,\chi]}_{\partial}, \mathscr{H}^{[S,\chi]}_{\bullet,\partial}\right),$$

taken along the boundary IR dilation prescribed in Chapter 9.

Definition 9.215 (Edge status (healing/persistent/spontaneous selection))**.** Fix $(S,[\chi])$. Let $\mathrm{Quad}^{[S,\chi]}_{\mathrm{bulk}}$ (resp. $\mathrm{Quad}^{[S,\chi]}_{\partial}$) be the typed quadrant on $\mathfrak{P}$ (resp. $\mathfrak{P}_{\partial}$), as in Definition 9.211. Define the *edge status* $\mathrm{Edge}^{[S,\chi]} \in \{\mathrm{heal}, \mathrm{persist}, \mathrm{sel}\}$ by:

1. heal if $\mathrm{Quad}^{[S,\chi]}_{\partial} \in \{\mathrm{QI}, \mathrm{QIII}\}$ with $\mathscr{H}^{[S,\chi]}_{L,\partial} = 0$ (law heals at the edge);
2. persist if $\mathrm{Quad}^{[S,\chi]}_{\partial} = \mathrm{QIV}$ with $\mathscr{H}^{[S,\chi]}_{L,\partial} > 0$ (explicit breaking persists at the edge);

3. sel (*spontaneous edge selection*) if $\mathrm{Quad}^{[S,\chi]}_{\mathrm{bulk}} = \mathrm{QI}$ and $\mathrm{Quad}^{[S,\chi]}_{\partial} = \mathrm{QII}$ with $\mathscr{H}^{[S,\chi]}_{S,\partial} = 0$ (edge-only SSB, bulk symmetric).

Definition 9.216 (T–L–O stamp)**.** For each typed mode $(S,[\chi])$ we define its *T–L–O stamp* as the triplet

$$\mathbf{TLO}^{[S,\chi]} := \Big(\underbrace{\mathrm{Type}}_{[\chi]},\ \underbrace{\mathrm{Loc}^{[S,\chi]}}_{\text{bulk or boundary}},\ \underbrace{\mathrm{On}^{[S,\chi]}}_{\text{scale/time onset}} \Big),$$

where $\mathrm{Loc}^{[S,\chi]}$ and $\mathrm{On}^{[S,\chi]}$ are as in Definition 9.190. For boundary rows we also record the edge status $\mathrm{Edge}^{[S,\chi]}$ from Definition 9.215 as auxiliary metadata.

Proposition 9.217 (Existence, uniqueness, and stability of T–L–O)**.** *For any certified plateau (bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$) and any type $[\chi]$ in sector S, the stamp $\mathbf{TLO}^{[S,\chi]}$ of Definition 9.216 exists, is unique, and is stable under Chapter 8 tolerances. In the boundary case, the auxiliary $\mathrm{Edge}^{[S,\chi]}$ is well defined by Definition 9.215.*

Proof. Existence/uniqueness of $\mathrm{Loc}^{[S,\chi]}$ and $\mathrm{On}^{[S,\chi]}$ follow from Definition 9.190 once $\mathrm{Quad}^{[S,\chi]}$ is fixed (cf. Proposition 9.212). Stability is inherited from the aggregation $\mathcal{A}_{\mathfrak{P}}$ and the Slope/Curv/Osc tolerances (Chapter 8). The boundary status is determined by the quadrants and healing indicators on $\mathfrak{P}_\partial$, hence is well posed. □

Corollary 9.218 (Ledger update with T–L–O)**.** *Each row of the Typed Quadrant Ledger (Definition 9.198) is augmented by the T–L–O stamp (Definition 9.216):*

$$\mathbf{L}^{[S,\chi]} \ \mapsto\ \Big(\mathbf{L}^{[S,\chi]},\ \mathbf{TLO}^{[S,\chi]}\ ;\ \textit{if}\ \mathrm{Loc}^{[S,\chi]} = \text{boundary},\ \mathrm{Edge}^{[S,\chi]} \Big).$$

This augmentation is performed after *the quadrant assignment of §9.16.3, on the* same *certified plateau (bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$; Definition 9.185), thereby maintaining BRST/Nielsen safety (Proposition 9.191) and typed consistency (cf. Proposition 9.207).*

Proof. Existence and stability. By Corollary 9.194, each row $\mathbf{L}^{[S,\chi]}$ exists once the typed witness and quadrant are fixed on a certified plateau. After the quadrant decision (§9.16.3, Proposition 9.212), the T–L–O stamp $\mathbf{TLO}^{[S,\chi]}$ exists and is stable by Definitions 9.190 and 9.216 and the well-posedness result Proposition 9.217; in the boundary case the auxiliary edge status $\mathrm{Edge}^{[S,\chi]}$ is defined by Definition 9.215 using the bulk–boundary overlay Definition 9.214.

Gauge/BRST safety. Because the augmentation uses the *same* diagnostic realized reference configuration as the meters and quadrant (no change of tags or projectors), Nielsen flatness and BRST invariance from Proposition 9.191 carry over. Channel/type order-independence (Proposition 9.207) ensures that inserting the T–L–O metadata does not alter previously certified meters or the quadrant.

Uniqueness. Uniqueness of $\mathrm{Loc}^{[S,\chi]}$ and $\mathrm{On}^{[S,\chi]}$ follows from the certification tolerances along the control axis (Chapter 8) encoded in Definition 9.190 and guaranteed in Proposition 9.217. Since $\mathbf{L}^{[S,\chi]}$ was already unique (Corollary 9.194), appending a unique $\mathbf{TLO}^{[S,\chi]}$ (and, when applicable, $\mathrm{Edge}^{[S,\chi]}$) yields a unique augmented row.

Therefore, performing the update after the quadrant assignment on the same diagnostic realized reference configuration produces a BRST/Nielsen-safe and uniquely defined ledger augmentation, as claimed. □

Operational note. In the *bulk* we use the standard typed meters $\mathbf{V}^{[S,\chi]}_{\text{bulk}} := \mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P})$ of Definition 9.214; at *edges* we replace them by the boundary overlay $\mathbf{V}^{[S,\chi]}_{\partial} := \mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P}_\partial)$ and classify the edge via $\text{Edge}^{[S,\chi]} \in \{\text{heal}, \text{persist}, \text{sel}\}$ (healing vs. persistence vs. spontaneous selection) as in Definition 9.215, before stamping $\mathbf{TLO}^{[S,\chi]}$ (Definition 9.216) and updating the ledger (Corollary 9.218). Practically:

1. **Fix the diagnostic realized reference configuration and tags.** Choose bulk $\mathfrak{P}$ or boundary $\mathfrak{P}_\partial$ on the diagnostic realized reference configuration (Definition 9.185), with the same band tags $P_x(\lambda_{\text{UV}}), K^{(\ell)}_{\text{IR}}$ used throughout the typed workflow (§9.16.2).

2. **Insert identical typed/channel filters.** For the chosen $(S,[\chi])$, insert $\Pi^{[\chi]}_S$ (Definition 9.186) and the triadic Π_α into the readouts to form the typed witness $\mathbf{W}^{[S]}_{[\chi]}$ (Definition 9.187); channel/type order is immaterial (Proposition 9.207).

3. **Evaluate meters and healing.** Compute the diagnostic realized reference configuration SynTh triplet $\mathbf{V}^{[S,\chi]}(\ell;\mathfrak{P})$ from the local two–mode construction (Definitions 9.204 and 9.205), and the typed healing indicators $\mathscr{H}^{[S,\chi]}_\bullet$ (Definition 9.188); bounds/baselines follow Lemma 9.206.

4. **Boundary overlay (if applicable).** For edges, push bulk data through the comparison map $\mathcal{O}^{[S,\chi]}_{\partial\leftarrow\text{bulk}}$ (Definition 9.214) to obtain $\mathbf{V}^{[S,\chi]}_\partial$ and $\mathscr{H}^{[S,\chi]}_{\bullet,\partial}$.

5. **Decide the quadrant per type.** Apply the canonical predicate on the same diagnostic realized reference configuration (Definition 9.189, pipeline in §9.16.3) using $\mathbf{V}$ and $\mathscr{H}_\bullet$ (Definition 9.208 and Corollary 9.209); well-posed/Nielsen-flat by Proposition 9.191.

6. **Classify the edge (boundary only).** Read $\text{Edge}^{[S,\chi]}$ from Definition 9.215: heal vs. persist vs. sel (spontaneous edge selection, i.e. bulk QI but boundary QII).

7. **Stamp T–L–O and record.** Set $\text{Loc}^{[S,\chi]}$ and $\text{On}^{[S,\chi]}$ via Definition 9.190, form $\mathbf{TLO}^{[S,\chi]}$ (Definition 9.216), and append to the ledger row $\mathbf{L}^{[S,\chi]}$ (Definition 9.198 and Corollary 9.218).

Throughout, use the *same* diagnostic realized reference configuration and tags to preserve BRST/Nielsen safety (Proposition 9.191) and typed decoupling within tolerances (Lemma 9.192); any bulk/edge differences are attributed solely to the diagnostic realized reference configuration choice and IR dilation (Chapter 9), not to a change of types or channels.

9.17 The Gaiamiti Field Potential and the Origin of the Apeiron

Typed Parasymmetric TLO Prelude (Gaiamiti)

Before drawing any SSB conclusions from the Gaiamiti potential (cf. §9.17, §9.17), we first perform the typed parasymmetric analysis on the diagnostic realized reference configuration

(Definition 9.185) and *fix* the per–type quadrant and T–L–O data for the $(\Phi\Phi)$ sector. This ensures BRST/Nielsen safety and operational determinacy prior to any particle naming (Corollary 9.199).

Diagnostic realized reference configuration and types. Work on a certified bulk (or boundary) plateau $\mathfrak{P}$ ($\mathfrak{P}_\partial$) with tags $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}$ (Definition 9.185). Choose the Gaiamiti typed projectors from the menu $[\chi] \in \{\mathrm{Tr}, \mathrm{TT}\}$ and optional helicities $\lambda = \pm 2$ when available (Definitions 9.195 and 9.200); these supply the typed filter $\Pi_{\Phi\Phi}^{[\chi]}$ (Definition 9.186).

Witness and meters. Insert $\Pi_{\Phi\Phi}^{[\chi]}$ and the triadic channel projectors $\{\Pi_\alpha\}$ into the readouts on H^0 to form the typed witness $\mathbf{W}_{[\chi]}^{[\Phi\Phi]}$ (Definition 9.187). Compute the local two–mode reductions and SynTh meters (Definitions 9.204 and 9.205); the bounds/baselines and phase properties are given in Lemma 9.206. Gauge/Nielsen safety and channel/type order independence are ensured by Propositions 9.191 and 9.207.

Quadrant decision (typed). Evaluate the typed healing indicators $\left(\mathscr{H}_L^{[\Phi\Phi,\chi]}, \mathscr{H}_S^{[\Phi\Phi,\chi]}\right)$ (Definition 9.188) and apply the canonical predicate to obtain $\mathrm{Quad}^{[\Phi\Phi,\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$ (Definition 9.189, pipeline §9.16.3). Typed decoupling and stability on the plateau follow from Lemma 9.192, Definition 9.210, and Proposition 9.212.

T–L–O stamp and ledger. Stamp the location and onset $\left(\mathrm{Loc}^{[\Phi\Phi,\chi]}, \mathrm{On}^{[\Phi\Phi,\chi]}\right)$ (Definition 9.190); for boundary diagnostic realized reference configuration classify the edge via $\mathrm{Edge}^{[\Phi\Phi,\chi]} \in \{\mathrm{heal}, \mathrm{persist}, \mathrm{sel}\}$ (Definitions 9.214 and 9.215). Record the row $\mathbf{L}^{[\Phi\Phi,\chi]}$ in the Typed Quadrant Ledger (Definition 9.198 and Corollaries 9.194 and 9.218). By Corollaries 9.199 and 9.213, this fixes the *operational* spin/polarization labels for the typed mode $[\chi]$ *before* any SSB naming.

Proposition 9.219 (SSB naming gated by typed T–L–O)**.** *Let* $[\chi] \in \{\mathrm{Tr}, \mathrm{TT}\}$ *(with optional* $\lambda = \pm 2$*) be fixed. If and only if the ledger row* $\mathbf{L}^{[\Phi\Phi,\chi]}$ *exists with a certified quadrant* $\mathrm{Quad}^{[\Phi\Phi,\chi]}$ *(Definition 9.198), may SSB nomenclature be applied in §9.17; in particular, a* $(\Phi\Phi, \mathrm{TT})$ *entry with* QII *may be* called *"graviton" (and* QIV *implies pNG semantics) in accordance with Proposition 9.197 and Corollary 9.199.*

Proof. Existence, gauge independence, and uniqueness of the typed meters and quadrant follow from Propositions 9.191, 9.207 and 9.212 together with typed orthogonality/decoupling (Proposition 9.202 and Lemma 9.192). Location/onset (and edge status, when applicable) are well posed by Definitions 9.190 and 9.216 and Proposition 9.217. Hence the ledger row $\mathbf{L}^{[\Phi\Phi,\chi]}$ is uniquely determined (Corollaries 9.194 and 9.218). By Proposition 9.197 and Corollary 9.199, NG/pNG semantics and any SSB naming are to be applied *after* these typed determinations. □

Potential–driven typed quadrant evaluation (Gaiamiti)

We connect the explicit Gaiamiti potential of §9.17 to the typed SynTh meters on the diagnostic realized reference configuration (Definition 9.185) so that the canonical predicate

$\mathrm{Quad}^{[\Phi\Phi,\chi]}$ (Definition 9.189) can be computed directly from the potential's typed curvature data, *before* any SSB naming (cf. Corollary 9.199).

Definition 9.220 (Typed curvature and order parameter from the potential)**.** Let $\mathcal{U}_{\Phi\Phi}$ denote the Gaiamiti potential (or the zero–momentum limit of the effective action) specified in §9.17, evaluated on the certified plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$). For a typed projector $\Pi^{[\chi]}_{\Phi\Phi}$ (Definitions 9.186 and 9.200) define:

(i) Typed order parameter.
At a candidate background $\bar{\Phi}$, the typed order parameter is

$$\varphi^{[\chi]} := \Pi^{[\chi]}_{\Phi\Phi}\,\bar{\Phi},$$

where $\bar{\Phi}$ is determined by the diagnostic realized reference configuration variational problem (Chapter 8) and the tags specified in Definition 9.185.

(ii) Typed curvature operator.
The typed curvature operator (Hessian restricted to the type) is

$$\mathcal{K}^{[\chi]}_{\Phi\Phi} \;:=\; \Pi^{[\chi]}_{\Phi\Phi}\,\frac{\delta^2\mathcal{U}_{\Phi\Phi}}{\delta\Phi\,\delta\Phi}\Big|_{\bar{\Phi}}\,\Pi^{[\chi]}_{\Phi\Phi}\,,$$

viewed as a positive (semi)definite operator on the typed subspace, with principal symbol inside the $\bar{\Sigma}$–cones (cone preservation in Definition 9.186).

Definition 9.221 (Potential–based SynTh operators and sources)**.** On the same diagnostic realized reference configuration and type $[\chi]$, choose the SynTh channel operators of Definitions 9.204 and 9.205 as:

$$\mathcal{O}^{(L)}(\ell) \;\equiv\; f_L\Big(\mathcal{K}^{[\chi]}_{\Phi\Phi}(\ell)\Big), \qquad \mathcal{O}^{(S)}(\ell) \;\equiv\; f_S\Big(\varphi^{[\chi]}(\ell)\Big), \qquad \mathcal{O}^{(LS)}(\ell) \;\equiv\; f_{LS}\Big(\mathcal{K}^{[\chi]}_{\Phi\Phi}(\ell),\varphi^{[\chi]}(\ell)\Big),$$

with $f_\bullet$ the diagnostic realized reference configuration–normalized maps used by the SynTh construction (cf. §9.16.2); insert them as $\Pi_\alpha\,\Pi^{[\chi]}_{\Phi\Phi}(\cdot)\Pi^{[\chi]}_{\Phi\Phi}\,\Pi_\alpha$ per Definition 9.187. Define the typed *law* and *state* sources $\delta^{[\Phi\Phi,\chi]}_{L,S}$ and healing indicators $\mathscr{H}^{[\Phi\Phi,\chi]}_{L,S}$ exactly as in Definition 9.188, now computed from these potential–based operators.

Remark 9.222 (On the notation $\mathcal{O}$ in Definition 9.221)**.** Throughout this chapter, $\mathcal{O}$ denotes a *SynTh channel operator*—an operator–valued, scale–tagged map acting on the physical Hilbert space $\mathcal{H}_{\mathrm{phys}}$ after insertion into the typed/triadic subspace. For a fixed type $[\chi]$ and window ℓ, the three instances $\mathcal{O}^{(L)}(\ell)$, $\mathcal{O}^{(S)}(\ell)$, $\mathcal{O}^{(LS)}(\ell)$ are defined by applying the diagnostic realized reference configuration–normalized functional calculi f_L, f_S, f_{LS} (cf. Section 9.16.2) to the typed *law–side* input $\mathcal{K}^{[\chi]}_{\Phi\Phi}(\ell)$ and the typed *state–side* input $\varphi^{[\chi]}(\ell)$, and then sandwiching with the typed and triadic projectors as prescribed in Definition 9.187:

$$\mathcal{O}^{(\bullet)}(\ell) \;\equiv\; \Pi_\alpha\,\Pi^{[\chi]}_{\Phi\Phi}\,f_\bullet\Big(\;\cdot\;\Big)\,\Pi^{[\chi]}_{\Phi\Phi}\,\Pi_\alpha \;:\; \mathcal{H}_{\mathrm{phys}}\to\mathcal{H}_{\mathrm{phys}}, \qquad \alpha\in\{\mathrm{corr},\mathrm{vac},\mathrm{spec}\}.$$

Here, the superscripts indicate the *channel content*: (L) uses only the law–side curvature $\mathcal{K}^{[\chi]}_{\Phi\Phi}(\ell)$; (S) uses only the state probe $\varphi^{[\chi]}(\ell)$; and (LS) is the mixed, jointly typed construction

$f_{LS}\big(\mathcal{K}^{[\chi]}_{\Phi\Phi}(\ell), \varphi^{[\chi]}(\ell)\big)$. When the type $[\chi]$ and triadic channel α are fixed by context, we write simply $\mathcal{O}^{(\bullet)}(\ell)$ or $\mathcal{O}^{(\bullet)}$. This is *operator* notation (not big-O asymptotics).

If the inputs are self–adjoint and $f_\bullet$ are real Borel maps, then $\mathcal{O}^{(\bullet)}(\ell)$ is self–adjoint; diagnostic realized reference configuration normalization ensures $0 \le \mathcal{O}^{(\bullet)}(\ell) \le \mathbb{1}$ in spectral order, so the typed sources $\delta^{[\Phi\Phi,\chi]}_{L,S}$ and healing indicators $\mathscr{H}^{[\Phi\Phi,\chi]}_{L,S}$ of Definition 9.188 are well-posed and scale–stable on certified windows. Moreover, because the typed projectors commute with the triadic channels and are BRST–closed (cf. Definition 9.186 and Proposition 9.207), all resulting $\mathcal{O}^{(\bullet)}(\ell)$ are Nielsen–flat and BRST–safe on $\mathcal{H}_{\text{phys}}$.

Proposition 9.223 (Equivalence of potential–driven and correlational drivers (typed))**.** *For Gaiamiti types $[\chi] \in \{\mathrm{Tr}, \mathrm{TT}\}$ (and helicity refinements when applicable), the typed SynTh meters $\mathbf{V}^{[\Phi\Phi,\chi]}(\ell;\mathfrak{P})$ built from the potential–based operators of Definition 9.221 are, on a certified plateau, equivalent (within Chapter 8 tolerances) to those obtained from the usual correlational channel (Π_{corr}) used in §9.16.2. Consequently, the canonical predicate $\mathrm{Quad}^{[\Phi\Phi,\chi]}$ (Definition 9.189) and the NG/pNG semantics (Proposition 9.197) agree for both constructions.*

Sketch. On the diagnostic realized reference configuration, the (typed) curvature $\mathcal{K}^{[\chi]}_{\Phi\Phi}$ is the zero–momentum limit of the 1PI two–point kernel $\Gamma^{(2)}$ restricted by $\Pi^{[\chi]}_{\Phi\Phi}$. By standard effective action relations, $\Gamma^{(2)}$ is the inverse (in the appropriate sense) of the retarded correlator kernel used in the correlational channel; zeros of $\Gamma^{(2)}$ correspond to poles of the correlator, and small explicit masses map to pNG GMOR slopes. Typed insertion preserves this correspondence by triadic compatibility and cone preservation (Definition 9.186 and Proposition 9.202), while diagnostic realized reference configuration aggregation ensures numerical agreement within tolerances (Definition 9.210). Gauge/Nielsen safety follows from Propositions 9.191 and 9.207. Thus the resulting meters and healing indicators (and hence the quadrant) coincide up to $\mathcal{O}(\varepsilon_{\mathfrak{P}})$. □

Corollary 9.224 (Potential–first recipe for the typed quadrant (Gaiamiti))**.** *To assign $\mathrm{Quad}^{[\Phi\Phi,\chi]}$ using the explicit potential of §9.17:*

(i) Fix the diagnostic realized reference configuration and type (Definitions 9.185 and 9.200); compute $\varphi^{[\chi]}$ and $\mathcal{K}^{[\chi]}_{\Phi\Phi}$ (Definition 9.220).

(ii) Build the potential–based SynTh operators and the typed witness (Definitions 9.187 and 9.221); obtain the diagnostic realized reference configuration meters $\mathbf{V}^{[\Phi\Phi,\chi]}$ (Definition 9.205) and healing indicators (Definition 9.188).

(iii) Apply the canonical predicate (Definition 9.189); NG/pNG semantics then follow from Proposition 9.197.

(iv) Stamp T–L–O on the same diagnostic realized reference configuration and update the ledger (Definitions 9.190, 9.198 and 9.216 and Corollary 9.218).

By Proposition 9.223, this potential–first route yields the same typed quadrant as the correlational route in §9.16.2.

Remark 9.225 (Gaiamiti: salient quadrants and their semantics)**.** For the Gaiamiti sector $S = \Phi\Phi$ (types from Definitions 9.195 and 9.200), evaluated on the diagnostic realized reference

configuration (Definition 9.185) and assigned via the canonical predicate (Definition 9.189), the operationally relevant quadrants are:

- **TT (spin–2):** $\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII}$ in the canonical (law–symmetric, state–selecting) case. This yields an NG pole in the correlational typed channel $\Pi_{\mathrm{corr}}\Pi_{\Phi\Phi}^{[\mathrm{TT}]}$ (Proposition 9.197). The decision may be computed equivalently from the potential via the typed curvature/order parameter (Definitions 9.220 and 9.221 and Proposition 9.223). After stamping T–L–O (Definition 9.190) and recording the ledger row (Definition 9.198 and Corollary 9.194), the TT mode may be *named* "graviton" (Corollary 9.199).
- **TT with explicit breaking:** $\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QIV}$ iff the typed law source persists ($\mathscr{H}_L^{[\Phi\Phi,\mathrm{TT}]} > 0$; Definition 9.188); then the typed channel shows a pNG band with GMOR slope on $\mathfrak{P}$ (Proposition 9.197).
- **Tr (spin–0):** generically $\mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI}$ with a gapped radial (Apeiron) mass read from the typed curvature; no NG/pNG in this typed channel (cf. Proposition 9.197).
- **QIII (explicit, healing):** may occur at finite scale if a typed law source is present but heals in the IR ($\mathscr{H}_L^{[\Phi\Phi,\chi]} = 0$); it is recorded via T–L–O (Definition 9.190) but is not the asymptotic (IR) regime.

Boundary diagnostic realized reference configuration $\mathfrak{P}_\partial$ use the same predicate; differences show up only in the *Loc/On* fields of the ledger (bulk vs. boundary onset), not in the spin/type semantics (Definitions 9.190 and 9.198).

Standing assumption (SSB–only regime for Gaiamiti). Throughout this subsection we assume a law–symmetric diagnostic realized reference configuration (no explicit symmetry–breaking spurions in the typed TT channel) and certified plateau control as in Definition 9.185. Typed meters and the quadrant are fixed *first* via Definitions 9.187 to 9.189 and 9.205, and the ledger row is populated per Definition 9.198 and Corollary 9.194. In particular, we work with the potential–driven drivers $\varphi^{[\chi]}, \mathcal{K}_{\Phi\Phi}^{[\chi]}$ (Definitions 9.220 and 9.221) or, equivalently, the correlational route (Proposition 9.223).

Proposition 9.226 (Consistency of the SSB–only treatment)**.** *Under Section 9.17, the Gaiamiti SSB subsection is consistent iff the typed quadrants satisfy*

$$\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII}, \qquad \mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI},$$

(with optional helicity refinement for TT when available), and the typed healing indicators obey $\mathscr{H}_L^{[\Phi\Phi,\mathrm{TT}]} = \mathscr{H}_S^{[\Phi\Phi,\mathrm{TT}]} = 0$, $\mathscr{H}_L^{[\Phi\Phi,\mathrm{Tr}]} = \mathscr{H}_S^{[\Phi\Phi,\mathrm{Tr}]} = 0$. *In this case the TT channel exhibits an NG pole and the Tr channel remains gapped; boundary diagnostic realized reference configuration alter only* Loc/On *in the ledger, not the spin/type semantics.*

Proof. By the canonical typed predicate Definition 9.189, SSB corresponds to QII: law–symmetric with state selection and asymptotic healing. Thus $\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII}$ is equivalent to $\mathscr{H}_L^{[\Phi\Phi,\mathrm{TT}]} = \mathscr{H}_S^{[\Phi\Phi,\mathrm{TT}]} = 0$ plus the TT NG residue in $\Pi_{\mathrm{corr}}\Pi_{\Phi\Phi}^{[\mathrm{TT}]}$ (Proposition 9.197). For the trace channel, the SSB–only regime (no explicit breaking, no state selection) gives $\mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI}$ with positive typed curvature $\mathcal{K}_{\Phi\Phi}^{[\mathrm{Tr}]}$ (gapped radial), consistent with Proposition 9.197. Potential– and correlator–driven meters are equivalent on a certified plateau by

Proposition 9.223, and gauge/Nielsen safety follows from Proposition 9.191 with channel/type compatibility Proposition 9.207. Boundary overlays (if used) affect only the T–L–O stamp (Definition 9.190 and Corollary 9.218) and do not change the typed quadrant provided the same diagnostic realized reference configuration discipline is maintained. Hence the subsection's SSB claims are consistent exactly under the stated quadrant conditions. □

Remark 9.227 (What is excluded by the SSB–only restriction)**.** Cases with persistent typed law sources (QIV) or finite–scale sources that heal (QIII) in the TT channel are *not* part of the SSB–only narrative and should be deferred to the explicit–breaking analysis. Detecting these is automatic in the workflow via $\mathscr{H}_L^{[S,\chi]}$ and the predicate of Definition 9.189.

While the kinetic term in the action governs the propagation of the Gaiamiti field, the *potential term*, $\mathcal{V}_\Phi(\hat{\mathbf{\Phi}})$, dictates its self-interaction and determines the energetically preferred ground state structure of the emergent geometry. It is the source of the vacuum's intrinsic stability and the mechanism by which the fundamental quantum of geometry—the Apeiron—acquires its properties and gives rise to gravitational excitations.

Invariant Construction of the Gaiamiti Potential

It is both necessary and illuminating to demonstrate how the specific form of the Gaiamiti potential—as given in eq. (9.95)—arises naturally from the representation theory, invariance principles, and the functional role of the Gaiamiti field $\hat{\mathbf{\Phi}}(x)$ within the theory. We shall now construct this expression from these first principles.

1. The Fundamental Invariant of the Gaiamiti Field

The Gaiamiti field is an operator–valued vector field

$$\hat{\mathbf{\Phi}}(x) \;\in\; T_{|\Omega(x)\rangle}\mathcal{M}_{\text{vac}} \quad \text{for each locus } x,$$

i.e., a section of the vacuum–tangent bundle determined by the Gaiamiti sector (Definition 6.118). The fibrewise inner product on the vacuum–tangent space,

$$g_T(|V\rangle, |W\rangle) \;:=\; \langle V|W\rangle_{\mathcal{H}_{\text{em}}},$$

is induced from the ambient emergent Hilbert space and is positive–definite on the tangent fibre (Definition 6.104). Any admissible potential energy density $\mathcal{V}_\Phi(x)$ must be a Hermitian scalar operator constructed from $\hat{\mathbf{\Phi}}(x)$ and invariant under the symmetries of the theory (base diffeomorphisms compatible with the Relational Levi–Civita structure and unitary gauge on the operator bundle; cf. Definition 6.7, Section 6.5.3, and eq. (6.257)).

Definition 9.228 (Gaiamiti tangent norm and fundamental invariant)**.** The *fundamental invariant* of the Gaiamiti field is the fibrewise scalar operator

$$\mathcal{I}_\Phi(x) \;:=\; g_T\Big(\hat{\mathbf{\Phi}}(x),\, \hat{\mathbf{\Phi}}(x)\Big)\,. \tag{9.91}$$

This is the canonical (norm–squared) quadratic invariant available because $\hat{\mathbf{\Phi}}(x)$ takes values in a tangent space. It is the precise analogue of $|\phi|^2$ for a complex scalar field, with g_T replacing the flat inner product.

Lemma 9.229 (Hermiticity, positivity, and scalar character)**.** *For each x, the operator $\mathcal{I}_\Phi(x)$ is Hermitian and positive, with $\mathcal{I}_\Phi(x) \geq 0$ and $\mathcal{I}_\Phi(x) = 0$ iff $\hat{\mathbf{\Phi}}(x)$ is the zero section of the vacuum–tangent bundle. Moreover, $\mathcal{I}_\Phi(x)$ transforms as a scalar under base diffeomorphisms compatible with the Relational Levi–Civita connection and is invariant under unitary frame changes in the operator bundle.*

Proof sketch. Hermiticity and positivity follow from $g_T(\cdot,\cdot)$ being the restriction of the ambient inner product (Definition 6.104). Unitary changes of fibre frame act by $|V\rangle \mapsto U(x)|V\rangle$ with $U(x)$ unitary, hence $g_T(U\hat{\mathbf{\Phi}}, U\hat{\mathbf{\Phi}}) = g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$. Compatibility of the Relational Levi–Civita connection with the unified chronogeometric tensor implies scalar behaviour under base diffeomorphisms (Definition 6.7). □

Definition 9.230 (Admissible Gaiamiti potential density)**.** An admissible Gaiamiti potential energy density is any Hermitian operator of the form

$$\mathcal{V}_\Phi(x) \;=\; F\Big(\mathcal{I}_\Phi(x)\Big)\,, \qquad \mathcal{I}_\Phi(x) = g_T\Big(\hat{\mathbf{\Phi}}(x), \hat{\mathbf{\Phi}}(x)\Big)\,, \tag{9.92}$$

for some real functional F chosen to ensure spectral/variational well–posedness on the operative band. In particular, a polynomial ansatz

$$\mathcal{V}_\Phi(x) \;=\; \frac{m_\Phi^2}{2}\,\mathcal{I}_\Phi(x) \;+\; \frac{\lambda_\Phi}{4}\,\mathcal{I}_\Phi(x)^2 \;+\; \sum_{k\geq 3} \frac{c_k}{k!}\,\mathcal{I}_\Phi(x)^{\,k} \tag{9.93}$$

(with real couplings $m_\Phi^2, \lambda_\Phi, c_k$) is admissible whenever F renders the Hamiltonian bounded below and compatible with the band–limited calculus used in Chapter VI (Section 6.5.3 and eq. (6.259)).

Remark 9.231 (From density to scalar action via the invariant volume)**.** The potential contributes to the (wordwise or standard) action once integrated against the invariant volume element. In the HS formulation,

$$d\boldsymbol{\mu}(x) = d^d x\, \boldsymbol{\varpi}(x), \qquad \boldsymbol{\varpi}(x) = \Big(\det{}_{\mathrm{HS}}\Big(-\boldsymbol{g}^{\mathrm{Lor}}(x)\Big)\Big)^{1/2} \quad (\textit{Definition 6.34}),$$

with expectation reduction $\langle d\boldsymbol{\mu}\rangle = \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\, d^d x$ (Remark 6.35). The pure–potential contribution to the action is therefore

$$S_\Phi^{(\mathrm{pot})} \;=\; \int_{\mathcal{X}_q} d\boldsymbol{\mu}(x)\; \mathcal{V}_\Phi(x) \tag{9.94}$$

(and analogously in the standard expectation–level presentation).

Proposition 9.232 (Symmetry invariance of $\mathcal{V}_\Phi$)**.** *If $\mathcal{V}_\Phi(x) = F(\mathcal{I}_\Phi(x))$ as in Definition 9.230, then $\mathcal{V}_\Phi$ is:*

(i) a Hermitian operator at each x;

(ii) a scalar under base diffeomorphisms compatible with the Relational Levi–Civita connection (Definition 6.7);

(iii) invariant under unitary gauge transformations of the operator bundle (the bundle connection enters only through kinetic/covariant terms; cf. Section 6.5.3 and eqs. (6.257) and (6.259)).

Consequently, the action contribution (9.94) is fully gauge– and diffeo–invariant when paired with the invariant volume (Definition 6.34).

Proof sketch. Items (1)–(2) are immediate from Lemma 9.229. For (3), unitary bundle transformations act as fibre isometries on g_T, hence preserve $\mathcal{I}_\Phi$ and thus $F(\mathcal{I}_\Phi)$. The volume element is constructed to be invariant (HS) and reduces to the standard invariant measure under expectation (Definition 6.34 and Remark 6.35). □

Remark 9.233 (Holosymmetric wordwise counterpart)**.** All statements admit a holosymmetric–wordwise rewriting by replacing g_T with the HS inner product g_T^{HS} on the vacuum–tangent fibre:

$$\mathcal{I}_\Phi^{\mathrm{HS}}(x) \;:=\; g_T^{\mathrm{HS}}\Big(\hat{\mathbf{\Phi}}(x), \hat{\mathbf{\Phi}}(x)\Big)\,,$$

where g_T^{HS} is defined via the HS projector and coincides with the standard g_T at expectation level (Definition 6.106 and eq. (6.167)). Then $\mathcal{V}_\Phi(x) = F(\mathcal{I}_\Phi^{\mathrm{HS}}(x))$ and the action uses $d\boldsymbol{\mu}$ as above (Definition 6.34).

Corollary 9.234 (Stationarity and mass term)**.** *For a polynomial F with $F'(0) = \frac{m_\Phi^2}{2}$, the quadratic variation of $S_\Phi^{(\mathrm{pot})}$ around a vacuum configuration determines the Gaiamiti mass parameter m_Φ^2 in the potential sector, with higher coefficients λ_Φ, c_k controlling self–interaction strength; compatibility with the dynamical (kinetic/covariant) sector is governed by the Relational Levi–Civita principle (Definition 6.7) and the total derivative structure (Section 6.5.3 and eq. (6.259)).*

Summary. Because $\hat{\mathbf{\Phi}}(x)$ is a vacuum–tangent vector, the scalar operator

$$g_T\Big(\hat{\mathbf{\Phi}}(x), \hat{\mathbf{\Phi}}(x)\Big)$$

is the unique, canonical quadratic invariant (Definition 6.104). *All* admissible Gaiamiti potentials are functions of this invariant, $\mathcal{V}_\Phi = F(\mathcal{I}_\Phi)$, ensuring Hermiticity and invariance under the theory's symmetries, with integration performed against the invariant volume (Definition 6.34 and Remark 6.35).

2. Constraints of Stability and Symmetry

Any physically viable potential must satisfy two crucial constraints:

Stability: The potential must be bounded from below to ensure the existence of a stable vacuum state. This requires that for large field values, the potential approaches $+\infty$. This condition immediately disfavors odd powers of the field and requires that the highest-order term in any polynomial expansion have a positive coefficient.

Symmetry for Spontaneous Breaking: For symmetry to be broken *spontaneously* rather than explicitly, the Lagrangian itself must possess the symmetry. The simplest relevant symmetry is a $\mathbb{Z}_2$ invariance under which the field transforms as $\hat{\mathbf{\Phi}}(x) \mapsto -\hat{\mathbf{\Phi}}(x)$. The invariant $g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ respects this symmetry, as it is quadratic in the field. To preserve this symmetry, the potential must be an even function of $\hat{\mathbf{\Phi}}$, which means it must be a polynomial in powers of the invariant $g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$.

These two principles together demand that the potential must be a polynomial of the form $\mathcal{V}_\Phi = \sum_n c_n [g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})]^n$ with a positive leading coefficient c_n.

3. The Principle of Minimality and Universality

Among all possible polynomials, physical theories favor the simplest form capable of describing the required phenomena. This is guided by two related principles:

Renormalizability: In standard quantum field theory, only potentials with terms up to the fourth power of the field (quartic interactions) are renormalizable in four spacetime dimensions [82, 14]. Higher-order terms are suppressed at low energies. While the IQR framework may possess its own regularization scheme, the principle of selecting the lowest-order relevant terms remains a powerful guide.

Universality: The theory of critical phenomena shows that near a phase transition, a vast number of disparate physical systems are described by the same universal Landau-Ginzburg potential, which is a simple polynomial in the order parameter [101]. The minimal form that allows for a second-order phase transition (i.e., spontaneous symmetry breaking) is precisely the quadratic-plus-quartic form.

These principles compel us to select the lowest-order even polynomial in $\hat{\mathbf{\Phi}}$ that can support a non-trivial vacuum structure.

The Unique Minimal Potential

The confluence of these principles—invariance, stability, symmetry, and minimality—uniquely determines the form of the Gaiamiti potential. The simplest non-trivial, Hermitian, and symmetric potential constructed from the invariant $g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ is the operator-valued analogue of the classic ϕ^4 Higgs potential:

$$\mathcal{V}_\Phi(\hat{\mathbf{\Phi}}) = \frac{1}{2} m_A^2 \, g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}}) + \frac{\lambda_A}{4!} \left[g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}}) \right]^2$$

This expression therefore arises as the unique and necessary consequence of the foundational requirements for a consistent and stable theory of emergent geometry that supports spontaneous symmetry breaking.

The Gaiamiti Field Potential

Definition 9.235 (Gaiamiti Field Potential)**.** Let $\hat{\mathbf{\Phi}}(x) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}}) \otimes T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ be the operator-valued Gaiamiti field. The *potential energy operator density*, $\mathcal{V}_\Phi(\hat{\mathbf{\Phi}}(x))$, is a Hermitian

operator-valued function constructed from invariants in the tangent space:

$$\boxed{\mathcal{V}_\Phi(\hat{\mathbf{\Phi}}(x)) := \frac{1}{2}m_A^2\, g_T\left(\hat{\mathbf{\Phi}}(x), \hat{\mathbf{\Phi}}(x)\right) + \frac{\lambda_A}{4!}\left[g_T\left(\hat{\mathbf{\Phi}}(x), \hat{\mathbf{\Phi}}(x)\right)\right]^2 + \dots,} \tag{9.95}$$

where:

(i) g_T is the inner product on the tangent space $T_{|\Omega(x)\rangle}\mathcal{M}_{\text{vac}}$ (Definition 6.104).

(ii) m_A^2 is a parameter setting the mass scale of the fundamental Apeiron quantum.

(iii) λ_A is a dimensionless self-interaction coupling constant for the Apeiron field.

Physical Interpretation: From Potential to Graviton Emergence The physically relevant potential landscape is the classical, scalar-valued function $V_\Phi(x)$, obtained by taking the expectation value of the operator density in the Quantum Holo-State:

$$V_\Phi(x) := \langle \overset{\circ}{\mathbf{\Psi}} | \mathcal{V}_\Phi(\hat{\mathbf{\Phi}}(x)) | \overset{\circ}{\mathbf{\Psi}} \rangle. \tag{9.96}$$

The structure of this classical potential governs the fundamental properties of the emergent geometry. The minima of V_Φ, where $\frac{\delta V_\Phi}{\delta \hat{\mathbf{\Phi}}} = 0$, define the vacuum expectation value (VEV) of the field, $\bar{\Phi}(x)$, which corresponds to the stable, ground-state configuration of the geometry.

Holosymmetric Wordwise Gaiamiti Field Potential

We now dress the standard Gaiamiti potential of Section 9.17 in the *holosymmetric wordwise* (HS) formalism developed in Chapter VI, using the HS vacuum–tangent inner product (Definition 6.106 and eq. (6.167)) and the HS bundle/gauge structure (Sections 6.4.1 and 6.6.1). Chronogeometric compatibility is with the Relational Levi–Civita structure (Definition 6.7).

Definition 9.236 (HS fundamental invariant for the Gaiamiti field)**.** Let $\hat{\mathbf{\Phi}}(x) \in \mathrm{End}(\mathcal{H}_{\text{em}}) \otimes T_{|\Omega(x)\rangle}\mathcal{M}_{\text{vac}}$ (Definition 6.118). The holosymmetric fundamental invariant is the fibrewise scalar operator

$$\boxed{\mathcal{I}_\Phi^{\text{HS}}(x) \;:=\; g_T^{\text{HS}}\Big(\hat{\mathbf{\Phi}}(x),\, \hat{\mathbf{\Phi}}(x)\Big),} \tag{9.97}$$

where g_T^{HS} is the HS inner product on $T_{|\Omega\rangle}\mathcal{M}_{\text{vac}}$ (Definition 6.106). At expectation level, $\mathcal{I}_\Phi^{\text{HS}}$ reduces to $g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ (Definition 6.104).

Definition 9.237 (HS Gaiamiti potential operator density)**.** The *HS potential energy operator density* is any Hermitian function of $\mathcal{I}_\Phi^{\text{HS}}$:

$$\boxed{\mathcal{V}_\Phi^{\text{HS}}\Big(\hat{\mathbf{\Phi}}(x)\Big) \;:=\; \frac{1}{2}\, m_A^2\, \mathcal{I}_\Phi^{\text{HS}}(x) \;+\; \frac{\lambda_A}{4!}\left[\mathcal{I}_\Phi^{\text{HS}}(x)\right]^2 \;+\; \sum_{k\geq 3}\frac{c_k}{k!}\left[\mathcal{I}_\Phi^{\text{HS}}(x)\right]^k,} \tag{9.98}$$

with real couplings m_A^2, λ_A, c_k. For $m_A^2 \geq 0$ and $\lambda_A > 0$ (and c_k bounded appropriately), $\mathcal{V}_\Phi^{\text{HS}}$ is bounded below on the HS band. The pair (m_A^2, λ_A) coincides with the standard parameters in Definition 9.235.

Proposition 9.238 (HS gauge/frame invariance and diffeo covariance)**.** *Under HS modal frame changes $g(x) \in U(n)$ and vacuum–tangent rotations $R(x) \in O(r)$,*

$$\hat{\mathbf{\Phi}} \mapsto \hat{\mathbf{\Phi}}' = \Big(\mathrm{Ad}_g\, \hat{\mathbf{\Phi}}\Big) \cdot R, \qquad g_T^{\mathrm{HS}}(\mathrm{Ad}_g\, X \cdot R, \mathrm{Ad}_g\, Y \cdot R) = g_T^{\mathrm{HS}}(X, Y),$$

so $\mathcal{I}_\Phi^{\mathrm{HS}}$ and hence $\mathcal{V}_\Phi^{\mathrm{HS}}$ are invariant. Moreover, $\mathcal{V}_\Phi^{\mathrm{HS}}$ is a base scalar for diffeomorphisms compatible with $\nabla^{(\mathrm{rel})}$ (Definition 6.7).

Proof idea. g_T^{HS} is defined by the HS projector and is preserved by HS unitaries on the operator slot and orthogonal rotations on $T\mathcal{M}_{\mathrm{vac}}$ (Definition 6.106); hence $\mathcal{I}_\Phi^{\mathrm{HS}}$ is invariant and any functional of it is invariant. Because g_T^{HS} is a fibrewise pairing and carries no free base indices, $\mathcal{V}_\Phi^{\mathrm{HS}}$ is a base scalar; compatibility of $\nabla^{(\mathrm{rel})}$ with $\bar{\Sigma}$ ensures scalar behaviour under the allowed diffeomorphisms.

Holosymmetric wordwise proof. We show invariance under HS modal frame changes $g(x) \in U(n)$ and vacuum–tangent rotations $R(x) \in O(r)$, and then establish that $\mathcal{V}_\Phi^{\mathrm{HS}}$ is a base scalar for diffeomorphisms compatible with $\nabla^{(\mathrm{rel})}$.

Preliminaries and notation. Fix a g_T–orthonormal local frame $\{|e_i(x)\rangle\}_{i=1}^r$ of $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ with dual $\{\langle e^i(x)|\}$, so that $\hat{\mathbf{\Phi}} = \sum_i \hat{\Phi}^i\, |e_i\rangle$ with operator components $\hat{\Phi}^i \in \mathrm{End}(\mathcal{H}_{\mathrm{em}})$. A vacuum–tangent rotation $R(x) \in O(r)$ acts as $|e_i\rangle \mapsto |e'_i\rangle := R_i{}^j |e_j\rangle$, while an HS modal frame change $g(x) \in U(n)$ acts by the adjoint automorphism $\mathrm{Ad}_g(X) = gXg^\dagger$ on the operator slot. Accordingly,

$$\hat{\Phi}'^i \;=\; \mathrm{Ad}_g(\hat{\Phi}^j)\, R_j{}^i, \qquad \hat{\mathbf{\Phi}}' \;=\; \Big(\mathrm{Ad}_g\, \hat{\mathbf{\Phi}}\Big) \cdot R, \tag{9.99}$$

which is the component form of the transformation stated in the proposition.

Step 1: $O(r)$–invariance of g_T^{HS} on the tangent index. By Definition 6.106, g_T^{HS} is a fibrewise inner product on the vacuum–tangent space, hence in the orthonormal frame $g_T^{\mathrm{HS}}(|e_i\rangle, |e_j\rangle) = \delta_{ij}$. For two HS–tangent fields $\hat{\mathbf{X}} = \hat{X}^i |e_i\rangle$ and $\hat{\mathbf{Y}} = \hat{Y}^i |e_i\rangle$,

$$g_T^{\mathrm{HS}}(\hat{\mathbf{X}}, \hat{\mathbf{Y}}) \;=\; \sum_i g_T^{\mathrm{HS}}\Big(\hat{X}^i |e_i\rangle,\; \hat{Y}^i |e_i\rangle\Big) \;=\; \sum_i \mathsf{B}\Big(\hat{X}^i, \hat{Y}^i\Big),$$

where B denotes the operator–slot pairing induced by the HS construction (precise form immaterial here). Under a rotation $R \in O(r)$,

$$\begin{aligned} \hat{X}'^i &= \hat{X}^j R_j{}^i, & \hat{Y}'^i &= \hat{Y}^k R_k{}^i, \\ \sum_i \mathsf{B}(\hat{X}'^i, \hat{Y}'^i) &= \sum_{i,j,k} R_j{}^i R_k{}^i\, \mathsf{B}(\hat{X}^j, \hat{Y}^k) \\ &= \sum_j \mathsf{B}(\hat{X}^j, \hat{Y}^j). \end{aligned}$$

using orthogonality $R^T R = \mathbf{1}$. Thus g_T^{HS} is $O(r)$–invariant on the tangent index.

Step 2: $U(n)$–invariance of g_T^{HS} on the operator slot. By Definition 6.106, g_T^{HS} is defined via the HS projector and is preserved by HS unitaries on the operator slot; in particular, for all operator entries X, Y,

$$g_T^{\mathrm{HS}}(\mathrm{Ad}_g X, \mathrm{Ad}_g Y) \;=\; g_T^{\mathrm{HS}}(X, Y), \qquad g \in U(n). \tag{9.100}$$

This follows from unitarity of g and the fact that the HS pairing is built from unitary–invariant expressions on the operator fibre (e.g. Hilbert–Schmidt–type or FD–trace–reduced pairings in the HS construction).

Step 3: Invariance of the HS fundamental invariant and of the potential. Applying (9.99) and Steps 1–2 to the HS fundamental invariant $\mathcal{I}_\Phi^{\mathrm{HS}} = g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ (Definition 9.236),

$$\begin{aligned}
\mathcal{I}_\Phi^{\mathrm{HS}}[\hat{\mathbf{\Phi}}'] &= g_T^{\mathrm{HS}}\Big(\mathrm{Ad}_g\, \hat{\mathbf{\Phi}} R, \mathrm{Ad}_g\, \hat{\mathbf{\Phi}} R\Big) \\
&= \sum_i \mathsf{B}\Big(\mathrm{Ad}_g\, \hat{\Phi}^j R_j{}^i, \mathrm{Ad}_g\, \hat{\Phi}^k R_k{}^i\Big) \\
&= \sum_{j,k} (R^{\mathrm{T}} R)_{jk}\, \mathsf{B}\Big(\mathrm{Ad}_g\, \hat{\Phi}^j, \mathrm{Ad}_g\, \hat{\Phi}^k\Big) \\
&= \sum_j \mathsf{B}(\mathrm{Ad}_g\, \hat{\Phi}^j, \mathrm{Ad}_g\, \hat{\Phi}^j) \\
&= \sum_j \mathsf{B}(\hat{\Phi}^j, \hat{\Phi}^j) \\
&= \mathcal{I}_\Phi^{\mathrm{HS}}[\hat{\mathbf{\Phi}}].
\end{aligned}$$

where we used orthogonality $R^T R = \mathbf{1}$ and the isometry (9.100). Therefore $\mathcal{I}_\Phi^{\mathrm{HS}}$ is invariant under $U(n) \times O(r)$, and for any real functional F,

$$\mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}}) := F\Big(\mathcal{I}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}})\Big) \quad \text{obeys} \quad \mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}}') = \mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}}),$$

proving HS gauge/frame invariance (cf. Definition 9.237).

Step 4: Base–scalar behaviour under diffeomorphisms compatible with $\nabla^{(\mathrm{rel})}$. Let $\varphi : \mathcal{X}_q \to \mathcal{X}_q$ be a diffeomorphism and denote the induced pullback on sections by φ^*. Because g_T^{HS} is a *fibrewise* pairing with no free base indices and the Relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$ is compatible with $\bar{\Sigma}$ (Definition 6.7), the HS inner product is transported naturally:

$$\mathcal{I}_\Phi^{\mathrm{HS}}(\varphi^* \hat{\mathbf{\Phi}}) \;=\; \varphi^*\Big(\mathcal{I}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}})\Big),$$

i.e. $\mathcal{I}_\Phi^{\mathrm{HS}}$ is a *scalar function* on the base. Hence so is $\mathcal{V}_\Phi^{\mathrm{HS}} = F\Big(\mathcal{I}_\Phi^{\mathrm{HS}}\Big)$, establishing diffeo covariance in the sense stated:

$$\mathcal{V}_\Phi^{\mathrm{HS}}(\varphi^* \hat{\mathbf{\Phi}}) \;=\; \varphi^*\Big(\mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}})\Big).$$

Conclusion. Combining Steps 1–4, $\mathcal{I}_\Phi^{\mathrm{HS}}$ and therefore $\mathcal{V}_\Phi^{\mathrm{HS}}$ are invariant under HS modal frame changes $g \in U(n)$ and vacuum–tangent rotations $R \in O(r)$, and $\mathcal{V}_\Phi^{\mathrm{HS}}$ is a base scalar for diffeomorphisms compatible with $\nabla^{(\mathrm{rel})}$. This proves Proposition 9.238. □

Remark 9.239 (HS action contribution and reduction to standard)**.** The HS potential contributes to the action through the HS invariant volume $d\boldsymbol{\mu} = d^d x\, \boldsymbol{\varpi}$, $\boldsymbol{\varpi} = (\det_{\mathrm{HS}}(-\boldsymbol{g}^{\mathrm{Lor}}))^{1/2}$ (Definition 6.34):

$$\boxed{\widehat{\boldsymbol{S}}_{\Phi,\mathrm{pot}} := \int_{\mathcal{X}_q} d\boldsymbol{\mu}(x)\ \mathrm{Tr}_{\mathrm{FD}}\Big\{\mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}})\Big\},} \tag{9.101}$$

where $\mathrm{Tr}_{\mathrm{FD}}$ is the field–dialectic trace (Definition 6.45). Applying the expectation/volume push–throughs (Remark 6.35 and eq. (6.114)) yields the standard potential sector with $g_T^{\mathrm{HS}} \to g_T$ and $d\boldsymbol{\mu} \to \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\, d^d x$ (Section 9.17).

Lemma 9.240 (First variation and stationarity)**.** *Let $\delta\hat{\boldsymbol{\Phi}}$ be a compactly supported variation in the HS tangent fibre. Then*

$$\boxed{\delta\,\mathrm{Tr}_{\mathrm{FD}}\Big\{\mathcal{V}_\Phi^{\mathrm{HS}}\Big\} = \mathrm{Tr}_{\mathrm{FD}}\left\{\left(\tfrac{1}{2}\,m_A^2 + \tfrac{\lambda_A}{3!}\,\mathcal{I}_\Phi^{\mathrm{HS}} + \sum_{k\geq 3} \tfrac{c_k}{(k-1)!}\,[\mathcal{I}_\Phi^{\mathrm{HS}}]^{k-1}\right)\delta\Big(g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}})\Big)\right\}.} \tag{9.102}$$

Using bilinearity of g_T^{HS}, $\delta g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}}) = 2\,\mathrm{Re}\, g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\delta\hat{\boldsymbol{\Phi}})$, so the stationary condition contributes the fibrewise "mass+self–interaction" term proportional to $\hat{\boldsymbol{\Phi}}$ in the Euler–Lagrange equation.

Holosymmetric wordwise proof. By Definition 9.237, the HS Gaiamiti potential is a real functional of the HS invariant $\mathcal{I}_\Phi^{\mathrm{HS}} = g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}})$ (Definition 9.236 and eq. (9.97)), with polynomial presentation

$$\mathcal{V}_\Phi^{\mathrm{HS}} = \frac{1}{2}m_A^2\,\mathcal{I}_\Phi^{\mathrm{HS}} + \frac{\lambda_A}{4!}\,(\mathcal{I}_\Phi^{\mathrm{HS}})^2 + \sum_{k\geq 3}\frac{c_k}{k!}\,(\mathcal{I}_\Phi^{\mathrm{HS}})^k \quad (\text{cf. } eq.\ (9.98)).$$

Let $F(s) = \frac{1}{2}m_A^2 s + \frac{\lambda_A}{4!}s^2 + \sum_{k\geq 3}\frac{c_k}{k!}s^k$ so that $\mathcal{V}_\Phi^{\mathrm{HS}} = F(\mathcal{I}_\Phi^{\mathrm{HS}})$. Using linearity/cyclicity of the field–dialectic trace (Definition 6.45 and eq. (6.99)) and the chain rule in the strong–operator topology (cf. Remark 6.187), we obtain

$$\delta\,\mathrm{Tr}_{\mathrm{FD}}\{\mathcal{V}_\Phi^{\mathrm{HS}}\} = \mathrm{Tr}_{\mathrm{FD}}\Big\{F'(\mathcal{I}_\Phi^{\mathrm{HS}})\,\delta\mathcal{I}_\Phi^{\mathrm{HS}}\Big\}, \qquad F'(s) = \tfrac{1}{2}m_A^2 + \tfrac{\lambda_A}{3!}\,s + \sum_{k\geq 3}\tfrac{c_k}{(k-1)!}\,s^{k-1}. \tag{9.103}$$

It remains to compute $\delta\mathcal{I}_\Phi^{\mathrm{HS}}$. By definition (Definition 9.236),

$$\mathcal{I}_\Phi^{\mathrm{HS}} = g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}}),$$

and since g_T^{HS} is a Hermitian fibrewise inner product on the HS vacuum–tangent space (Definition 6.106 and eq. (6.167)), its bilinearity yields

$$\delta\mathcal{I}_\Phi^{\mathrm{HS}} = \delta g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}}) = g_T^{\mathrm{HS}}(\delta\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}}) + g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\delta\hat{\boldsymbol{\Phi}}) = 2\,\mathrm{Re}\, g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\delta\hat{\boldsymbol{\Phi}}). \tag{9.104}$$

Substituting (9.104) into (9.103) gives exactly the boxed identity (9.102):

$$\delta\,\mathrm{Tr}_{\mathrm{FD}}\Big\{\mathcal{V}_\Phi^{\mathrm{HS}}\Big\} = \mathrm{Tr}_{\mathrm{FD}}\left\{\left(\tfrac{1}{2}\,m_A^2 + \tfrac{\lambda_A}{3!}\,\mathcal{I}_\Phi^{\mathrm{HS}} + \sum_{k\geq 3}\tfrac{c_k}{(k-1)!}\,[\mathcal{I}_\Phi^{\mathrm{HS}}]^{k-1}\right)\delta\Big(g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}},\hat{\mathbf{\Phi}})\Big)\right\}.$$

Because $\delta\hat{\mathbf{\Phi}}$ is compactly supported in the HS tangent fibre, no boundary terms arise (the potential has no derivatives). Inserting (9.104) into the variation of the full HS action for the Gaiamiti field (cf. the HS action template and volume element in Section 6.5.2 and Definition 6.34) shows that the potential contributes the fibrewise *mass+ self–interaction* term proportional to $\hat{\mathbf{\Phi}}$ in the Euler–Lagrange equation, as claimed. □

Corollary 9.241 (Boundedness and vacuum types)**.** *If $\lambda_A > 0$ and all higher c_k obey the usual positivity bounds, then $\mathcal{V}_\Phi^{\mathrm{HS}}$ is bounded below. For $m_A^2 > 0$ the symmetric vacuum $\hat{\mathbf{\Phi}} = 0$ is stationary; for $m_A^2 < 0$ a "Mexican-hat" structure arises in the HS tangent norm $\mathcal{I}_\Phi^{\mathrm{HS}}$, with symmetry breaking analyzed via the HS vacuum manifold of Chapter 6 (Section 6.1.9).*

Proof. Let $s(x) := \mathcal{I}_\Phi^{\mathrm{HS}}(x) = g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}}(x),\hat{\mathbf{\Phi}}(x)) \geq 0$ by positivity of the HS vacuum–tangent inner product (Definition 6.106 and eq. (6.167)). By Definition 9.237, the HS potential is the polynomial functional

$$\mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}}) \;=\; F(s) \quad \text{with} \quad F(s) = \tfrac{1}{2}m_A^2 s + \tfrac{\lambda_A}{4!}s^2 + \sum_{k\geq 3}\tfrac{c_k}{k!}\,s^k \qquad (s \geq 0). \tag{9.105}$$

(i) Boundedness from below. Assume $\lambda_A > 0$ and that the "usual positivity bounds" on higher couplings hold (e.g. $c_k \geq 0$ for all even $k \geq 4$ and any odd-power contributions are chosen so that $F(s) \to +\infty$ as $s \to \infty$).[6] Then F is coercive on $[0,\infty)$:

$$\lim_{s\to\infty} F(s) = +\infty.$$

Since F is continuous on the closed ray $[0,\infty)$, it attains a global minimum $F(s_\star)$ with $s_\star \geq 0$. Hence $\mathcal{V}_\Phi^{\mathrm{HS}} = F(\mathcal{I}_\Phi^{\mathrm{HS}})$ is bounded below on field configurations, proving the first claim.

(ii) Stationarity and vacuum type for $m_A^2 > 0$. By Lemma 9.240, the first variation of the potential sector is

$$\delta\,\mathrm{Tr}_{\mathrm{FD}}\{\mathcal{V}_\Phi^{\mathrm{HS}}\} = \mathrm{Tr}_{\mathrm{FD}}\Big\{F'(s)\,\delta s\Big\}, \qquad F'(s) = \tfrac{1}{2}m_A^2 + \tfrac{\lambda_A}{3!}s + \sum_{k\geq 3}\tfrac{c_k}{(k-1)!}s^{k-1},$$

with $\delta s = \delta g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}},\hat{\mathbf{\Phi}}) = 2\,\mathrm{Re}\,g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}},\delta\hat{\mathbf{\Phi}})$ (Lemma 9.240). At $\hat{\mathbf{\Phi}} = 0$ one has $s = 0$ and $\delta s = 0$, so $\hat{\mathbf{\Phi}} = 0$ is always a stationary point. To classify it, consider the second variation at $\hat{\mathbf{\Phi}} = 0$:

$$\delta^2\mathrm{Tr}_{\mathrm{FD}}\{\mathcal{V}_\Phi^{\mathrm{HS}}\}\Big|_{\hat{\mathbf{\Phi}}=0} = m_A^2\;\mathrm{Tr}_{\mathrm{FD}}\Big\{\,g_T^{\mathrm{HS}}(\delta\hat{\mathbf{\Phi}},\delta\hat{\mathbf{\Phi}})\Big\}.$$

If $m_A^2 > 0$, positivity of g_T^{HS} implies $\delta^2 \geq 0$ with equality only for $\delta\hat{\mathbf{\Phi}} = 0$, so $\hat{\mathbf{\Phi}} = 0$ is a (strict) local minimum of the potential sector. Hence the *symmetric vacuum* is stationary (and, by coercivity, globally minimizing for sufficiently small higher couplings).

[6] These are the standard coercivity conditions for polynomial potentials on $[0,\infty)$ ensuring that the highest even-order coefficient is positive and dominates at large s.

(iii) "Mexican-hat" structure and symmetry breaking for $m_A^2 < 0$. If $m_A^2 < 0$ while $\lambda_A > 0$ (and higher terms obey the positivity bounds above), then F has a local maximum at $s = 0$ and, by coercivity, admits a nonzero minimizing radius $s_\star > 0$ solving $F'(s_\star) = 0$ with $F''(s_\star) > 0$:

$$\tfrac{1}{2}m_A^2 + \tfrac{\lambda_A}{3!}\, s_\star + \sum_{k\geq 3} \tfrac{c_k}{(k-1)!}\, s_\star^{k-1} = 0, \qquad F''(s_\star) = \tfrac{\lambda_A}{3!} + \sum_{k\geq 3} \tfrac{c_k}{(k-2)!}\, s_\star^{k-2} > 0. \tag{9.106}$$

In the quartic truncation ($c_k = 0$ for $k \geq 3$) this gives the familiar closed form $s_\star = \frac{3!}{2}\,\frac{|m_A^2|}{\lambda_A} > 0$. Since $\mathcal{V}_\Phi^{\mathrm{HS}}$ depends only on $s = g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ (Definitions 9.236 and 9.237) and is invariant under the HS gauge/frame group $U(n) \times O(r)$ (Proposition 9.238), the set of minimizers is the HS orbit at fixed radius $s_\star$:

$$\mathcal{M}_{\mathrm{vac}}^{(\mathrm{HS})} \;\cong\; \Big\{\hat{\mathbf{\Phi}} : g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}}) = s_\star\Big\}/\Big(U(n) \times O(r)\Big),$$

i.e. a *Mexican-hat* degeneracy in the HS tangent norm. The associated symmetry breaking pattern and the ground-state selection are analyzed by the HS vacuum–manifold machinery of Chapter VI (Section 6.1.9), where the minimizing shell is encoded by the ground spectral projector on the HS vacuum manifold.

Conclusion. Under the stated positivity hypotheses, $\mathcal{V}_\Phi^{\mathrm{HS}}$ is bounded below; the symmetric vacuum $\hat{\mathbf{\Phi}} = 0$ is stationary and locally minimizing for $m_A^2 > 0$, while for $m_A^2 < 0$ the minimum occurs at nonzero HS radius $s_\star > 0$ with the usual Mexican-hat degeneracy in g_T^{HS}, completing the proof. □

Summary. The holosymmetric wordwise machinery replaces the standard invariant $g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ with its HS counterpart $g_T^{\mathrm{HS}}(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ (Definition 6.106), builds the HS potential as a function of the scalar operator $\mathcal{I}_\Phi^{\mathrm{HS}}$ (9.97) via (9.98), proves gauge/frame invariance (Proposition 9.238), and integrates it with the HS measure (Definition 6.34) to contribute to the HS action (9.101), reducing to the standard form under the expectation push–through (Remark 6.35).

The excitations of the Gaiamiti field around this vacuum are what we observe as gravitational phenomena. This framework leads to a crucial distinction:

Definition 9.242 (Apeiron (trace, spin-0) and its intrinsic scale)**.** Work on the diagnostic realized reference configuration (Definition 9.185) in the Gaiamiti sector $S = \Phi\Phi$ with the trace type $[\chi] = \mathrm{Tr}$ (Definitions 9.195 and 9.200). Let $\mathcal{U}_{\Phi\Phi}$ be the potential of §9.17 and write its typed curvature (Hessian) at the certified background $\bar{\Phi}$ as $\mathcal{K}_{\Phi\Phi}^{[\mathrm{Tr}]}$ (Definition 9.220). Define the *Apeiron* to be the fundamental trace excitation and set its intrinsic scale $m_A > 0$ by the plateau identification

$$m_A^2 \;\equiv\; \mathrm{eig}_{\min}\Big(\mathcal{K}_{\Phi\Phi}^{[\mathrm{Tr}]}\Big) \quad \text{on the typed subspace.}$$

Then m_A is interpreted *not* as a matter mass but as the *geometric inertia / energy scale* of the Apeiron field: it fixes the characteristic interaction (correlation) length $\xi_A \sim m_A^{-1}$ for trace-type geometric fluctuations. Operationally this is the typed channel $(S, [\chi]) = (\Phi\Phi, \mathrm{Tr})$ in quadrant QI (law-symmetric, no state selection; Definition 9.189), with no NG/pNG content in this channel (Proposition 9.197). After stamping $\big(\mathrm{Loc}^{[\Phi\Phi,\mathrm{Tr}]}, \mathrm{On}^{[\Phi\Phi,\mathrm{Tr}]}\big)$ (Definition 9.190), the ledger row $\mathbf{L}^{[\Phi\Phi,\mathrm{Tr}]}$ is recorded (Definition 9.198 and Corollaries 9.194 and 9.218).

Proposition 9.243 (Graviton as the massless TT Goldstone in SSB)**.** *Consider the TT type* $[\chi] = \mathrm{TT}$ *(with optional helicities* $\lambda = \pm 2$ *when available; Definitions 9.195 and 9.200). Assume a law-symmetric, state-selecting diagnostic realized reference configuration (SSB-only regime) so that the typed order parameter* $\varphi^{[\mathrm{TT}]}$ *can align on a vacuum manifold* $\mathcal{M}_{\mathrm{vac}}$ *with continuous symmetry (§9.17). Then the typed quadrant is*

$$\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII},$$

and the correlational typed channel $\Pi_{\mathrm{corr}}\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$ *exhibits an* exact *NG pole on* H^0 *with positive residue (Definition 9.189 and Proposition 9.197). Equivalently, in the potential route,* $\mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi}$ *has a null direction tangent to* $\mathcal{M}_{\mathrm{vac}}$ *while the law source heals (Definitions 9.188 and 9.220 and Proposition 9.223). Hence the* graviton *is* not *the Apeiron: it is the massless spin-2 Goldstone excitation in the TT typed channel (cf. [93, 94]; see also Corollary 9.199 for naming after ledger population).*

Remark 9.244 (Separation of roles and operational workflow)**.** The Apeiron (trace, spin-0) carries the intrinsic geometric scale m_A and is typically QI (gapped radial), while the graviton (TT, spin-2) appears as the QII NG mode in the SSB-only regime. Both statements are decided *operationally* via the typed meters and healing indicators on the same diagnostic realized reference configuration (Definitions 9.187 to 9.189 and 9.205), and are then stamped with T–L–O and recorded in $\mathbf{L}^{[S,\chi]}$ (Definitions 9.190 and 9.198 and Corollary 9.218). This framework maintains a massless carrier for the observable gravitational interaction (TT NG mode) while distinguishing it sharply from the field's intrinsic energy scale m_A (trace channel).

Therefore, the potential $\mathcal{V}_\Phi$ plays a dual role: it sets the intrinsic properties of the underlying Apeiron field while its symmetries and minima dictate the conditions under which massless gravitons emerge as the observable, long-range carriers of the gravitational force. This is analogous to how massless phonons arise as collective excitations in a solid lattice composed of massive atoms [458, 391]. Similar analogies have been drawn in emergent gravity frameworks, where graviton-like modes are viewed as emergent collective phenomena [459, 460]. Therefore, the Apeiron can possess an intrinsic energy scale (m_A) while its observable, long-range excitation—the graviton—remains massless, consistent with observation.

With the potential operator now specified, it is natural to record the associated symmetry–breaking structure explicitly. This clarifies which symmetry group is broken by a chosen vacuum, what the resulting vacuum manifold looks like, and how the Goldstone directions are realized. The following proposition formalizes this data in the Gaiamiti sector.

Proposition 9.245 (SSB data of the Gaiamiti sector (typed TT identification))**.** *Let the modal Hilbert bundle carry structure group* $G \subseteq \mathrm{U}(4)$ *with* $u(4)$ *connection* $\mathcal{A}$ *(Section 4.1.4). Let the Gaiamiti potential* $\mathcal{V}_\Phi$ *be built from the invariant* $g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$*. A realized vacuum* $\bar{\Phi}$ *spontaneously breaks* G *to its stabilizer* $H = \{\, g \in G \mid g \cdot \bar{\Phi} = \bar{\Phi} \,\}$ *with vacuum manifold* $\mathcal{M}_{\mathrm{vac}} \cong G/H$ *and Goldstone space* $T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}}$*.*

On the diagnostic realized reference configuration (Definition 9.185), in the typed TT channel $[\chi] = \mathrm{TT}$ *(Definitions 9.186, 9.195 and 9.200), assume the SSB-only regime so*

that $\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII}$ *(Definition 9.189). Then the graviton is identified as the TT-typed Goldstone deformation of the realized chronogeometry,*

$$\boxed{\delta\hat{g}^{[\mathrm{TT}]}_{\mu\nu} \;:=\; \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\Big[\;\delta\hat{g}_{\mu\nu}\Big(\delta\Phi_{\mathrm{tang}}\Big)\;\Big]} \quad \text{on } \mathcal{H}_{\mathrm{phys}},$$

where $\delta\Phi_{\mathrm{tang}} \in T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}}$ *and* $\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$ *is the BRST-closed, cone-preserving typed projector that commutes with the triadic channels (Definition 9.186 and Proposition 9.202). Equivalently, with a* $\bar{\Sigma}$*-admissible spatial direction, one may refine to helicities*

$$\boxed{\delta\hat{g}^{[\lambda]}_{\mu\nu} := \Pi^{[\lambda]}_{\Phi\Phi}\,\delta\hat{g}_{\mu\nu}\Big(\delta\Phi_{\mathrm{tang}}\Big), \quad \lambda = \pm 2}\,.$$

The correlational TT channel $\Pi_{\mathrm{corr}}\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$ *exhibits an exact NG pole on* H^0 *with positive residue (Proposition 9.197); the potential route yields the same decision via a null direction of the typed curvature* $\mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi}$ *(Definition 9.220 and Proposition 9.223). All statements are Nielsen-flat and BRST-safe (Propositions 9.191 and 9.207).*

9.17.1 The Apeiron as the Fundamental Quantum of Geometry

Definition 9.246 (Apeiron: typed formal definition and dynamics on H^0)**.** Work on the realized, diagnostic realized reference configuration (Definition 9.185) in the Gaiamiti sector $S = \Phi\Phi$. Let the dynamical field admit the background–fluctuation split (cf. eq. (10.87))

$$\hat{\mathbf{\Phi}}(x) = \bar{\Phi}(x)\,\mathbb{I}_x + \delta\hat{\mathbf{\Phi}}(x), \qquad \bar{\Phi}(x) = \langle\hat{\mathbf{\Phi}}(x)\rangle \;\; (\text{Quantum Holo–State } |\mathring{\mathbf{\Psi}}\rangle;\; \textit{Definition } 1.27),$$

so that $\langle\delta\hat{\mathbf{\Phi}}(x)\rangle = 0$. Insert the BRST–closed, cone–preserving *trace* projector $\Pi^{[\mathrm{Tr}]}_{\Phi\Phi}$ (Definitions 9.186, 9.195 and 9.200) and define the *Apeiron fluctuation*

$$\delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}(x) := \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\,\delta\hat{\mathbf{\Phi}}(x) \;\in\; \mathrm{Ran}\,\Pi^{[\mathrm{Tr}]}_{\Phi\Phi} \subset \mathcal{H}_{\mathrm{phys}}.$$

The **Apeiron** is the fundamental, operator–valued quantum of the trace–typed fluctuation $\delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}$.

Dynamics. Linearizing the Euler–Lagrange equations from the Gaiamiti action (cf. §6.5) and projecting to the trace type yields the covariant, operator–valued Klein–Gordon form (cf. eq. (10.126))

$$\Big(\bar{\nabla}^{\mu}\bar{\nabla}_{\mu} - \mathcal{M}_{[\mathrm{Tr}]}(x)\Big)\,\delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}(x) = 0,$$

where $\bar{\nabla}$ is the Levi–Civita derivative of $\bar{\Sigma}_{\mu\nu}$ (Definition 6.7) and

$$\mathcal{M}_{[\mathrm{Tr}]}(x) := \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\;\frac{\delta^2\mathcal{V}_{\Phi}}{\delta\hat{\mathbf{\Phi}}^{\dagger}\,\delta\hat{\mathbf{\Phi}}}\bigg|_{\hat{\mathbf{\Phi}}=\bar{\Phi}(x)}\;\Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\,,$$

where this defines the typed effective mass operator (cf. eq. (10.125)). with $\mathcal{V}_{\Phi}$ the Gaiamiti potential (Definition 9.235).

Intrinsic scale. If $\mathcal{V}_\Phi \supset \frac{1}{2} m_A^2\, g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$ (§9.17), identify the *intrinsic energy scale / geometric inertia*

$$m_A^2 \;\equiv\; \mathrm{eig}_{\min}\Big(\mathcal{K}_{\Phi\Phi}^{[\mathrm{Tr}]}\Big), \qquad \mathcal{K}_{\Phi\Phi}^{[\mathrm{Tr}]} := \Pi_{\Phi\Phi}^{[\mathrm{Tr}]}\, \frac{\delta^2 \mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}\,\delta\hat{\mathbf{\Phi}}}\bigg|_{\bar{\Phi}}\, \Pi_{\Phi\Phi}^{[\mathrm{Tr}]},$$

so that the characteristic interaction (correlation) length of trace–typed geometric fluctuations is $\xi_A \sim m_A^{-1}$ (Definition 9.220).

Quadrant and ledger. On a law–symmetric diagnostic realized reference configuration the Apeiron sits in the $[\chi] = \mathrm{Tr}$ typed channel with $\mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI}$ (no NG/pNG in this channel; Definition 9.189 and Proposition 9.197). After stamping $(\mathrm{Loc}^{[\Phi\Phi,\mathrm{Tr}]}, \mathrm{On}^{[\Phi\Phi,\mathrm{Tr}]})$ (Definition 9.190), record the ledger row $\mathbf{L}^{[\Phi\Phi,\mathrm{Tr}]}$ (Definition 9.198 and Corollaries 9.194 and 9.218).

Separation from the graviton. The long–range gravitational carrier is *not* the Apeiron. It is the massless spin–2 Goldstone excitation in the TT typed channel under SSB, operationally identified by the TT projector and the typed QII predicate (Propositions 9.197 and 9.243 and Definition 9.189).

Remark 9.247 (Physical vs. pre-physical Apeiron)**.** Definitions and results in §9.17.1 are taken on the realized, diagnostic realized reference configuration (Definition 9.185), after plateau certification and projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$. Accordingly, the *Apeiron* here is the $[\chi] = \mathrm{Tr}$ typed fluctuation evaluated on H^0, with meters, quadrant, and T–L–O recorded in the ledger (Definitions 9.190 and 9.198 and Corollary 9.218).

By contrast, the sub-Planckian (pre-physical) "Apeiron" in the pre-physics arena is merely an operator-level trace fluctuation: diagnostics may be performed, but no plateau certification and no projection to H^0 are permitted (*cf.* PQS–anchored scale principle and *No realization below the Planck scale*, Definition 9.1 and Lemma 9.3). We may write

$$\begin{aligned} \text{Pre-physical:} \quad & \delta\hat{\mathbf{\Phi}}_{\mathrm{pre}}^{[\mathrm{Tr}]} \quad (\text{operator for } \ell < \ell_P;\ \text{diagnostics only}) \\ \text{Physical:} \quad & \delta\hat{\mathbf{\Phi}}_{\mathrm{phys}}^{[\mathrm{Tr}]} := \Pi_{\Phi\Phi}^{[\mathrm{Tr}]}\, \delta\hat{\mathbf{\Phi}}\,\big|_{H^0,\,\mathfrak{P}} \end{aligned}$$

(physical typed fluctuation on H^0, $\ell \geq \ell_P$). Only the latter admits SynTh meters, quadrant assignment, and SSB semantics (Definitions 9.187 and 9.189 and Proposition 9.197).

Remark 9.248 (Philosophical Provenance of the Apeiron)**.** The name *Apeiron* is drawn from Anaximander's cosmology (ἄπειρον): the boundless, formless, and indefinite substratum of reality, from which order emerges through the action of delimiting principles (*peras*) [69, 70]. This reflects the Apeiron's role as the primordial excitation of geometric potential, prior to metricity, form, or localization.

Derivation of the Mass Operator $\mathcal{M}(x)$

Setup and conventions. Work on a certified plateau $\mathfrak{P}$ with BRST projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ and band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$. The Gaiamiti potential $\mathcal{V}_\Phi$ enters the Lagrangian density

$$\mathcal{L}_\Phi(x) = \mathrm{Tr}\Big\{\bar{\Sigma}^{\mu\nu}(x)\, g_T\Big(\nabla_\mu\hat{\mathbf{\Phi}}(x),\, \nabla_\nu\hat{\mathbf{\Phi}}(x)\Big) + \mathcal{V}_\Phi\Big(\hat{\mathbf{\Phi}}(x)\Big)\Big\},$$

with $g_T : T\mathcal{M}_{\rm vac} \times T\mathcal{M}_{\rm vac} \to \mathrm{End}(\mathcal{H}_{\rm em})$, and $\hat{\mathbf{\Phi}}$ taking values in the vacuum tangent bundle $T\mathcal{M}_{\rm vac}$ (orthonormal bases from $T_{|\Omega\rangle}\mathcal{M}_{\rm vac}$ as needed).

The potential piece we use is (quadratic + quartic):

$$\boxed{\mathcal{V}_\Phi(\hat{\mathbf{\Phi}}) = \tfrac{1}{2}\, m_A^2\, g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}}) + \tfrac{\lambda_A}{4!}\left[g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})\right]^2 + \cdots}$$

Typed projection and EL split. Decompose fluctuations by the BRST-closed typed projectors in the $\Phi\Phi$ block,

$$\delta\hat{\mathbf{\Phi}} = \delta\hat{\mathbf{\Phi}}^{[\mathrm{TT}]} \oplus \delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}, \qquad \delta\hat{\mathbf{\Phi}}^{[\chi]} := \Pi^{[\chi]}_{\Phi\Phi}\, \delta\hat{\mathbf{\Phi}},$$

so that, on $\mathcal{H}_{\rm phys}$, the typed EL equations read

$$\underbrace{\left(\bar\nabla^\mu\bar\nabla_\mu - \mathcal{M}_{[\mathrm{Tr}]}(x)\right)\delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}(x) = 0}_{\text{trace/radial channel}}, \qquad \underbrace{\Pi^{[\mathrm{TT}]}_{\Phi\Phi}\,\mathcal{L}_{\mathrm{TT}}[\bar\Sigma]\Big(\delta\hat g(\delta\Phi_{\rm tang})\Big) = 0}_{\text{TT/Goldstone channel}},$$

with $\bar\nabla$ the Levi–Civita connection of $\bar\Sigma$. The typed mass operator $\mathcal{M}_{[\mathrm{Tr}]}$ is obtained from the potential Hessian at the background $\bar\Phi$.

Local orthonormal coordinates. Choose a g_T–orthonormal basis $\{|e_i\rangle\}$ of $T_{|\Omega(x)\rangle}\mathcal{M}_{\rm vac}$ and write

$$\hat{\mathbf{\Phi}} = \sum_i \hat\Phi^i\, |e_i\rangle, \qquad S := g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}}) = \sum_i (\hat\Phi^i)^\dagger \hat\Phi^i.$$

1. First variation w.r.t. $\hat{\mathbf{\Phi}}^\dagger$ (independent variables)

Treat $\hat{\mathbf{\Phi}}$ and $\hat{\mathbf{\Phi}}^\dagger$ as independent. Then

$$\frac{\delta\mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger} = \tfrac{1}{2}\, m_A^2\, \hat{\mathbf{\Phi}} + \frac{\lambda_A}{4!}\,(2S)\,\hat{\mathbf{\Phi}} = \boxed{\tfrac{1}{2}\, m_A^2\, \hat{\mathbf{\Phi}} + \tfrac{\lambda_A}{12}\, S\, \hat{\mathbf{\Phi}}}.$$

2. Mixed second variation (mass operator before typing)

Differentiate once more w.r.t. $\hat{\mathbf{\Phi}}$. Componentwise,

$$\frac{\delta^2\mathcal{V}_\Phi}{\delta\hat\Phi^{j\dagger}\,\delta\hat\Phi^k} = \tfrac{1}{2}\, m_A^2\, \delta_{jk} + \tfrac{\lambda_A}{12}\left(S\,\delta_{jk} + \hat\Phi^j\hat\Phi^{k\dagger}\right).$$

Equivalently, as an operator on the field space,

$$\boxed{\frac{\delta^2\mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger\,\delta\hat{\mathbf{\Phi}}} = \tfrac{1}{2}\, m_A^2\, \mathbb{I} + \tfrac{\lambda_A}{12}\Big(S\,\mathbb{I} + \hat{\mathbf{\Phi}}\otimes\hat{\mathbf{\Phi}}^\dagger\Big)}.$$

3. Typed projection and evaluation at the background

Define the *typed* mass operator by projection,

$$\boxed{\mathcal{M}_{[\mathrm{Tr}]}(x) := \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\, \frac{\delta^2 \mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger\, \delta\hat{\mathbf{\Phi}}}\bigg|_{\hat{\mathbf{\Phi}}=\bar{\Phi}(x)} \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}}.$$

Symmetric (unbroken) background $\bar{\Phi} = 0$. Here $S = 0$ and the rank-1 term drops out:

$$\boxed{\mathcal{M}_{[\mathrm{Tr}]}(x) = \tfrac{1}{2}\, m_A^2\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}}, \qquad (\bar{\Phi} = 0).$$

Generic background $\bar{\Phi} \neq 0$. One obtains

$$\boxed{\mathcal{M}_{[\mathrm{Tr}]}(x) = \tfrac{1}{2}\, m_A^2\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi} + \tfrac{\lambda_A}{12}\Big(\|\bar{\Phi}\|^2_{g_T}\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi} + \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\, \bar{\Phi} \otimes \bar{\Phi}^\dagger\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi} \Big)}.$$

Remark on the "curvature" (same-variable) Hessian and the intrinsic scale. For potential-driven diagnostics also use the same-variable (curvature) Hessian

$$\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi} := \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\, \frac{\delta^2 \mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}\, \delta\hat{\mathbf{\Phi}}}\bigg|_{\bar{\Phi}} \Pi^{[\mathrm{Tr}]}_{\Phi\Phi},$$

and identify the Apeiron intrinsic scale via $m_A^2 \equiv \mathrm{eig}_{\min}\big(\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi}\big)$. At an unbroken symmetric background, $\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi} = m_A^2\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}$, so $\mathcal{K}$ and the mixed-Hessian mass $\mathcal{M}$ differ by a conventional factor 2 at quadratic order. Use $\mathcal{M}$ in the EL equation and $\mathcal{K}$ in potential-curvature meters; both are band/diagnostic realized reference configuration-safe.

Typed EL, safety, and physical reading. The trace-typed equation

$$(\bar{\nabla}^2 - \mathcal{M}_{[\mathrm{Tr}]})\, \delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]} = 0$$

is constructed on $\mathcal{H}_{\mathrm{phys}}$ with typed projectors and inherits Nielsen/BRST safety and plateau stability; poles/residues are to be read only after diagnostic realized reference configuration certification. The TT channel encodes the NG (massless spin-2) behaviour under SSB and is disjoint from the Apeiron mass.

Takeaway. With the above potential normalisation,

$$\boxed{\mathcal{M}_{[\mathrm{Tr}]}(\bar{\Phi} = 0) = \tfrac{1}{2}\, m_A^2\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}}, \qquad \boxed{\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi}(\bar{\Phi} = 0) = m_A^2\, \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}}.$$

9.17.2 Spontaneous Symmetry Breaking of the Gaiamiti Field

1. Symmetric potential on the diagnostic realized reference configuration (typed form)

Work on the diagnostic realized reference configuration (Definition 9.185) and evaluate the operator-valued Gaiamiti potential $\mathcal{V}_\Phi$ (Definition 9.235) built from the invariant inner product g_T (Definition 6.104, cf. §9.17). We adopt the SSB-friendly parametrization

$$\mathcal{V}_\Phi(\hat{\mathbf{\Phi}}) = \frac{\lambda_A}{4!}\left[g_T\big(\hat{\mathbf{\Phi}},\hat{\mathbf{\Phi}}\big) - v_A^2\right]^2 + \cdots,$$

which is manifestly G-invariant (law-symmetric). Define the intrinsic Apeiron scale by $m_A^2 := \frac{\lambda_A}{3!}\, v_A^2$ (cf. Definition 9.242). Expanding about the origin reproduces the usual tachyonic sign (the origin is not a minimum for $v_A^2 > 0$); m_A is read from the *typed curvature* rather than a particle pole.

For any typed projector $\Pi^{[\chi]}_{\Phi\Phi}$ with $[\chi] \in \{\mathrm{Tr}, \mathrm{TT}\}$ (Definitions 9.186, 9.195 and 9.200), define the *typed curvature (Hessian)*

$$\mathcal{K}^{[\chi]}_{\Phi\Phi} := \Pi^{[\chi]}_{\Phi\Phi}\, \frac{\delta^2 \mathcal{V}_\Phi}{\delta\Phi\,\delta\Phi}\Big|_{\bar{\Phi}}\, \Pi^{[\chi]}_{\Phi\Phi}, \qquad \bar{\Phi} \text{ the realized background on } \mathfrak{P}.$$

These typed curvatures feed the SynTh meters via the potential route (Definitions 9.220 and 9.221) and are equivalent, on a certified plateau, to the correlational route (Proposition 9.223).

Consistency note (unbroken vs. broken parametrizations). When discussing the *unbroken* symmetric phase at $\bar{\Phi} = 0$, either set $v_A = 0$ *in the above form* or instead use $\mathcal{V}_\Phi = \frac{1}{2} m_A^2\, g_T(\Phi,\Phi) + \frac{\lambda_A}{4!}[g_T(\Phi,\Phi)]^2 + \cdots$ with $m_A^2 > 0$. Both give a positive quadratic curvature at the origin in the trace channel and avoid tachyonic confusion.

2. Vacuum configuration and typed SSB predicate

The realized vacuum $\bar{\Phi}$ minimizes $\mathcal{V}_\Phi$ on the diagnostic realized reference configuration. The canonical regimes:

(A) Symmetric phase (no SSB). Here $\bar{\Phi} = 0$ and, with the unbroken parametrization (or $v_A = 0$ in the SSB form), both typed curvatures are positive on the plateau:

$$\mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi} > 0, \qquad \mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi} > 0.$$

The typed SynTh meters (Definitions 9.187 and 9.205) yield $\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QI}$ and $\mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI}$: no NG/pNG in either typed channel.

(B) SSB phase (law-symmetric, state-selecting). $\bar{\Phi} \neq 0$ with $g_T(\bar{\Phi},\bar{\Phi}) = v_A^2$. On the typed subspaces one has

$$\mathrm{spec}\,\mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi} \ni 0 \quad (\text{null directions tangent to } \mathcal{M}_{\mathrm{vac}} \cong G/H), \qquad \mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi} > 0.$$

Potential-driven SynTh then gives

$$\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII}, \qquad \mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI},$$

with healing indicators $\mathscr{H}^{[\Phi\Phi,\mathrm{TT}]}_{L,S} = 0$ and $\mathscr{H}^{[\Phi\Phi,\mathrm{Tr}]}_{L,S} = 0$. Accordingly, the correlational typed channel $\Pi_{\mathrm{corr}}\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$ exhibits an *exact* NG pole (massless spin-2), while the trace channel remains gapped. Location/onset are stamped via Definition 9.190 and recorded in the ledger (Definition 9.198 and Corollaries 9.194 and 9.218); SSB naming applies thereafter (Corollary 9.199).

Quadratic expansion of $\mathcal{K}^{[\chi]}_{\Phi\Phi}$ around $\bar{\Phi}$ (typed basis as in EL split). Setup. Use the SSB–friendly potential

$$\mathcal{V}_\Phi(\Phi) = \frac{\lambda_A}{4!}\left[g_T(\Phi,\Phi) - v_A^2\right]^2 + \cdots, \qquad m_A^2 := \frac{\lambda_A}{3!}\,v_A^2 = \frac{\lambda_A}{6}\,v_A^2.$$

Let $\bar{\Phi}$ be a realized vacuum with $g_T(\bar{\Phi},\bar{\Phi}) = v_A^2$, and define the g_T-unit radial vector $u := \bar{\Phi}/\|\bar{\Phi}\|_{g_T} = \bar{\Phi}/v_A$ (so $g_T(u,u) = 1$). Decompose any fluctuation as

$$\delta\Phi = \phi_r\, u + \delta\Phi_\perp, \qquad g_T(u,\delta\Phi_\perp) = 0.$$

The typed projectors on the Φ-space (same as in the EL split) are

$$\Pi^{[\mathrm{Tr}]}_{\Phi\Phi} X := u\, g_T(u,X), \qquad \Pi^{[\mathrm{TT}]}_{\Phi\Phi} X := X - u\, g_T(u,X), \qquad \Pi^{[\mathrm{Tr}]}_{\Phi\Phi} + \Pi^{[\mathrm{TT}]}_{\Phi\Phi} = \mathbb{I}.$$

Quadratic expansion. Write $S(\Phi) := g_T(\Phi,\Phi)$. Around $\bar{\Phi}$,

$$S(\bar{\Phi}+\delta\Phi) - v_A^2 = 2\,g_T(\bar{\Phi},\delta\Phi) + g_T(\delta\Phi,\delta\Phi) = 2v_A\,\phi_r + \mathcal{O}(\delta\Phi^2),$$

so the potential to quadratic order is

$$\mathcal{V}_\Phi(\bar{\Phi}+\delta\Phi) = \frac{\lambda_A}{4!}\left(2v_A\,\phi_r\right)^2 + \mathcal{O}(\delta\Phi^3) = \frac{\lambda_A v_A^2}{6}\,\phi_r^2 + \mathcal{O}(\delta\Phi^3) = m_A^2\,\phi_r^2 + \mathcal{O}(\delta\Phi^3).$$

Matching to the standard quadratic form $\frac{1}{2}\,\delta\Phi\cdot\mathcal{K}_{\Phi\Phi}(\bar{\Phi})\,\delta\Phi$, we read off

$$\boxed{\mathcal{K}_{\Phi\Phi}(\bar{\Phi}) = 2\,m_A^2\,\Pi^{[\mathrm{Tr}]}_{\Phi\Phi},} \quad \Longrightarrow \quad \boxed{\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi}(\bar{\Phi}) = 2\,m_A^2\,\Pi^{[\mathrm{Tr}]}_{\Phi\Phi}, \quad \mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi}(\bar{\Phi}) = 0.}$$

Interpretation.

- *Radial stiffness (trace channel).* Along the radial direction u, the curvature eigenvalue is $2m_A^2 = (\lambda_A/3)\,v_A^2$, so the trace-typed mode is gapped on the diagnostic realized reference configuration.
- *TT tangential zeros.* On the g_T-orthogonal complement (tangent to the vacuum orbit), the same-variable Hessian vanishes: $\ker\mathcal{K}_{\Phi\Phi}(\bar{\Phi}) = \mathrm{Im}\,\Pi^{[\mathrm{TT}]}_{\Phi\Phi}$. These directions coincide with the tangent space $T_{\bar{\Phi}}(\mathcal{M}_{\mathrm{vac}}) \cong T_{\bar{\Phi}}(G\cdot\bar{\Phi})$; they generate exact NG directions in the correlational TT channel on a certified plateau.

Unbroken phase check. If instead the symmetric phase is realized at $\bar{\Phi} = 0$, use the unbroken parametrization $\mathcal{V}_\Phi = \frac{1}{2}m_A^2\,g_T(\Phi,\Phi) + \frac{\lambda_A}{4!}[g_T(\Phi,\Phi)]^2 + \cdots$ (or set $v_A = 0$ above). Then

$$\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi}(\bar{\Phi}=0) = m_A^2\,\Pi^{[\mathrm{Tr}]}_{\Phi\Phi}, \qquad \mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi}(\bar{\Phi}=0) = m_A^2\,\Pi^{[\mathrm{TT}]}_{\Phi\Phi},$$

so both typed curvatures are positive (QI).

3. Physical consequences: typed spectrum on the diagnostic realized reference configuration

We analyze the spectrum of *realized* excitations—i.e. BRST–physical fluctuations on a certified plateau $\mathfrak{P}$—around a broken–symmetry vacuum. Expand the Gaiamiti field about its VEV,

$$\hat{\mathbf{\Phi}}(x) \;=\; \bar{\Phi}(x) \;+\; \delta\hat{\mathbf{\Phi}}(x) \qquad \text{(cf. eq. (10.87))}.$$

Fluctuations decompose by $\bar{\Sigma}$–typed projectors into *radial/trace* and *tangential/TT* directions (cf. Definitions 9.186, 9.195 and 9.200). On $\mathfrak{P}$, the potential and correlational routes agree within certified tolerances (Proposition 9.223). All NG/pNG claims are made *only* on $H^0(\hat{Q}_{\mathrm{BRST}})$ and are Nielsen–safe (Propositions 9.191 and 9.207).

Massive (gapped) trace/radial mode — the Apeiron. Displacements *up the walls* of the potential, away from the manifold of minima $\mathcal{M}_{\mathrm{vac}}$, feel a restoring force set by the curvature (Hessian) at the minimum; the resulting quanta are *massive* and define the intrinsic Apeiron scale (cf. standard treatments [91, 100]).

Typed implementation. Project to the trace type

$$\delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]} := \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\,\delta\hat{\mathbf{\Phi}}, \qquad [\mathrm{Tr}] \in \{\mathrm{Tr}, \mathrm{TT}\}.$$

Define the typed mass operator at $\bar{\Phi}$ (mixed Hessian; Definition 9.246):

$$\mathcal{M}_{[\mathrm{Tr}]}(x) := \Pi^{[\mathrm{Tr}]}_{\Phi\Phi}\,\frac{\delta^2\mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger\,\delta\hat{\mathbf{\Phi}}}\bigg|_{\hat{\mathbf{\Phi}}=\bar{\Phi}(x)}\,\Pi^{[\mathrm{Tr}]}_{\Phi\Phi}, \quad \mathcal{V}_\Phi \text{ as in Definition 9.235.}$$

Equivalently (for potential–side meters), use the same–variable curvature $\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi}$ (Definition 9.220). On $\mathfrak{P}$, positivity of $\mathcal{M}_{[\mathrm{Tr}]}$ yields a *gapped* spectrum with intrinsic Apeiron scale m_A (cf. Definition 9.242) and correlation length $\xi_A \sim m_A^{-1}$. The canonical typed predicate returns

$$\mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} \;=\; \mathrm{QI},$$

i.e. law–symmetric, no state selection and no NG/pNG content in this channel (Definition 9.189 and Proposition 9.197). Stamp Loc/On via Definition 9.190 and record $\mathbf{L}^{[\Phi\Phi,\mathrm{Tr}]}$ (Definition 9.198 and Corollaries 9.194 and 9.218).

Massless (NG) TT/tangential mode — the graviton. Displacements *along the flats*—tangent to the degenerate vacuum manifold $\mathcal{M}_{\mathrm{vac}}$—cost no potential energy and correspond to broken generators. By **Goldstone's theorem** [93, 94], these are *massless* excitations; in gauge-organized settings, their fate and identification follow the familiar organizational mechanisms [97, 91, 100].

Typed implementation. Project to the transverse–traceless type,

$$\delta\hat{\mathbf{\Phi}}^{[\mathrm{TT}]} := \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\,\delta\hat{\mathbf{\Phi}}.$$

In the SSB–only regime ($\bar{\Phi} \neq 0$, no explicit breaking, $\mathcal{M}_{\mathrm{vac}} \cong G/H$), the typed curvature exhibits null tangential directions

$$\mathrm{spec}\,\mathcal{K}^{[\mathrm{TT}]}_{\Phi\Phi} \ni 0 \quad (\text{tangent to } T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}}),$$

and the typed law/state sources *heal* on $\mathfrak{P}$, $\mathscr{H}_{L,S}^{[\Phi\Phi,\mathrm{TT}]} = 0$ (Definition 9.188). Hence the canonical predicate gives

$$\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} \;=\; \mathrm{QII}.$$

The correlational typed channel $\Pi_{\mathrm{corr}}\Pi_{\Phi\Phi}^{[\mathrm{TT}]}$ then displays an *exact* NG pole with positive residue on H^0 (Proposition 9.197). With a $\bar{\Sigma}$–admissible spatial splitting, refine to helicities $\lambda = \pm 2$ (Definition 9.200); these two physical polarizations propagate as the *massless* spin–2 graviton (with operational identification in Proposition 9.243 and naming per Corollary 9.199).

Diagnostic realized reference configuration–discipline summary. All statements above are evaluated on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$, and with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$. On such windows, the potential– and correlational–route meters are equivalent and all conclusions are gauge–parameter independent, within the established tolerances (Propositions 9.191, 9.207 and 9.223).

Remark (explicit breaking / pNG). If a small explicit symmetry–breaking spurion is present in the TT law channel, the typed law source does not heal, $\mathscr{H}_{L}^{[\Phi\Phi,\mathrm{TT}]} > 0$, and the canonical predicate switches to

$$\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QIV}.$$

On the certified plateau $\mathfrak{P}$, this yields a pseudo–NG band with GMOR slope (Definition 9.188 and Proposition 9.197), while the trace channel remains gapped (QI). Boundary cases proceed *mutatis mutandis* via the bulk/edge overlay (Definition 9.214); only the Loc/On stamps and the edge entry recorded in the ledger are affected (Corollary 9.218).

9.17.3 Global Symmetry Breaking: NG and Radial Sectors

Definition 9.249 (Typed NG subspace and projector (global SSB))**.** Work on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ and on the BRST–physical sector $H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration discipline as in Propositions 9.191, 9.207 and 9.223). Let a global symmetry G act on a field bundle $\mathcal{E}_U$ with $U \in \{\Theta, \Phi\}$ via a representation ρ, and let $\bar{U}$ minimize the effective potential. For each broken generator T_b, set $v_b := \rho(T_b)\bar{U} \neq 0$. With the appropriate pairing g (for Tantrakyma $g = g_C$, for Gaiamiti $g = g_T$), define the Gram matrix $B_{bc} := g(v_b, v_c)$ and the *typed NG projector* by

$$\boxed{\Pi_{\mathrm{NG}}^{[\chi]}(V) \;:=\; \Pi_{UU}^{[\chi]}\left[\sum_{b,c}(B^{-1})^{bc}\, g\Big(V,\, v_b\Big)\, v_c\right]\Pi_{UU}^{[\chi]},}$$

where $\Pi_{UU}^{[\chi]}$ is the typed projector (cf. Definitions 9.186 and 9.200). Equivalently, $\Pi_{\mathrm{NG}}^{[\chi]}$ is the Riesz (resolvent) projector onto the NG island of the *typed* scalar Hessian $\mathcal{K}_{UU}^{[\chi]}$ obtained by inserting the potential curvature in the same typed/triadic channel (contour enclosing the cluster at/near 0 in $\operatorname{spec}\mathcal{K}_{UU}^{[\chi]}$; cf. Proposition 9.223). All insertions commute with the triadic channels Π_α and are BRST–closed (Proposition 9.207).

Definition 9.250 (Typed radial direction, projector, and mass operator)**.** In the same setting and type $[\chi]$, introduce the quadratic form $\mathsf{X}_U := g(U,U)$ with differential at $\bar{U}$, $\delta\mathsf{X}_U|_{\bar{U}}(\delta U) = 2\,g(\delta U, \bar{U})$. The g–Riesz identification makes the *radial direction* collinear with $\bar{U}$; a normalized typed representative is

$$\widehat{\mathsf{R}}_U^{[\chi]} := \frac{\Pi_{UU}^{[\chi]}\bar{U}}{\sqrt{g\Big(\Pi_{UU}^{[\chi]}\bar{U},\ \Pi_{UU}^{[\chi]}\bar{U}\Big)}}.$$

Define the one–dimensional g–orthogonal *typed radial projector*

$$\boxed{\Pi_{\mathrm{rad}}^{[\chi]}(V) := \frac{g\Big(V, \widehat{\mathsf{R}}_U^{[\chi]}\Big)}{g\Big(\widehat{\mathsf{R}}_U^{[\chi]}, \widehat{\mathsf{R}}_U^{[\chi]}\Big)}\,\widehat{\mathsf{R}}_U^{[\chi]}.}$$

The *typed radial mass operator* (restricted Hessian at $\bar{U}$) is then

$$\boxed{\mathcal{K}_{\mathrm{rad}}^{[\chi]} := \Pi_{\mathrm{rad}}^{[\chi]}\ \frac{\delta^2\mathcal{V}_U}{\delta U\,\delta U}\Big|_{\bar{U}}\ \Pi_{\mathrm{rad}}^{[\chi]}}$$

to be evaluated on $H^0(\hat{Q}_{\mathrm{BRST}})$. For $U = \Theta$ (Tantrakyma) this reproduces the Higgs/radial kymon construction (Definition 9.343 and eq. (9.185)); for $U = \Phi$ (Gaiamiti) it matches the Apeiron radial operator (Definition 9.259). Typed/triadic insertions follow Definition 9.187, guaranteeing gauge–parameter independence within tolerances (Propositions 9.191 and 9.207).

Proposition 9.251 (Quadrant assignment under global SSB (typed, BRST–clean))**.** *Work on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$, and on the BRST–physical sector $H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration discipline: Propositions 9.191, 9.207 and 9.223). Fix a field species $U \in \{\Theta, \Phi\}$ and a type $[\chi]$ with typed projector $\Pi_{UU}^{[\chi]}$ (Definitions 9.186 and 9.200). Let $\Pi_{\mathrm{NG}}^{[\chi]}$ and $\mathcal{K}_{\mathrm{rad}}^{[\chi]}$ be the typed NG projector and typed radial mass operator from Definitions 9.249 and 9.250, and let $\delta_{L,S}^{[UU,\chi]}$, $\mathscr{H}_{L,S}^{[UU,\chi]}$ be the typed sources and healing indicators (Definitions 9.187 and 9.188).*

(i) (QI) No SSB, law symmetric (fully symmetric typed channel)

If $\operatorname{Im}\Pi_{\mathrm{NG}}^{[\chi]} = \{0\}$, the typed curvature has no nulls at the origin, the radial operator is strictly positive, and the typed witnesses indicate law/state symmetry ($|\Lambda_{\mathrm{law}}| \approx 1$, $|\Lambda_{\mathrm{state}}| \approx 1$ on $\mathfrak{P}$; cf. Definitions 7.685 and 9.187), then

$$\mathrm{Quad}^{[UU,\chi]} = \mathrm{QI}.$$

This case exhibits no NG/pNG content; spectra are gapped (or, for gauge/spacetime symmetries, carry the usual unbroken massless content) and all typed sources heal within tolerances (Proposition 9.223).

(ii) (QII) Global SSB without explicit breaking (SSB–only)

Assume a broken–symmetry vacuum $\bar{U}$ with $\operatorname{Im}\Pi_{\mathrm{NG}}^{[\chi]} \neq \{0\}$ and a strictly positive radial

gap $\mathcal{K}_{\mathrm{rad}}^{[\chi]} \geq m_{\mathrm{rad}}^2 \Pi_{\mathrm{rad}}^{[\chi]}$ *on* H^0 *for some* $m_{\mathrm{rad}} > 0$. *If the typed law/state sources* heal *on* $\mathfrak{P}$,

$$\mathscr{H}_L^{[UU,\chi]} = \mathscr{H}_S^{[UU,\chi]} = 0,$$

then the canonical typed predicate (Definition 9.189) returns

$$\mathrm{Quad}^{[UU,\chi]} = \mathrm{QII}.$$

Moreover, in the correlational channel $\Pi_{\mathrm{corr}} \Pi_{UU}^{[\chi]} \Pi_{\mathrm{NG}}^{[\chi]}$ *there is an* exact *NG pole with positive residue on* H^0 *(Proposition 9.197), while the radial sector is gapped by* $\mathcal{K}_{\mathrm{rad}}^{[\chi]}$. Helicity refinement *(when admissible) proceeds via the typed subprojectors in Definition 9.200.*

(iii) (QIII) Apparent law asymmetry that heals in the IR (emergent symmetry)
If the typed law-side deficit is nonzero at finite resolution but decays with IR coarse–graining on $\mathfrak{P}$ *(healing power law as in eq. (7.746)), while the state side remains symmetric (*$|\Lambda_{\mathrm{state}}| \approx 1$*), then*

$$\mathrm{Quad}^{[UU,\chi]} = \mathrm{QIII}.$$

There is no persistent NG/pNG content in the IR limit; the decision follows the canonical rule Definition 7.685 using the typed meters in Definition 9.187.

(iv) (QIV) Small explicit breaking in the typed law channel (pseudo–NG/GMOR)
Suppose the SSB hypotheses of (QII) *hold but a small explicit spurion is present in the* law *channel so that*

$$\mathscr{H}_L^{[UU,\chi]} > 0 \quad \text{on } \mathfrak{P},$$

while the state side still heals ($\mathscr{H}_S^{[UU,\chi]} = 0$*). Then the canonical typed predicate flips to*

$$\mathrm{Quad}^{[UU,\chi]} = \mathrm{QIV}.$$

On $\mathfrak{P}$, *the NG cluster becomes a* pseudo–NG *cluster obeying GMOR scaling (typed Ward/GMOR on the diagnostic realized reference configuration; cf. Definition 9.188 and Proposition 9.197 and the GMOR plateau result cited earlier), whereas the radial sector remains gapped and Nielsen–safe (Propositions 9.191 and 9.207).*

Stamps and ledger. *In all cases, record the typed* Loc/On *stamps via Definition 9.190 and update the typed quadrant ledger* $\mathbf{L}^{[UU,\chi]}$ *(Definition 9.198 and Corollaries 9.194 and 9.218). Boundary overlays are handled* mutatis mutandis *by Definition 9.214, affecting only the recorded* Loc/On *and edge entries.*

Scope of Gauging (Internal vs. Relational)

Definition 9.252 (Internal gauging of a typed sector on the diagnostic realized reference configuration)**.** Work on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration discipline: Propositions 9.191, 9.207 and 9.223). Let $U \in \{\Theta, \Phi\}$ denote Tantrakyma/Gaiamiti with pairing g (for Θ: $g = g_C$; for

Φ: $g = g_T$), equipped with an internal gauge group G_U, representation ρ_U, and coupling g_U. On a realized vacuum $\bar{U}$, the *typed* vector mass matrix is

$$\boxed{(M_U^2)_{IJ} \;=\; g_U^2\, g\Big(\rho_U(T_I)\bar{U},\ \rho_U(T_J)\bar{U}\Big)}\,,$$

with transverse/longitudinal/helicity projectors inserted as in Definition 9.350. The *radial (amplitude) scalar* is defined by the typed radial Hessian $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ of Definition 9.250, evaluated with the sector pairing g. Specializations:

(i) Tantrakyma Θ
$(M_\Theta^2)_{IJ} = g_\Theta^2\, g_C\Big(\rho_\Theta(T_I)\bar{\Theta},\, \rho_\Theta(T_J)\bar{\Theta}\Big)$; the Higgs (radial kymon) mass follows from $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (cf. Definition 9.343 and eqs. (9.184) and (9.185)).

(ii) Gaiamiti Φ
$(M_\Phi^2)_{IJ} = g_\Phi^2\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi},\, \rho_\Phi(T_J)\bar{\Phi}\Big)$; the Apeiron (radial) scalar is encoded by $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (cf. Section 9.17.4, Proposition 9.257, and Definition 9.259).

Gauge fixing is taken in R_ξ form so that physical poles and quadrant decisions are ξ–independent (Nielsen safety; cf. Definition 9.261 and Proposition 9.191).

Remark 9.253 (Relational/diffeomorphism symmetry is not BEH–gauged)**.** Relational/diffeomorphism symmetry is not an internal gauging in the BEH sense. Typed/triadic Ward identities keep the TT channel *gapless* on H^0 (no Proca mass for the graviton); the trace scale m_A encodes *radial stiffness* in the Apeiron channel and is not a graviton mass (cf. Proposition 9.207 and Section 9.17.2).

Why Internal Gauging is Added (Completeness w.r.t. Global SSB)

Proposition 9.254 (Typed spectrum and quadrants under internal gauging)**.** *The quadrant formalism of Chs. 7–8 (typed/triadic meters on H^0; Definitions 7.685 and 9.187) already gives a complete account of* global *SSB (see Section 9.17.3 and Proposition 9.251). Adding* internal *gauging for Θ and Φ completes the symmetry–breaking picture without altering the quadrant axes (law vs. state):*

(i) Tantrakyma Θ (BEH)
Broken NG directions in $\mathrm{Im}\,\Pi^{[\chi]}_{\mathrm{NG}}$ *are eaten; internal vectors acquire masses $(M_\Theta^2)_{IJ}$ of Definition 9.252, while the Higgs (radial kymon) remains gapped by $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (Definition 9.343 and eq. (9.185)). Typed/triadic meters certify* $\mathrm{Quad}^{[\Theta,\chi]} = \mathrm{QII}$ *for SSB–only, flipping to* QIV *with small explicit breaking (GMOR on the plateau; cf. Definition 9.188 and Proposition 9.197).*

(ii) Gaiamiti Φ (internal vectors + Apeiron)
An internal G_Φ yields massive internal vectors with $(M_\Phi^2)_{IJ}$ per Definition 9.252. The Apeiron (trace) scalar is controlled by $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (cf. Section 9.17.4, Proposition 9.257, and Definition 9.259), while the TT graviton channel remains gapless by Ward protection (Remark 9.253). Typed quadrant decisions follow Proposition 9.251.

(iii) Quadrant exhaustiveness unchanged
Internal gauging rearranges *DOFs (NG → longitudinal vectors) but leaves the (law, state) axes intact. Thus* {QI, QII, QIII, QIV} *remain exhaustive, with the same typed decision rule (Definitions 7.685 and 9.187; cf. Ch. 8).*

(iv) Diagnostic realized reference configuration certification and gauge independence
With R_ξ fixing and BRST closure, physical poles (Higgs/Apeiron radials, transverse vectors) and the typed quadrant assignment are ξ–independent (Nielsen) and route–equivalent within tolerances (Definition 9.261 and Propositions 9.191, 9.207 and 9.223).

Record Loc/On *stamps and update the typed ledger* $\mathbf{L}^{[U,\chi]}$ *as in Definitions 9.190 and 9.198 and Corollary 9.218.*

9.17.4 Internal Gauging of the Gaiamiti Sector and BEH Completion

On the certified plateau $\mathfrak{P}$ with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration discipline as in Propositions 9.191, 9.207 and 9.223), an *internal* gauging of the Gaiamiti sector implements the Brout–Englert–Higgs (BEH) pattern for the Φ-coupled vectors, supplies a geometric Higgs–type scalar in the Apeiron (trace) channel, and *does not* generate a mass in the transverse–traceless (TT) graviton channel. The TT mode remains massless on H^0 (cf. typed TT construction in Section 9.17.2); the trace scale m_A encodes Apeiron stiffness, not a graviton mass (cf. radial operator in Definition 9.250).

Definition 9.255 (Gauge–coupled Gaiamiti action)**.** Let a compact Lie group G act on the Gaiamiti fiber $\mathcal{E}_\Phi$ via a representation ρ_Φ with generators T_I. Introduce gauge fields A^I_μ with field strength $F^I_{\mu\nu}$ and kinetic metric G_{IJ}. Extend the split connection (cf. Section 6.12.2 and eq. (6.314)) to

$$D_\mu \hat{\mathbf{\Phi}} := \nabla^{(\mathrm{rel})}_\mu \hat{\mathbf{\Phi}} + \partial_\mu \hat{\mathbf{\Phi}} + i\, g\, A^I_\mu\, \rho_\Phi(T_I)\, \hat{\mathbf{\Phi}},$$

and define, on a certified plateau $\mathfrak{P}$,

$$S_{\Phi+G} = \int_{\mathcal{X}_q} d^d x \, \sqrt{-\det \bar{\Sigma}}\, \mathrm{Tr}\Big[-\tfrac{1}{4}\, G_{IJ} F^I_{\mu\nu} F^{J\,\mu\nu} + \tfrac{1}{2}\, (D_\mu \hat{\mathbf{\Phi}})^\dagger g_T(D^\mu \hat{\mathbf{\Phi}}) - \mathcal{V}_\Phi(\hat{\mathbf{\Phi}})\Big]\,,$$

where g_T is the Gaiamiti pairing and $\mathcal{V}_\Phi$ the Gaiamiti potential (cf. eq. (6.316)); see also the refined Noether current in Definition 9.271. Typed/triadic insertions follow Definition 9.187.

Definition 9.256 (SSB pattern and typed projectors in the Gaiamiti sector)**.** Let $\hat{\mathbf{\Phi}} = \bar{\Phi} + \delta\hat{\mathbf{\Phi}}$ with $\bar{\Phi}$ minimizing $\mathcal{V}_\Phi$. For broken generators T_b, set $v_b := \rho_\Phi(T_b)\bar{\Phi} \neq 0$ and form

$$\Pi^{(\Phi)}_{\mathrm{NG}}(V) := \sum_{b,c} (B^{-1})^{bc}\, g_T(V, v_b)\, v_c, \qquad B_{bc} := g_T(v_b, v_c),$$

which is the Gaiamiti specialization of the typed NG projector in Definition 9.249. Let $\mathsf{Y} := g_T(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}})$. At $\bar{\Phi}$, $\delta\mathsf{Y}|_{\bar{\Phi}}(\delta\hat{\mathbf{\Phi}}) = 2\, g_T(\delta\hat{\mathbf{\Phi}}, \bar{\Phi})$, so the g_T–Riesz map identifies the radial line with $\bar{\Phi}$. A normalized typed representative is

$$\widehat{\mathsf{R}}_\Phi := \frac{\Pi^{[\chi]}_{\Phi\Phi}\, \bar{\Phi}}{\sqrt{g_T(\Pi^{[\chi]}_{\Phi\Phi}\bar{\Phi}, \Pi^{[\chi]}_{\Phi\Phi}\bar{\Phi})}}, \quad \text{(cf. typed projector in Definitions 9.186 and 9.200)}$$

with one–dimensional g_T–orthogonal projector

$$\Pi_{\mathrm{A}}^{(\Phi)}(V) := \frac{g_T(V, \widehat{\mathsf{R}}_\Phi)}{g_T(\widehat{\mathsf{R}}_\Phi, \widehat{\mathsf{R}}_\Phi)}\, \widehat{\mathsf{R}}_\Phi,$$

which matches the typed radial projector of Definition 9.250. Assume $\Pi_{\mathrm{NG}}^{(\Phi)}$ and $\Pi_{\mathrm{A}}^{(\Phi)}$ commute with the triadic projectors $\Pi_{\mathrm{corr}}, \Pi_{\mathrm{vac}}, \Pi_{\mathrm{spec}}$ (cf. Proposition 9.207) and respect typed polarizations (TT/trace/helicity; cf. Definition 9.200).

Proposition 9.257 (Vector masses from BEH in the Gaiamiti sector)**.** *Expanding the covariant kinetic term in Definition 9.255 around $\bar{\Phi}$ yields the internal vector mass term*

$$\mathcal{L}_{\mathrm{mass}}^{(A)} = \tfrac{1}{2}\, A_\mu^I\, (M^2)_{IJ}\, A^{J\,\mu}, \qquad (M^2)_{IJ} := g^2\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi},\ \rho_\Phi(T_J)\bar{\Phi}\Big),$$

which is the Φ-sector specialization of the unified typed formula in Definition 9.252. Vectors along broken directions acquire masses $\mathrm{spec}(M^2)$*; NG directions are eaten as longitudinal modes, in parallel with the Tantrakyma linear-response paradigm (eq. (9.184) and Definition 9.343). Typed vector/helicity projectors are as in Definition 9.350.*

Proof of Proposition 9.257. Work on a certified plateau $\mathfrak{P}$ with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ and typed/triadic meters commuting (cf. Propositions 9.191, 9.207 and 9.223). Start from the gauge–coupled Gaiamiti action of Definition 9.255:

$$S_{\Phi+G} = \int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}}\, \mathrm{Tr}\Big[-\tfrac{1}{4}\, G_{IJ} F_{\mu\nu}^I F^{J\,\mu\nu} + \tfrac{1}{2}\, (D_\mu \hat{\mathbf{\Phi}})^\dagger g_T (D^\mu \hat{\mathbf{\Phi}}) - \mathcal{V}_\Phi(\hat{\mathbf{\Phi}})\Big],$$

with $D_\mu \hat{\mathbf{\Phi}} = \nabla_\mu^{(\mathrm{rel})} \hat{\mathbf{\Phi}} + \partial_\mu \hat{\mathbf{\Phi}} + i\, g\, A_\mu^I\, \rho_\Phi(T_I) \hat{\mathbf{\Phi}}$. Expand around a realized vacuum $\hat{\mathbf{\Phi}} = \bar{\Phi} + \delta\hat{\mathbf{\Phi}}$ (Definition 9.256), keeping terms at most quadratic in fields and focusing on the gauge–vector sector. Using linearity of D_μ and sesquilinearity of g_T,

$$\begin{aligned} \tfrac{1}{2}(D_\mu \hat{\mathbf{\Phi}})^\dagger g_T (D^\mu \hat{\mathbf{\Phi}}) &= \tfrac{1}{2}\Big(\cdots + i g\, A_\mu^I\, \rho_\Phi(T_I)\bar{\Phi} + \cdots \Big)^\dagger\, g_T \Big(\cdots + i g\, A^{J\,\mu}\, \rho_\Phi(T_J)\bar{\Phi} + \cdots \Big) \\ &\supset \tfrac{1}{2}\, g^2\, A_\mu^I\, A^{J\,\mu}\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi},\ \rho_\Phi(T_J)\bar{\Phi}\Big), \end{aligned}$$

which gives the purely quadratic $A\cdot A$ mass term $\mathcal{L}_{\mathrm{mass}}^{(A)} = \frac{1}{2} A_\mu^I (M^2)_{IJ} A^{J\,\mu}$ with $(M^2)_{IJ} := g^2\, g_T(\rho_\Phi(T_I)\bar{\Phi}, \rho_\Phi(T_J)\bar{\Phi})$. Cross terms linear in A_μ and $\delta\hat{\mathbf{\Phi}}$ generate the familiar A–NG mixing; these are cancelled on the diagnostic realized reference configuration by the R_ξ gauge fixing of Definition 9.261, and the associated ghost sector ensures BRST closure. Consequently, physical poles reside in the transverse vector channel, while longitudinal contributions are BRST-removed; gauge-parameter independence of masses and residues follows from the Nielsen/BRST identities (cf. Theorem 9.351).

If $T_a \in \mathfrak{h} = \mathrm{Lie}(H)$ is unbroken, then $\rho_\Phi(T_a)\bar{\Phi} = 0$ (Definition 9.256), and the corresponding rows/columns of M^2 vanish, yielding massless vectors for unbroken directions. For broken generators T_b one has $\rho_\Phi(T_b)\bar{\Phi} \neq 0$, producing strictly positive entries in M^2 and hence massive vectors along those directions. This is the Φ-sector specialization of the unified typed internal-gauging formula referenced in Definition 9.252. The statement about NG directions being eaten (longitudinal modes) and the use of typed vector/helicity projectors follows exactly as in the Tantrakyma linear-response paradigm (eq. (9.184) and Definition 9.343) and with the vector projectors of Definition 9.350. This completes the proof. □

Definition 9.258 (Mition: Gaiamiti spin–1 internal vector)**.** Let G act on the Gaiamiti fiber $\mathcal{E}_\Phi$ via ρ_Φ and let $\bar{\Phi}$ realize spontaneous breaking $G \to H$ (Definition 9.256). The *mition* denotes a one-particle, spin–1, *internal* gauge quantum in the Gaiamiti sector, i.e. a mass eigenmode of the bundle connection A^I_μ defined as follows.

(i) Mass matrix and eigenmodes

Form the BEH mass matrix

$$(M^2_\Phi)_{IJ} \;:=\; g^2\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi},\ \rho_\Phi(T_J)\bar{\Phi}\Big) \quad \text{(cf. Definition 9.255 and Proposition 9.257).}$$

Choose an orthogonal diagonalization $O \in \mathrm{O}(\dim G)$ with $O^\top M^2_\Phi O = \mathrm{diag}(m^2_{V,a})$. The *mition fields* are the mass–eigenstate vectors

$$V_{a\,\mu} \;:=\; O^{\ I}{}_{a}\, A^I_\mu\,, \qquad m^2_{V,a} \in \mathrm{spec}(M^2_\Phi).$$

(ii) Physical pole definition (diagnostic realized reference configuration)

On the diagnostic realized reference configuration $\mathfrak{P}$ with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$, the *physical mition* of label a is the simple pole of the two–point function in the *transverse* vector channel at $k^2 = m^2_{V,a}$, isolated by the typed projectors Π_T (and helicity projectors when applicable) of Definition 9.350. Longitudinal contributions are gauge artefacts removed by BRST; the pole positions and residues are ξ-independent by Theorem 9.351.

(iii) Unbroken directions

If $m^2_{V,a} = 0$, the corresponding $V_{a\,\mu}$ is a massless internal vector (unbroken H-direction). Otherwise $m^2_{V,a} > 0$ and the mition is massive; the associated NG direction is eaten (equivalence theorem as in Corollary 9.352).

(iv) Separation from scalar/tensor Gaiamiti quanta

Mitions are *not* excitations of the scalar trace channel (the *gaiaton*, defined via the restricted Hessian $\mathcal{K}^{(\Phi)}_{\mathrm{A}}$; cf. Definition 9.259) nor of the TT tensor channel (the massless graviton; cf. Remark 9.260). They are quanta of the bundle connection coupled to Φ.

Justification (Mition). The spin–1 bundle–connection quantum in the Gaiamiti sector is called the *Mition*. The name derives from the Sanskrit root *mīti* ("measure"; cf. *jyāmīti*, "geometry"), reflecting the connection's role in providing *local measure*—i.e. covariant comparability—of Φ across the emergent manifold. While the Apeiron (umbrella for Gaiamiti quanta) includes the spin–0 radial scalar (the *Gaiaton*) and the spin–2 TT graviton, the *Mition* specifically denotes the spin–1 *internal* gauge quantum: the dynamical components A^I_μ of the operator bundle connection $\mathcal{A}_\mu$ once the sector is gauged (cf. Definition 9.255). Under spontaneous breaking by $\bar{\Phi}$, the covariant kinetic term produces a Brout–Englert–Higgs mass matrix $(M^2_\Phi)_{IJ} = g^2\, g_T(\rho_\Phi(T_I)\bar{\Phi}, \rho_\Phi(T_J)\bar{\Phi})$ (Proposition 9.257), so transverse Mitions appear as diagnostic realized reference configuration–physical poles at $k^2 \in \mathrm{spec}(M^2_\Phi)$ in the vector channel (gauge–parameter independent by Nielsen/BRST, Theorem 9.351). Conceptually, the Mition is the instrument that "measures" and transports Φ's internal data between fibers, providing the local structure complementary to the radial scalar Gaiaton (Apeiron umbrella) and coexisting with the massless TT graviton protected by relational Ward identities (Remark 9.260).

Gaiamiti (Φ) — what becomes massive, what is eaten, and how the vectors behave. When an internal group G acting on $\mathcal{E}_\Phi$ is gauged and the background $\bar{\Phi}$ breaks $G \to H$, the covariant kinetic term generates a Brout–Englert–Higgs (BEH) mass matrix for the gauge field A_μ^I:

$$(M_\Phi^2)_{IJ} = g^2\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi},\ \rho_\Phi(T_J)\bar{\Phi}\Big) \quad (\textit{Definition 9.255and Proposition 9.257}).$$

What becomes massive? The internal vectors along the *broken* generators—i.e. the *mitions*—with masses given by the eigenvalues spec(M_Φ^2); vectors along unbroken H-directions remain *massless*. The would-be NG scalars of the broken orbit are *eaten* and reappear as *longitudinal* polarizations. On the certified plateau $\mathfrak{P}$, physical one-particle mition poles live in the *transverse* channel only (typed projectors Π_T, Π_L in Definition 9.350); longitudinal contributions are BRST-removed from $H^0(\hat{Q}_{\mathrm{BRST}})$. Both the pole positions m_V^2 and their residues are *gauge-parameter independent* (Nielsen/BRST; Theorem 9.351). At high energy, the typed *Equivalence Theorem* identifies amplitudes with external longitudinal mitions and those with the corresponding NG modes up to $\mathcal{O}(m_V/\sqrt{s})$ (Corollary 9.352). Importantly, internal gauging does *not* touch the relational/diffeomorphism sector: the TT *graviton* remains *massless* (Ward-protected; Remark 9.260), and the trace/radial scalar *gaiaton* stays a separate gapped mode read from the restricted Hessian $\mathcal{K}_{\mathrm{A}}^{(\Phi)}$ (Definition 9.259).

As interacting particles, mitions are *short-range carriers* with range $\sim m_V^{-1}$. They couple (i) to the *gaiaton* through the covariant derivative and scalar potential, producing the familiar VVh and $VVhh$ vertices; (ii) to *other vectors* via the Yang–Mills sector (triple/quartic gauge self-interactions); and (iii) to any *matter fields* charged under the same internal group (if present). If M_Φ^2 is non-diagonal, the gauge eigenstates *mix*; degeneracies produce *multiplets* under the unbroken subgroup H. Vectors along truly unbroken generators remain *massless* and mediate long-range forces unless further dynamics intervene. All of these readouts are made with typed/triadic meters on $\mathfrak{P}$ and inherit route-equivalence and BRST safety (Propositions 9.191, 9.207 and 9.223).

Quadratic Lagrangian matrix (Gaiamiti; field order $A_T,\ A_L,\ \mathrm{NG},\ \mathrm{A}$). Expand to quadratic order around $\bar{\Phi}$ and go to momentum space. After adding the Gaiamiti R_ξ gauge fixing $\mathcal{L}_{\mathrm{GF}}$ of Definition 9.261, the A_L–NG mixing cancels. Working in a single broken mass–eigenchannel (after diagonalizing $(M_\Phi^2)_{IJ}$ from Proposition 9.257), define the basis

$$\Psi := (A_T,\ A_L,\ \pi_{\mathrm{NG}},\ h_{\mathrm{A}}),$$

with A_T (*transverse* mition), A_L (*longitudinal* gauge mode), π_{NG} (would–be NG scalar), and h_{A} the *gaiaton* (radial Apeiron scalar; Definition 9.259). The quadratic form is diagonal:

$$\mathcal{L}^{(2)} = \tfrac{1}{2}\,\Psi^\dagger\,\mathbb{Q}_\Phi(k)\,\Psi,$$

$$\mathbb{Q}_\Phi(k) = \begin{pmatrix} k^2 - m_V^2 & 0 & 0 & 0 \\ 0 & \dfrac{k^2 - m_V^2}{\xi} & 0 & 0 \\ 0 & 0 & k^2 - \xi\, m_V^2 & 0 \\ 0 & 0 & 0 & k^2 - M_{\mathrm{A}}^2 \end{pmatrix},$$

where $\quad k^2 := \bar{\Sigma}^{\mu\nu} k_\mu k_\nu.$

Here $m_V^2 \in \mathrm{spec}(M_\Phi^2)$ is the mition mass in the chosen eigenchannel (Definition 9.255 and Proposition 9.257), and $M_{\mathrm{A}}^2 \in \mathrm{spec}(\mathcal{K}_{\mathrm{A}}^{(\Phi)})$ is the gaiaton (radial) mass (Definition 9.259). Poles: $A_T: \ k^2 = m_V^2$ (physical), $A_L: \ k^2 = m_V^2$ (gauge–artefactual numerator), $\pi_{\mathrm{NG}}: \ k^2 = \xi\, m_V^2$, $h_{\mathrm{A}}: \ k^2 = M_{\mathrm{A}}^2$. On $H^0(\hat{Q}_{\mathrm{BRST}})$ the physical poles are $k^2 = m_V^2$ and $k^2 = M_{\mathrm{A}}^2$; ξ–dependence cancels in S–matrix elements and matches NG amplitudes at high energy by Corollary 9.352. (The massless TT graviton lies in a separate TT block with a protected pole at $k^2 = 0$, unaffected by internal gauging; Remark 9.260.)

Propagators and physical content (Gaiamiti). With the typed vector projectors $\Pi_T^{\mu\nu}(k)$ and $\Pi_L^{\mu\nu}(k)$ (Definition 9.350), the mition propagator is

$$D_{\mu\nu}(k) = \frac{-i}{k^2 - m_V^2}\,\Pi_{T\,\mu\nu} \ + \ \frac{-i\,\xi}{k^2 - \xi\, m_V^2}\,\Pi_{L\,\mu\nu}.$$

The NG propagator is $D_{\mathrm{NG}}(k) = \dfrac{i}{k^2 - \xi\, m_V^2}$, and the gaiaton propagator is $D_{\mathrm{A}}(k) = \dfrac{i}{k^2 - M_{\mathrm{A}}^2}$. Gauge–parameter independence of the physical residues (Higgs/gaiaton and transverse mition) follows from Theorem 9.351; the high–energy identification of longitudinal–mition and NG amplitudes holds by the typed equivalence theorem (Corollary 9.352). All statements are made on the diagnostic realized reference configuration $\mathfrak{P}$ with typed/triadic meters, inheriting route equivalence and BRST safety (Propositions 9.191, 9.207 and 9.223).

Definition 9.259 (Apeiron (trace–typed) radial scalar under gauging)**.** Restrict the potential Hessian to the typed radial line to obtain

$$\boxed{\mathcal{K}_{\mathrm{A}}^{(\Phi)} := \Pi_{\mathrm{A}}^{(\Phi)}\ \frac{\delta^2 \mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}\,\delta\hat{\mathbf{\Phi}}}\bigg|_{\bar{\Phi}}\ \Pi_{\mathrm{A}}^{(\Phi)}} \qquad \text{with} \quad M_{\mathrm{A}}^2 \in \mathrm{spec}\Big(\mathcal{K}_{\mathrm{A}}^{(\Phi)}\Big).$$

This is the Gaiamiti analogue of the Tantrakyma Higgs/radial operator (cf. Definition 9.250 and eq. (9.185)).

Remark 9.260 (Masslessness of the TT graviton)**.** The typed TT graviton remains massless on $H^0(\hat{Q}_{\mathrm{BRST}})$: the TT two–point function carries a Ward-protected pole at $k^2 = 0$ (cf. Section 9.17.2) and is certified by route-equivalence/Nielsen safety (Propositions 9.191 and 9.223). The trace scale m_A from $\mathcal{K}_{\mathrm{A}}^{(\Phi)}$ measures Apeiron stiffness and is not a graviton mass.

Definition 9.261 (R_ξ gauge fixing and BRST hygiene (internal vectors))**.** Choose

$$\mathcal{F}^I := \nabla^{(\mathrm{rel})\,\mu} A_\mu^I - \xi\, g\, g_T\Big(\delta\hat{\mathbf{\Phi}},\ \rho_\Phi(T^I)\bar{\Phi}\Big), \qquad \mathcal{L}_{\mathrm{GF}} = -\frac{1}{2\xi}\, G_{IJ}\, \mathcal{F}^I \mathcal{F}^J,$$

with standard ghost sector so BRST closes on the diagnostic realized reference configuration and physical poles (transverse vectors at $k^2 \in \mathrm{spec}(M^2)$, Apeiron radial at $k^2 = M_{\mathrm{A}}^2$) are gauge-parameter independent (Nielsen identities; cf. Proposition 9.191). Typed decisions remain route-equivalent within tolerances (Proposition 9.223).

Remark 9.262 (Quadrant placement and explicit breaking)**.** With spontaneous internal breaking in the Gaiamiti sector and no explicit spurions, the typed predicate gives QII (global SSB eaten by BEH; cf. Proposition 9.251). Small explicit breaking moves the NG cluster to a pseudo–NG band with GMOR scaling, yielding QIV (cf. Definitions 7.685 and 9.188 and Proposition 9.197). In all cases, the TT graviton's massless pole persists (Remark 9.260), and Loc/On stamps and ledger updates follow Definitions 9.190 and 9.198 and Corollary 9.218.

Spectrum (Gaiamiti sector).

(i) Spin-0 (Apeiron, massive) Radial/trace scalar of $\hat{\mathbf{\Phi}}$ defined by the restricted Hessian (cf. Definition 9.259): the typed radial direction is generated by the normalized $\widehat{\mathsf{R}}_\Phi$ built from the typed projector $\Pi^{[\chi]}_{\Phi\Phi}$ (cf. Definitions 9.186, 9.200 and 9.256),

$$\widehat{\mathsf{R}}_\Phi \propto \bar{\Phi}, \qquad \mathcal{K}_{\mathrm{A}}^{(\Phi)} = \Pi_{\mathrm{A}}^{(\Phi)} \frac{\delta^2 \mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}\,\delta\hat{\mathbf{\Phi}}}\Big|_{\bar{\Phi}} \Pi_{\mathrm{A}}^{(\Phi)}, \quad M_{\mathrm{A}}^2 \in \mathrm{spec}\Big(\mathcal{K}_{\mathrm{A}}^{(\Phi)}\Big),$$

with diagnostic realized reference configuration discipline and BRST safety as in Propositions 9.191, 9.207 and 9.223.

(ii) Spin-1 (internal gauge bosons; massive if gauged and SSB) For G *gauged* and broken by $\bar{\Phi}$, internal vectors acquire BEH masses (cf. Proposition 9.257 and Definition 9.252):

$$(M^2)_{IJ} = g^2\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi},\ \rho_\Phi(T_J)\bar{\Phi}\Big),$$

giving transverse vector poles at $k^2 = m_V^2 \in \mathrm{spec}(M^2)$ in the typed vector/helicity channels (Definition 9.350). If the symmetry is gauged but *unbroken*, vectors remain massless; if *ungauged*, no internal vectors appear. Quadrant placement follows Propositions 9.251 and 9.254.

(iii) Spin-2 (graviton, massless TT) The typed TT mode keeps a protected pole at $k^2 = 0$ on $H^0(\hat{Q}_{\mathrm{BRST}})$ by the relational/diffeomorphism Ward structure (cf. Section 9.17.2 and Remark 9.260); the trace-channel scale m_A encodes Apeiron stiffness and is *not* a graviton mass.

Quadrants under internal gauging (exhaustiveness). The quadrant classification (Chs. 7–8) is defined via typed/triadic diagnostic realized reference configuration visibilities (law vs. state) and the canonical decision rule (Definitions 7.685 and 9.187), evaluated on $H^0(\hat{Q}_{\mathrm{BRST}})$ with route equivalence and Nielsen safety (Propositions 9.191, 9.207 and 9.223). Internal gauging modifies only the *realization* of SSB (NG $\to$ longitudinal vectors) and leaves the axes unchanged (Section 9.17.3 and Proposition 9.254); thus the four quadrants remain exhaustive:

(i) (QI) Law symmetric, state symmetric No NG/pNG cluster (Π_{NG} null in the typed channel; cf. Definition 9.249); in a gauged realization, internal vectors stay massless; the radial scalar may be gapped via $\mathcal{K}_{\mathrm{A}}^{(\Phi)}$ (Definition 9.259). Decision per Definition 7.685.

(ii) (QII) Law symmetric, state SSB SSB occurs; in a gauged realization, NG directions are eaten and internal vectors gain BEH masses (M^2) (Proposition 9.257 and Definition 9.252), while the radial (Higgs-like/Apeiron) scalar remains gapped by $\mathcal{K}_{\mathrm{A}}^{(\Phi)}$ (Definition 9.259). Typed predicate per Proposition 9.251.

(iii) (QIII) Irrelevant explicit breaking, state symmetric Law-side nonconservation heals with IR coarse-graining on $\mathfrak{P}$ (healing power law as in eq. (7.746)); flows to the QI limit independently of gauging. Decision per Definition 7.685.

(iv) (QIV) Relevant/marginal explicit breaking, state unique The law channel remains explicitly broken in the IR; typed sources do *not* heal (cf. Definition 9.188). If some broken global directions are left *ungauged*, a pNG scalar cluster appears with GMOR scaling (diagnostic realized reference configuration-level GMOR/NG diagnostics Proposition 9.197); if all broken directions are *gauged*, no physical NG/pNG scalars remain on H^0 (the would-be NG become longitudinal vectors via Definition 9.252 and Proposition 9.257).

Gauge fixing in R_ξ form and BRST closure keep both the physical poles (Apeiron radial and transverse vectors) and quadrant assignment gauge-parameter independent (Nielsen) and route-equivalent within tolerances (Definition 9.261 and Propositions 9.191 and 9.223).

9.17.5 The Composite Nature of the Goldstone Mode

The identification of the graviton as a massless Goldstone excitation (Section 9.17.2) correctly attributes its masslessness to spontaneous symmetry breaking (SSB) of a continuous symmetry of the Gaiamiti potential $\mathcal{V}_\Phi$, which guarantees flat directions along the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ [93, 94]. This does *not* imply a monolithic, structureless object: in the IQR framework the underlying Gaiamiti field $\hat{\mathbf{\Phi}}(x)$ is composite, and its BRST–physical TT Goldstone excitation inherits a *triadic* internal structure tied to the $\{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ channels on the diagnostic realized reference configuration.

Formal supplement (diagnostic realized reference configuration, typing, and triads). All statements below hold on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}$ and BRST projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$; the triadic projectors $\{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}$ commute with the typed projectors $\Pi_S^{[\chi]}$ (Definitions 9.185 and 9.186 and Proposition 9.202).

Definition 9.263 (Triadic decomposition of TT graviton components)**.** For the Gaiamiti sector $S = \Phi\Phi$ and type $[\chi] = \mathrm{TT}$, decompose the fluctuation and its metric image as

$$\delta\hat{\mathbf{\Phi}} = \sum_\alpha \Pi_\alpha\, \delta\hat{\mathbf{\Phi}}, \qquad \delta\hat{g}_{\mu\nu}(\delta\hat{\mathbf{\Phi}}) = \sum_\alpha \Pi_\alpha\, \delta\hat{g}_{\mu\nu}(\delta\hat{\mathbf{\Phi}}),$$

and define the *triadic TT graviton components* (on $\mathcal{H}_{\mathrm{phys}}$) by

$$\hat{h}_{\mu\nu}^{(\alpha)} \;:=\; \Pi_\alpha\, \Pi_{\Phi\Phi}^{[\mathrm{TT}]} \Big[\, \delta\hat{g}_{\mu\nu}\big(\delta\Phi_{\mathrm{tang}}\big) \,\Big], \qquad \delta\Phi_{\mathrm{tang}} \in T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}} \;\; \text{(SSB tangent)}.$$

The (unnormalized) composite TT graviton is $\hat{h}_{\mu\nu} := \sum_\alpha \hat{h}_{\mu\nu}^{(\alpha)}$.

Proposition 9.264 (Orthogonality, completeness, and typed NG content)**.** *In the SSB regime with* $\mathrm{Quad}^{[\Phi\Phi,\mathrm{TT}]} = \mathrm{QII}$ *(Definition 9.189), on* $\mathcal{H}_{\mathrm{phys}}$*:*

(i) Triadic orthogonality/completeness

$\Pi_\alpha \Pi_\beta = \delta_{\alpha\beta}\Pi_\alpha$, $\sum_\alpha \Pi_\alpha = \mathbb{1}$*; hence* $\langle \hat{h}^{(\alpha)}, \hat{h}^{(\beta)} \rangle = 0$ *for* $\alpha \neq \beta$ *and* $\hat{h} = \sum_\alpha \hat{h}^{(\alpha)}$.

(ii) Typed NG poles

Each typed–triadic TT readout

$$\Pi_\alpha \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\, G^{\mathrm{R}}_{\Phi\Phi,\mathrm{phys}}(k)\, \Pi^{[\mathrm{TT}]}_{\Phi\Phi} \Pi_\alpha$$

exhibits an exact NG pole at $k^2 = 0$ *with nonnegative residue (Proposition 9.197); at least one residue is strictly positive in QII.*

(iii) Nielsen/BRST safety

Gauge–parameter and BRST–exact deformations leave the above invariant (Propositions 9.191 and 9.207).

Definition 9.265 (Residue weights and normalized composite graviton)**.** Let the nonnegative NG residues on $\mathfrak{P}$ be

$$\mathcal{R}_\alpha \;:=\; \mathrm{Res}_{k^2=0}\Big[\Pi_\alpha \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\, G^{\mathrm{R}}_{\Phi\Phi,\mathrm{phys}}(k)\, \Pi^{[\mathrm{TT}]}_{\Phi\Phi} \Pi_\alpha\Big].$$

Define $c_\alpha := \mathcal{R}_\alpha \big/ \sqrt{\sum_\beta \mathcal{R}_\beta^2}$ (so $\sum_\alpha c_\alpha^2 = 1$). The *normalized composite TT graviton* is

$$\hat{h}^{\mathrm{phys}}_{\mu\nu} \;:=\; \sum_\alpha c_\alpha\, \hat{h}^{(\alpha)}_{\mu\nu},$$

canonically fixed by plateau residues and independent of the order of typed/triadic insertions (Proposition 9.207).

Corollary 9.266 (Channel semantics and operational identification)**.** *In QII for* $(\Phi\Phi, \mathrm{TT})$*, the* TT Goldstone multiplet *is realized; with a* $\bar{\Sigma}$*–admissible spatial splitting, this resolves into the two physical helicities* $\lambda = \pm 2$ *(Definition 9.200 and Proposition 9.243). The components* $\hat{h}^{(\alpha)}$ *encode correlational/vacuum/spectral imprints, and the weights* $\{c_\alpha\}$ *are fixed by the NG residues on* $\mathfrak{P}$*. A* spectral–only parasymmetric protocol *can reconstruct spin/helicity content and diagnose breaking without the Ward ledger, while correlational and vacuum channels carry complementary information; all are read on the same diagnostic realized reference configuration with identical tags (Definition 9.185).*

Remark 9.267 (Structural consistency and typed/triadic compatibility)**.** Because $\sum_\alpha \Pi_\alpha = \mathbb{1}$ and $[\Pi^{[\chi]}_{\Phi\Phi}, \Pi_\alpha] = 0$ (Proposition 9.202), the Goldstone tangent $\delta\Phi_{\mathrm{tang}} \in T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}}$ decomposes consistently as $\delta\Phi_{\mathrm{tang}} = \sum_\alpha \Pi_\alpha \delta\Phi_{\mathrm{tang}}$, and so does the TT graviton operator (Definition 9.263). This formalizes the "composite Goldstone" narrative without introducing extra physical degrees of freedom; it is a *decomposition in channels* of a single TT Goldstone multiplet, not an enlargement of the state space.

The Principle of Structural Consistency

The Gaiamiti kinetics couple $\hat{\mathbf{\Phi}}$ to the chronogeometric tensor $\bar{\Sigma}_{\mu\nu}(x)$, and $\bar{\Sigma}$ itself is not monolithic but carries a triadic decomposition (correlational, vacuum, spectral). Structural consistency then demands that the *same* channel structure be visible in the linear response of the source field: a single, undifferentiated fluctuation could not consistently interface with a tri-faceted geometry while preserving gauge/BRST consistency and causality.

On the DRCC (Definition 9.185) $\mathfrak{P}$, let $\{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}$ be the triadic projectors and $\Pi_S^{[\chi]}$ the typed projectors ($\chi \in \{\mathrm{Tr}, \mathrm{TT}\}$) with $[\Pi_S^{[\chi]}, \Pi_\alpha] = 0$ (Definition 9.186 and Proposition 9.202). Then every BRST–physical fluctuation admits the orthogonal decomposition

$$\delta\hat{\mathbf{\Phi}}(x) = \sum_\alpha \Pi_\alpha\, \delta\hat{\mathbf{\Phi}}(x), \qquad \langle \Pi_\alpha \delta\hat{\mathbf{\Phi}}, \Pi_\beta \delta\hat{\mathbf{\Phi}}\rangle = 0 \quad (\alpha \neq \beta),$$

and the induced metric fluctuation obeys the same split,

$$\delta\hat{g}_{\mu\nu}\Big(\delta\hat{\mathbf{\Phi}}\Big) = \sum_\alpha \Pi_\alpha\, \delta\hat{g}_{\mu\nu}\Big(\delta\hat{\mathbf{\Phi}}\Big),$$

so that typed and triadic filtrations are compatible in the sense of $\Pi_S^{[\chi]} \sum_\alpha \Pi_\alpha = \sum_\alpha \Pi_\alpha \Pi_S^{[\chi]}$. This is the precise content of "structural consistency".

The Emergence of a Composite Graviton

Narrative. In the SSB regime, massless excitations follow *Goldstone's theorem* [93, 94]: they propagate along the flat directions of $\mathcal{M}_{\mathrm{vac}}$. In our typed framework, the graviton arises in the TT channel as a Goldstone excitation (massless spin–2) of the Gaiamiti sector; its existence and masslessness are *dynamical* consequences of SSB, not assumptions (cf. the standard lore [91, 100, 97]). Because the fluctuation space is triadically resolved on $\mathfrak{P}$, the *single* TT Goldstone multiplet decomposes into channel components. This is a *decomposition in channels*, not an increase of physical degrees of freedom: the realized graviton field operator is a coherent superposition fixed by NG residues on the diagnostic realized reference configuration.

Typed/triadic construction. Restrict to the TT type in the Gaiamiti sector ($S = \Phi\Phi$). As in Definition 9.263, define the triadic TT components on $\mathcal{H}_{\mathrm{phys}}$ by

$$\hat{h}^{(\alpha)}_{\mu\nu}(x) := \Pi_\alpha\, \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\Big[\ \delta\hat{g}_{\mu\nu}\Big(\delta\Phi_{\mathrm{tang}}(x)\Big)\ \Big], \qquad \delta\Phi_{\mathrm{tang}}(x) \in T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}},$$

and set $\hat{h}_{\mu\nu} := \sum_\alpha \hat{h}^{(\alpha)}_{\mu\nu}$. On a certified plateau, let

$$\mathcal{R}_\alpha := \mathrm{Res}_{k^2=0}\Big(\Pi_\alpha \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\, G^{\mathrm{R}}_{\Phi\Phi,\mathrm{phys}}(k)\, \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\Pi_\alpha\Big)\ \geq 0,$$

be the NG residues (Proposition 9.264). With normalized weights $c_\alpha := \mathcal{R}_\alpha/\sqrt{\sum_\beta \mathcal{R}_\beta^2}$ one obtains the *normalized composite graviton* (Definition 9.265)

$$\boxed{\hat{h}^{\mathrm{phys}}_{\mu\nu}(x) = \sum_{\alpha\in\{\mathrm{corr,vac,spec}\}} c_\alpha\, \hat{h}^{(\alpha)}_{\mu\nu}(x), \quad \sum_\alpha c_\alpha^2 = 1,}$$

whose definition is independent of the order of typed/triadic insertions (Proposition 9.207) and Nielsen/BRST–safe on $\mathfrak{P}$.

Operational semantics.

- **Spectral component** ($\alpha = \text{spec}$): Dominates conventional wave–detection protocols; reproduces the familiar propagating gravitational radiation sector and is often the most visible witness of the Goldstone mechanism in practice.
- **Correlational component** ($\alpha = \text{corr}$): Encodes entanglement– and coherence–induced geometric response (off–diagonal correlator structure); probed by parasymmetric protocols sensitive to information–geometric channels.
- **Vacuum component** ($\alpha = \text{vac}$): Captures moduli/zero–point geometry associated with the vacuum bundle; affects background–response and slow deformations of the diagnostic realized reference configuration.

All three are read on the same diagnostic realized reference configuration with identical tags (Definition 9.185); together they constitute the *TT Goldstone multiplet*. Their weights $\{c_\alpha\}$ are *not* arbitrary model choices but are fixed by the BRST–physical NG residues on the certified plateau, ensuring a structurally consistent, composite Goldstone description that remains within a single physical state space.

An Analogy: The Emergence of "White" Light

A helpful analogy is the phenomenon of white light. One may describe the *mechanism* of broadband light emission from a hot object via black–body radiation; this single process produces "light." When analyzed through a prism, however, its *composition* is revealed as a superposition of a continuous spectrum of colors.

IQR reading of the analogy.

(i) Spontaneous symmetry breaking (SSB) Is the single, unified mechanism that guarantees a massless, spin–2 excitation — the graviton — via the standard Goldstone logic [93, 94] (cf. Section 9.17.2).

(ii) Triadic decomposition as prism The triadic decomposition of the geometry/field (correlational, vacuum, spectral) is the "prism" that reveals the graviton's internal composition: a coherent superposition of three TT Goldstone components aligned with the triadic sectors (cf. Section 9.17.5).

Thus, *graviton* is the singular operational name for the massless spin–2 Goldstone excitation of the Gaiamiti sector, while the IQR framework predicts that this excitation is *composite*: three co–propagating, TT–typed, NG contributions with sector–set weights fixed by their NG residues (see Definition 9.265). This mirrors familiar emergent phenomena where a single long–wavelength quasiparticle encodes rich microstructural content (e.g. phonons in solids) [390, 391, 459, 460]. The compositeness is falsifiable: on a certified plateau $\mathfrak{P}$, the triadic TT readouts share an exact NG pole at $k^2{=}0$ with nonnegative residues, and at least one strictly positive, while the trace/radial channel remains gapped (QI) (cf. Proposition 9.197).

9.17.6 The Emergence of the Massless Graviton via SSB

Overview. How can the fundamental geometric field carry an intrinsic energy scale m_A while its observable force carrier—the graviton—remains massless? In the IQR framework the answer is *spontaneous symmetry breaking* (SSB): the Lagrangian is symmetric, the realized vacuum is not, and the ensuing Goldstone logic protects a long–range, massless mode in the appropriate typed channel [93, 94, 91, 100].

1. The Principle of Spontaneously Broken Geometric Symmetry Assume the Gaiamiti action, and in particular its potential $\mathcal{V}_\Phi(\hat{\mathbf{\Phi}})$, is invariant under a continuous internal symmetry $\mathcal{G}$ acting on the vacuum manifold $\mathcal{M}_{\text{vac}}$ (Definition 6.61). The realized background $\bar{\Phi}(x)$ may preserve only a subgroup $\mathcal{H} \subset \mathcal{G}$, thereby breaking $\mathcal{G} \to \mathcal{H}$. By **Goldstone's theorem** [93, 94], each broken generator yields a massless mode propagating along a flat direction of $\mathcal{M}_{\text{vac}}$.

In our typed/diagnostic realized reference configuration setting, this principle is applied to the geometric sector: the observable, massless spin–2 *graviton* is realized as a TT–typed Goldstone excitation of the Gaiamiti field on $H^0(\hat{Q}_{\text{BRST}})$. Its masslessness is thus *dynamically protected* by SSB (not assumed), mirroring familiar mechanisms in gauge theories (cf. Higgs/BEH and electroweak symmetry breaking) [97, 91].

2. The Graviton as a Composite Excitation of the Apeiron Field The graviton is a specific fluctuation of the underlying *Apeiron* field, i.e. the quantum of $\delta\hat{\mathbf{\Phi}}(x)$ (Section 9.17.1). Structural consistency (Section 9.17.5) requires that fluctuations be resolved by the triadic projectors $\{\Pi_{\text{corr}}, \Pi_{\text{vac}}, \Pi_{\text{spec}}\}$; hence

$$\delta\hat{\mathbf{\Phi}}(x) = \delta\hat{\mathbf{\Phi}}^{(\text{corr})}(x) + \delta\hat{\mathbf{\Phi}}^{(\text{vac})}(x) + \delta\hat{\mathbf{\Phi}}^{(\text{spec})}(x).$$

The Goldstone mode guaranteed by SSB is an excitation *of this composite field*. Consequently, the realized massless graviton inherits a triadic composition: in the TT type it is a coherent superposition of three channel components with weights fixed by NG residues on the certified plateau (Section 9.17.5):

$$\hat{h}_{\mu\nu}(x) = \hat{h}^{(\text{corr})}_{\mu\nu}(x) + \hat{h}^{(\text{vac})}_{\mu\nu}(x) + \hat{h}^{(\text{spec})}_{\mu\nu}(x), \qquad \hat{h}^{\text{phys}}_{\mu\nu}(x) = \sum_\alpha c_\alpha\, \hat{h}^{(\alpha)}_{\mu\nu}(x),$$

with $\sum_\alpha c_\alpha^2 = 1$ and c_α determined by the residues of the TT NG pole in each triadic channel (diagnostic realized reference configuration–certified; Nielsen/BRST–safe).

Correlators and propagators. Propagation of geometric fluctuations is encoded in the connected two–point function of the Gaiamiti sector, $\hat{G}_{\Phi\Phi}(x, x')$ (eq. (10.80)). The complete geometric two–point structure is organized in the matrix propagator $\mathbf{G}^{(2)}_\Sigma(x, x')$ (Definition 10.182). The graviton propagator is the TT–typed, spin–2 component,

$$G^{\text{grav}}_{\mu\nu\rho\sigma}(x, x') = \langle \Omega \,|\, T\{\hat{h}_{\mu\nu}(x)\, \hat{h}_{\rho\sigma}(x')\} \,|\, \Omega \rangle,$$

and—by the Goldstone mechanism—exhibits a long–range massless pole at $k^2 = 0$ with positive residue on H^0 in the SSB–only regime. Thus, even though the Apeiron sector carries an intrinsic scale m_A, there is *no* restoring force (and hence no mass term) along the TT Goldstone directions; gravity remains long–range.

3. Physical Interpretation and Resolution of the Mass Paradox This synthesis separates the constituent from the emergent excitation. The parameter m_A is not the graviton mass; it is an intrinsic *stiffness* scale of the relational vacuum encoded by $\mathcal{V}_\Phi$ (cf. Section 9.17.1). Large m_A means a geometry that is costly to deform in the radial/trace channel, while the TT channel retains an SSB–protected, massless Goldstone band. The apparent paradox—"intrinsic scale vs. massless force carrier''—is resolved exactly as in other emergent settings: long–wavelength quanta can behave very differently from their building blocks. Standard examples include phonons in crystals, where massive atoms yield nearly massless collective modes that carry sound and heat [390, 391, 459].

Emergence: Whole vs. Parts (operational view)

(i) Apeiron. The Apeiron is the constituent quantum of $\delta\hat{\mathbf{\Phi}}$, equipped with an intrinsic scale m_A; by structural consistency it lives in triadic channels (correlational, vacuum, spectral).

(ii) Graviton. The graviton is the *collective* massless TT Goldstone excitation—protected by SSB, realized on H^0, and *composite* across the triad with diagnostic realized reference configuration–fixed weights (Section 9.17.5).
Read together, these points show why geometry may possess an intrinsic energy scale while gravity remains long–range: the observable graviton is a massless, TT–typed Goldstone excitation of a triadically structured field, not a direct readout of the constituent stiffness. The framework's predictions (exact TT NG pole; gapped trace/Apeiron channel; triadic residue weights) are concrete, falsifiable features of the diagnostic realized reference configuration.

9.17.7 Euler–Lagrange Equation for the Gaiamiti Field

Having established the action functional for the Gaiamiti field, we now derive its dynamical law. By the Principle of Stationary Action ($\delta S_\Phi = 0$), we obtain an *operator–valued* equation of motion that governs how relational geometry evolves under quantum self–interaction. This is not a wave equation on a fixed background: it is the evolution equation *of the background itself*.

Diagnostic realized reference configuration/typed refinement (realized regime). Work on the diagnostic realized reference configuration $\mathfrak{P}$ (Definition 9.185) and vary the Gaiamiti action $S_\Phi[\hat{\mathbf{\Phi}}; \bar{\Sigma}]$ (cf. Definition 9.235 and §6.5). Project to the BRST–physical sector and impose the Euler–Lagrange (EL) equation as

$$\mathsf{P}_{\text{phys}} \frac{\delta S_\Phi}{\delta \hat{\mathbf{\Phi}}} = 0 \quad \text{on } \mathcal{H}_{\text{phys}},$$

with all limits taken inside the certified plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$) per Chapter 8.

Typed EL split. Insert the BRST–closed typed projectors $\Pi^{[\chi]}_{\Phi\Phi}$ (Definitions 9.186, 9.195 and 9.200) and decompose about the realized vacuum $\bar{\Phi}$ (cf. eq. (10.87)):

$$\delta\hat{\mathbf{\Phi}} = \delta\hat{\mathbf{\Phi}}^{[\mathrm{TT}]} \oplus \delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}, \qquad \delta\hat{\mathbf{\Phi}}^{[\chi]} := \Pi^{[\chi]}_{\Phi\Phi}\, \delta\hat{\mathbf{\Phi}}.$$

Then, on $\mathcal{H}_{\mathrm{phys}}$,

$$\begin{aligned} &\text{(trace / radial)} \quad \left(\bar{\nabla}^{\mu}\bar{\nabla}_{\mu} - \mathcal{M}_{[\mathrm{Tr}]}(x)\right) \delta\hat{\mathbf{\Phi}}^{[\mathrm{Tr}]}(x) = 0, \\ &\text{(TT / tangential)} \quad \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\, \mathcal{L}_{\mathrm{TT}}[\bar{\Sigma}] \left(\delta\hat{g}(\delta\Phi_{\mathrm{tang}})\right) = 0, \end{aligned}$$

where $\bar{\nabla}$ is the Relational Levi–Civita connection of $\bar{\Sigma}$ (Definition 6.7), $\mathcal{M}_{[\mathrm{Tr}]}$ is the typed mass operator from the potential Hessian at $\bar{\Phi}$ (Definition 9.246), and $\mathcal{L}_{\mathrm{TT}}[\bar{\Sigma}]$ is the (Lichnerowicz–type) linearized geometric operator acting on the TT metric deformation induced by the Goldstone tangent $\delta\Phi_{\mathrm{tang}} \in T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}}$ (§9.17.2). The TT equation encodes the null curvature along $\mathcal{M}_{\mathrm{vac}}$ (QII NG pole; Proposition 9.197); the trace equation shows a gap set by the Apeiron scale (QI).

Boundary terms and safety. Natural boundary conditions on $\mathfrak{P}_{\partial}$ follow from the same variation with the bulk/edge overlay (Definition 9.214); the resulting typed EL equations (bulk/edge) are Nielsen–flat and BRST–safe by Propositions 9.191 and 9.207. By Proposition 9.223, the solutions' typed spectra agree with the SynTh/correlational route within Chapter 8 tolerances.

Definition 9.268 (Euler–Lagrange Equation for $\hat{\mathbf{\Phi}}(x)$)**.** Let $\hat{\mathbf{\Phi}}(x)$ be the dynamical Gaiamiti field with action $S_{\Phi}[\hat{\mathbf{\Phi}}]$ (Definition 6.174). Using the shorthand measure $\sqrt{-\det\left(\bar{\Sigma}\right)}$ for the relational volume (as noted in Remark 6.7's discussion of the volume element), the operator–valued EL equation can be written in the manifestly covariant form:

$$\boxed{\frac{1}{\sqrt{-\det\left(\bar{\Sigma}\right)}}\, \nabla_{\mu}\left(\sqrt{-\det\left(\bar{\Sigma}\right)}\, \bar{\Sigma}^{\mu\nu}\, \nabla_{\nu}\hat{\mathbf{\Phi}}(x)\right) = \frac{\delta\mathcal{V}_{\Phi}}{\delta\hat{\mathbf{\Phi}}^{\dagger}(x)}.} \tag{9.107}$$

Expanding the covariant divergence gives the equivalent local form

$$\boxed{\bar{\Sigma}^{\mu\nu}(x)\, \nabla_{\mu}\nabla_{\nu}\hat{\mathbf{\Phi}}(x) + \left(\nabla_{\mu}\bar{\Sigma}^{\mu\nu}(x)\right) \nabla_{\nu}\hat{\mathbf{\Phi}}(x) = \frac{\delta\mathcal{V}_{\Phi}}{\delta\hat{\mathbf{\Phi}}^{\dagger}(x)}.} \tag{9.108}$$

By metric compatibility of the Relational Levi–Civita connection and the fact that the operator–bundle connection acts only on internal (fiber) indices, one has

$$\nabla_{\mu}\bar{\Sigma}^{\mu\nu} = 0,$$

so that (9.108) reduces on the diagnostic realized reference configuration to

$$\bar{\Sigma}^{\mu\nu}\, \nabla_{\mu}\nabla_{\nu}\hat{\mathbf{\Phi}} = \frac{\delta\mathcal{V}_{\Phi}}{\delta\hat{\mathbf{\Phi}}^{\dagger}},$$

which is identical to (9.107). Here:

(i) Total covariant derivative

The total covariant derivative $\nabla_\mu = \nabla_\mu^{(\mathrm{rel})} + D_\mu$ splits into the Relational Levi–Civita part acting on spacetime indices and the operator–bundle connection D_μ acting on internal operator–space indices (Section 6.6).

(ii) Source term

The source term $\delta\mathcal{V}_\Phi/\delta\hat{\mathbf{\Phi}}^\dagger$ is the functional derivative of the potential $\mathcal{V}_\Phi$, which is built from the tangent–space inner product g_T (Section 6.1.24).

Interpretation of the Equation. This equation is a background–independent, operator–valued generalization of the Klein–Gordon equation [461]. The left–hand side is a generalized covariant d'Alembertian built from the chronogeometric tensor $\bar{\Sigma}_{\mu\nu}(x)$; it governs the *propagation of relational geometric deformations*. The right–hand side is a *source term* that encodes self–interaction and the vacuum–selection dynamics through $\delta\mathcal{V}_\Phi/\delta\hat{\mathbf{\Phi}}^\dagger$. Using metric compatibility of the relational Levi–Civita connection, $\nabla_\mu\bar{\Sigma}^{\mu\nu} = 0$, the expanded form reduces on the diagnostic realized reference configuration to

$$\bar{\Sigma}^{\mu\nu}\nabla_\mu\nabla_\nu\hat{\mathbf{\Phi}}(x) = \frac{\delta\mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger(x)}\,,$$

so the *same* operator governs both propagation and self–consistent back–reaction: this is not a wave on a fixed background but the evolution equation *of* the backgrounded geometry itself.

Expectation–Level Equation. Taking the expectation value in the quantum holo–state $\left|\overset{\circ}{\mathbf{\Psi}}\right\rangle$ yields the semiclassical equation for the mean field $\varphi(x) := \langle\hat{\mathbf{\Phi}}(x)\rangle$:

$$\left\langle \frac{1}{\sqrt{-\det\bar{\Sigma}}}\,\nabla_\mu\Big(\sqrt{-\det\bar{\Sigma}}\,\bar{\Sigma}^{\mu\nu}\nabla_\nu\hat{\mathbf{\Phi}}(x)\Big)\right\rangle = \left\langle\frac{\delta\mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger(x)}\right\rangle.$$

Because the RHS is nonlinear in $\hat{\mathbf{\Phi}}$, expectations and variations do not commute in general. On a certified plateau one may package fluctuation effects into an *effective* potential, $\langle\delta\mathcal{V}_\Phi/\delta\hat{\mathbf{\Phi}}^\dagger\rangle = \delta\mathcal{V}_{\mathrm{eff}}/\delta\varphi^\dagger$, so that the expectation–level dynamics take the standard curved–spacetime semiclassical form [10, 245]:

$$\bar{\Sigma}^{\mu\nu}\nabla_\mu\nabla_\nu\varphi(x) = \frac{\delta\mathcal{V}_{\mathrm{eff}}}{\delta\varphi^\dagger(x)}\,, \qquad (\text{BRST/Nielsen–safe on } \mathcal{H}_{\mathrm{phys}}).$$

The Euler–Lagrange Equation as the Fundamental Dynamical Principle Governing the Apeiron (refined)

The EL equation for the Gaiamiti sector is the relativistic wave equation for the *Apeiron*—the quantum of relational geometry—prescribing both its propagation and its self–interaction on the emergent chronogeometric manifold.

1. Kinetic component: propagative dynamics of the Apeiron. The left–hand side, $\bar{\Sigma}^{\mu\nu}\nabla_\mu\nabla_\nu\hat{\mathbf{\Phi}}$, is a manifestly covariant d'Alembertian with the total derivative $\nabla_\mu = \nabla_\mu^{(\mathrm{rel})} + D_\mu$ (relational Levi–Civita on spacetime indices plus operator–bundle connection on internal indices). With $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Sections 5.2.6 and 5.2.8), this term describes not a field *on* a fixed stage, but the propagation of the geometric structure *itself*. The field $\hat{\mathbf{\Phi}}$ is at once dynamical and geometric.

2. Potential component: intrinsic scale and self–interaction of the Apeiron. The source term is the potential gradient $\delta\mathcal{V}_\Phi/\delta\hat{\mathbf{\Phi}}^\dagger$ (Section 9.17). For the unbroken–phase normalization used elsewhere,

$$\mathcal{V}_\Phi(\hat{\mathbf{\Phi}}) = \tfrac{1}{2}\, m_A^2\, g_T(\hat{\mathbf{\Phi}},\hat{\mathbf{\Phi}}) + \tfrac{\lambda_A}{4!}\,[g_T(\hat{\mathbf{\Phi}},\hat{\mathbf{\Phi}})]^2 + \cdots,$$

one finds near the symmetric background (treating $\hat{\mathbf{\Phi}}, \hat{\mathbf{\Phi}}^\dagger$ as independent)

$$\frac{\delta\mathcal{V}_\Phi{}^\dagger}{\delta\hat{\mathbf{\Phi}}} = \tfrac{1}{2}\, m_A^2\, \hat{\mathbf{\Phi}} + \tfrac{\lambda_A}{12}\, S\, \hat{\mathbf{\Phi}} + \cdots, \qquad S := g_T(\hat{\mathbf{\Phi}},\hat{\mathbf{\Phi}}),$$

so the leading restoring tendency is set by the intrinsic *Apeiron scale* m_A. This scale is not a "graviton mass"; it quantifies the stiffness of the radial/trace channel:

(i) Energetic cost It fixes the energetic cost of deforming the relational vacuum.

(ii) Curvature rigidity Larger m_A implies greater curvature rigidity (smaller susceptibility).

(iii) Correlation length The characteristic correlation length scales as $\xi_A \sim m_A^{-1}$ (up to the conventional normalization just noted).

By contrast, the TT (tangential) directions are flat in the SSB–only regime, so no mass term can arise there.

Synthesis: the unified principle of propagation. The EL equation,

$$\bar{\Sigma}^{\mu\nu}\nabla_\mu\nabla_\nu\hat{\mathbf{\Phi}} = \frac{\delta\mathcal{V}_\Phi{}^\dagger}{\delta\hat{\mathbf{\Phi}}},$$

unifies (i) the **kinematic** law of geometric propagation (generalized covariant d'Alembertian) with (ii) the **intrinsic energy/self–interaction** encoded by the potential gradient. In the typed split, the trace channel obeys a gapped KG–like law with mass operator $\mathcal{M}_{[\mathrm{Tr}]}$ (QI), whereas the TT channel satisfies a Lichnerowicz–type equation along Goldstone directions (QII) with an exact massless pole protected by SSB. Thus spacetime curvature and gravitational radiation emerge as *collective* solutions of a single operator equation, reconciling an intrinsic geometric scale m_A with a massless, long–range graviton consistent with observation.

Definition 9.269 (HS Euler–Lagrange equation for $\hat{\mathbf{\Phi}}$)**.** Let the HS Gaiamiti Lagrangian be

$$\mathcal{L}_\Phi^{\mathrm{HS}} = \mathrm{Tr}_{\mathrm{FD}}\Big\{\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}\, g_T^{\mathrm{HS}}\Big(\mathcal{D}_\mu^{\mathrm{HS}}\hat{\mathbf{\Phi}},\, \mathcal{D}_\nu^{\mathrm{HS}}\hat{\mathbf{\Phi}}\Big) - \mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\mathbf{\Phi}})\Big\} \quad (\text{cf. } \textit{Section } 6.5.2 \textit{and Definition } 6.34).$$

Varying $\widehat{\boldsymbol{S}}_\Phi = \int d\boldsymbol{\mu}\, \mathcal{L}_\Phi^{\mathrm{HS}}$ with $\mathcal{D}_\mu^{\mathrm{HS}}$ from eq. (6.259) and $d\boldsymbol{\mu}$ from Definition 6.34, the HS Euler–Lagrange equation reads

$$\boxed{\mathcal{D}_\mu^{\mathrm{HS}}\Big(\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}\,\mathfrak{J}_\nu\Big) \;-\; \frac{\delta}{\delta\hat{\boldsymbol{\Phi}}}\,\mathrm{Tr}_{\mathrm{FD}}\Big\{\mathcal{V}_\Phi^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}})\Big\} \;=\; 0,} \tag{9.109}$$

with conjugate HS current

$$\boxed{\mathfrak{J}_\nu := \frac{\delta}{\delta(\mathcal{D}_\nu^{\mathrm{HS}}\hat{\boldsymbol{\Phi}})}\,\mathrm{Tr}_{\mathrm{FD}}\Big\{\, g_T^{\mathrm{HS}}\Big(\mathcal{D}_\nu^{\mathrm{HS}}\hat{\boldsymbol{\Phi}},\,\cdot\,\Big)\Big\}.} \tag{9.110}$$

Here g_T^{HS} is the HS vacuum–tangent inner product (Definition 6.106), and $\mathcal{V}_\Phi^{\mathrm{HS}}$ is any real functional of $\mathcal{I}_\Phi^{\mathrm{HS}} = g_T^{\mathrm{HS}}(\hat{\boldsymbol{\Phi}},\hat{\boldsymbol{\Phi}})$ (Definitions 9.236 and 9.237).

Sketch. Use compactly supported variations and metric compatibility $\nabla_\lambda^{(\mathrm{rel})}\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu} = 0$ (Levi–Civita; Definition 6.7), plus the divergence identity with $d\boldsymbol{\mu}$ (Definition 6.34) to integrate by parts. The potential variation is given by Lemma 9.240. Cyclicity of $\mathrm{Tr}_{\mathrm{FD}}$ (Definition 6.45 and eq. (6.99)) and the inner-derivation property of $\mathcal{D}_\mu$ (Remark 6.187) yield (9.109)–(9.110). □

Remark 9.270 (Tantrakyma status)**.** The HS Euler–Lagrange equation for the Tantrakyma field is given in Definition 9.321, built from g_C^{HS}, $\mathcal{D}_\mu^{\mathrm{HS}}$ (eq. (9.150)), and $\boldsymbol{g}^{\mathrm{Lor}}$ with the same invariant measure (Definition 6.34).

9.17.8 Noether Current for the Dynamical Gaiamiti Field

Assume the Gaiamiti action $S_\Phi[\hat{\boldsymbol{\Phi}}]$ is invariant under a continuous internal symmetry generated by a Hermitian $\hat{Q}$ that preserves the kinetic structures $(\bar{\Sigma}_{\mu\nu},\, g_T)$ and is compatible with the split covariant derivative $\nabla_\mu = \nabla_\mu^{(\mathrm{rel})} + (\partial_\mu + i[\mathcal{A}_\mu,\cdot])$ (cf. Section 6.12.2 and eq. (6.316)). Then the infinitesimal transformation

$$\delta\hat{\boldsymbol{\Phi}}(x) = i\,\epsilon(x)\,[\hat{Q},\hat{\boldsymbol{\Phi}}(x)], \qquad \delta\hat{\boldsymbol{\Phi}}^\dagger(x) = -i\,\epsilon(x)\,[\hat{Q},\hat{\boldsymbol{\Phi}}^\dagger(x)]$$

leads, by Noether's procedure, to a conserved current on shell.

Definition 9.271 (Noether current for the Gaiamiti sector)**.** Let $\mathcal{L}_\Phi$ be the operator-valued Lagrangian density of the Gaiamiti field (Definition 6.174 and eq. (6.316)). The associated operator-valued Noether current is

$$\boxed{\hat{J}^\mu_{(\Phi)}(x) := -i\,\mathrm{Tr}\Big\{\frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\boldsymbol{\Phi}})}\,[\hat{Q},\hat{\boldsymbol{\Phi}}] - \frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\boldsymbol{\Phi}}^\dagger)}\,[\hat{Q},\hat{\boldsymbol{\Phi}}^\dagger]\Big\},} \tag{9.111}$$

where the Fréchet derivatives are taken at fixed $\bar{\Sigma}$ and $\mathcal{A}_\mu$. Equivalently, one may write

$$\hat{J}^\mu_{(\Phi)} = -i\,\mathrm{Tr}\Big\{\frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\boldsymbol{\Phi}})}[\hat{Q},\hat{\boldsymbol{\Phi}}]\Big\} + \mathrm{h.c.}$$

Specialization to the kinetic form. For

$$\mathcal{L}_\Phi = \mathrm{Tr}\Big\{\bar{\Sigma}^{\rho\nu}\, g_T(\nabla_\rho\hat{\mathbf{\Phi}}, \nabla_\nu\hat{\mathbf{\Phi}}) + \mathcal{V}_\Phi(\hat{\mathbf{\Phi}})\Big\} \quad \text{(cf. eq. (6.316))},$$

$$\frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})} = \bar{\Sigma}^{\mu\nu}\, g_T^\sharp\Big(\nabla_\nu\hat{\mathbf{\Phi}}, \cdot\Big),$$

so one may render (9.111) as

$$\hat{J}^\mu_{(\Phi)}(x) = -i\,\mathrm{Tr}\Big\{\bar{\Sigma}^{\mu\nu}\Big[g_T\Big(\nabla_\nu\hat{\mathbf{\Phi}}, [\hat{Q}, \hat{\mathbf{\Phi}}]\Big) - g_T\Big([\hat{Q}, \hat{\mathbf{\Phi}}^\dagger], \nabla_\nu\hat{\mathbf{\Phi}}^\dagger\Big)\Big]\Big\}.$$

Proposition 9.272 (Covariant conservation (diagnostic realized reference configuration/H^0))**.** *If $\hat{\mathbf{\Phi}}$ satisfies its Euler–Lagrange equation*

$$\frac{1}{\sqrt{-\det\bar{\Sigma}}}\,\nabla_\mu\Big(\sqrt{-\det\bar{\Sigma}}\,\bar{\Sigma}^{\mu\nu}\nabla_\nu\hat{\mathbf{\Phi}}\Big) = \frac{\delta\mathcal{V}_\Phi}{\delta\hat{\mathbf{\Phi}}^\dagger} \quad \textit{(cf. Definition 9.268)},$$

then the expectation-level current $\bar{J}^\mu_{(\Phi)} := \langle\overset{\circ}{\mathbf{\Psi}}|\hat{J}^\mu_{(\Phi)}|\overset{\circ}{\mathbf{\Psi}}\rangle$ is covariantly conserved on the certified plateau:

$$\boxed{\nabla^{(\mathrm{rel})}_\mu\, \bar{J}^\mu_{(\Phi)}(x) = 0 \qquad \textit{on } \mathcal{H}_{\mathrm{phys}}.} \tag{9.112}$$

Moreover, band-tagging and BRST improvements preserve the Ward identity: the BRST–improved, band-limited current obeys the scale-tagged Ward law stated in Definition 7.567, with exact conservation in QI/QII and adjoint sources only when explicit breaking spurions are present (QIV).

Proof. We work with the covariant density $\mathcal{L}_\Phi$ and the shorthand $S_\Phi = \int d^dx\,\sqrt{-\det\bar{\Sigma}}\,\mathcal{L}_\Phi$. Assume the internal symmetry generated by Hermitian $\hat{Q}$ is compatible with the split derivative, i.e. $[\nabla_\mu, \mathrm{ad}_{\hat{Q}}] = 0$ and it preserves the kinetic structures $(\bar{\Sigma}_{\mu\nu}, g_T)$. Treat $\hat{\mathbf{\Phi}}$ and $\hat{\mathbf{\Phi}}^\dagger$ as independent variables.

Step 1: Localized symmetry variation. Promote the global parameter to a smooth test function $\epsilon(x)$ (standard Noether trick) and set

$$\delta_\epsilon\hat{\mathbf{\Phi}} = i\,\epsilon(x)\,[\hat{Q}, \hat{\mathbf{\Phi}}], \qquad \delta_\epsilon\hat{\mathbf{\Phi}}^\dagger = -i\,\epsilon(x)\,[\hat{Q}, \hat{\mathbf{\Phi}}^\dagger].$$

By compatibility, $\delta_\epsilon(\nabla_\mu\hat{\mathbf{\Phi}}) = \nabla_\mu(\delta_\epsilon\hat{\mathbf{\Phi}})$, hence $\delta_\epsilon(\nabla_\mu\hat{\mathbf{\Phi}}) = i(\nabla_\mu\epsilon)\,[\hat{Q}, \hat{\mathbf{\Phi}}] + i\epsilon\,[\hat{Q}, \nabla_\mu\hat{\mathbf{\Phi}}]$, and similarly for $\hat{\mathbf{\Phi}}^\dagger$.

Step 2: Variation of the density and covariant integration by parts. Using the chain rule (including the $\hat{\mathbf{\Phi}}^\dagger$ sector) and suppressing explicit $\sqrt{-\det\bar{\Sigma}}$,

$$\begin{aligned}\delta_\epsilon\mathcal{L}_\Phi &= \mathrm{Tr}\Big\{\frac{\partial\mathcal{L}_\Phi}{\partial\hat{\mathbf{\Phi}}}\,\delta_\epsilon\hat{\mathbf{\Phi}} + \frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})}\,\delta_\epsilon(\nabla_\mu\hat{\mathbf{\Phi}})\Big\} + \mathrm{h.c.}\\ &= \mathrm{Tr}\Big\{\Big(\frac{\partial\mathcal{L}_\Phi}{\partial\hat{\mathbf{\Phi}}} - \nabla_\mu\frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})}\Big)\delta_\epsilon\hat{\mathbf{\Phi}}\Big\} + \nabla^{(\mathrm{rel})}_\mu\,\mathrm{Tr}\Big\{\frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})}\,\delta_\epsilon\hat{\mathbf{\Phi}}\Big\} + \mathrm{h.c.}\end{aligned}$$

Here we used metric compatibility of $\nabla^{(\mathrm{rel})}$ for the divergence and that the bundle connection acts only on fiber indices.

Step 3: Identify the current. Insert the explicit form of $\delta_\epsilon \hat{\mathbf{\Phi}}$ and collect the $\nabla_\mu \epsilon$ terms:

$$\delta_\epsilon \mathcal{L}_\Phi = -(\nabla_\mu^{(\mathrm{rel})} \epsilon)\, \hat{J}^\mu_{(\Phi)} + \epsilon\, \mathcal{E} \;+\; \mathrm{h.c.},$$

where

$$\hat{J}^\mu_{(\Phi)} := -i\,\mathrm{Tr}\Big\{ \frac{\partial \mathcal{L}_\Phi}{\partial(\nabla_\mu \hat{\mathbf{\Phi}})}\,[\hat{Q}, \hat{\mathbf{\Phi}}] - \frac{\partial \mathcal{L}_\Phi}{\partial(\nabla_\mu \hat{\mathbf{\Phi}}^\dagger)}\,[\hat{Q}, \hat{\mathbf{\Phi}}^\dagger] \Big\}$$

is exactly (9.111), and

$$\mathcal{E} := i\;\mathrm{Tr}\Big\{ \Big(\frac{\partial \mathcal{L}_\Phi}{\partial \hat{\mathbf{\Phi}}} - \nabla_\mu \frac{\partial \mathcal{L}_\Phi}{\partial(\nabla_\mu \hat{\mathbf{\Phi}})} \Big)[\hat{Q}, \hat{\mathbf{\Phi}}] \Big\} - \;i\;\mathrm{Tr}\Big\{ \Big(\frac{\partial \mathcal{L}_\Phi}{\partial \hat{\mathbf{\Phi}}}^{\dagger} - \nabla_\mu \frac{\partial \mathcal{L}_\Phi}{\partial(\nabla_\mu \hat{\mathbf{\Phi}}^\dagger)} \Big)[\hat{Q}, \hat{\mathbf{\Phi}}^\dagger] \Big\}.$$

Thus the variation of the action reads

$$\delta_\epsilon S_\Phi = \int d^d x\, \sqrt{-\det \bar{\Sigma}}\, \Big(-(\nabla_\mu^{(\mathrm{rel})} \epsilon)\, \hat{J}^\mu_{(\Phi)} + \epsilon\, \mathcal{E} + \mathrm{h.c.} \Big).$$

Step 4: Global invariance and on-shell conservation. For a *global* symmetry, $\epsilon = \mathrm{const}$ and invariance gives $\delta_\epsilon S_\Phi = 0$. Allowing $\epsilon(x)$ to have compact support and integrating by parts,

$$\delta_\epsilon S_\Phi = \int d^d x\, \sqrt{-\det \bar{\Sigma}}\, \epsilon(x) \Big(\nabla_\mu^{(\mathrm{rel})} \hat{J}^\mu_{(\Phi)} + \mathcal{E} + \mathrm{h.c.} \Big).$$

On shell, the Euler–Lagrange equations (Definition 9.268) annihilate $\mathcal{E} + \mathrm{h.c.}$. Since $\epsilon(x)$ is arbitrary, we obtain the operator identity $\nabla_\mu^{(\mathrm{rel})} \hat{J}^\mu_{(\Phi)} = 0$. Taking expectations in the Quantum Holo–State $\big|\mathring{\mathbf{\Psi}}\big\rangle$ yields

$$\nabla_\mu^{(\mathrm{rel})}\, \bar{J}^\mu_{(\Phi)}(x) = 0,$$

which is precisely (9.112). □

Diagnostic realized reference configuration and sector. Work on the instrumented diagnostic realized reference configuration (Definition 9.185) in the Gaiamiti sector $S = \Phi\Phi$. Let G act on $\hat{\mathbf{\Phi}}$ with generators T_A (Lie-algebra indices A), and let $\bar{\nabla}$ be the Levi–Civita derivative of $\bar{\Sigma}$ (Definition 6.7). All statements below are on $\mathcal{H}_{\mathrm{phys}}$ and within a certified plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$) per Chapter 8.

Definition 9.273 (Dynamical Noether current on H^0 (Gaiamiti))**.** Consider the Gaiamiti Lagrangian density $\mathcal{L}_\Phi(\hat{\mathbf{\Phi}}, \nabla\hat{\mathbf{\Phi}}; \bar{\Sigma})$ entering S_Φ (cf. §6.5, Definition 9.235). For an infinitesimal *global* transformation $\delta_A \hat{\mathbf{\Phi}} = i\,\epsilon\, T_A \hat{\mathbf{\Phi}}$, define the operator Noether current

$$\hat{\mathcal{J}}^\mu_A \;:=\; \frac{\partial \mathcal{L}_\Phi}{\partial(\nabla_\mu \hat{\mathbf{\Phi}})} \big(i\, T_A \hat{\mathbf{\Phi}} \big) \;+\; \mathrm{h.c.}$$

and its BRST–physical projection $\mathcal{J}^\mu_A := \mathsf{P}_{\mathrm{phys}}\, \hat{\mathcal{J}}^\mu_A\, \mathsf{P}_{\mathrm{phys}}$ on $\mathcal{H}_{\mathrm{phys}}$. For typed/triadic readings we use the commuting projectors $\Pi^{[\chi]}_{\Phi\Phi}$ (Definitions 9.186 and 9.200) and Π_α with $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Chapter 9 triad), and write the typed/triadic current as

$$\mathcal{J}^{\mu,[\chi]}_{A,(\alpha)} \;:=\; \Pi_\alpha\, \Pi^{[\chi]}_{\Phi\Phi}\, \mathcal{J}^\mu_A\, \Pi^{[\chi]}_{\Phi\Phi}\, \Pi_\alpha.$$

Remark 9.274 (Notation: generator index A vs. kinetic operator A_x)**.** In Definition 9.273 (and Definition 9.278) the symbol A is a *Lie–algebra index* that labels the generator T_A, the charge $\hat{Q}_A$, and the current $\mathcal{J}^\mu_A$. It is not an operator. Summation over A contracts with the invariant internal metric (equivalently via the Hermitian–completion map $\mathsf{H}[\cdot]$ componentwise) and has no relation to the Legendre/Riesz identification.

By contrast, A_x in Proposition 9.292 (case B) is a *fiberwise kinetic/inertia operator* on the vacuum tangent space $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$, appearing in the diagnostic realized reference configuration kinetic term

$$\mathcal{L}_{\Phi,\mathrm{kin}} = \tfrac{1}{2}\, g_T^{(x)}\Big(\dot{\Phi},\ \mathsf{A}_x\,\dot{\Phi}\Big),$$

with A_x positive, boundedly invertible, and $g_T^{(x)}$–self–adjoint. It implements the Legendre/Riesz isometry $\mathcal{R}_x^{(\mathsf{A})} : T_{|\Omega}\mathcal{M}_{\mathrm{vac}} \to T^*_{|\Omega}\mathcal{M}_{\mathrm{vac}}$ and, on the diagnostic realized reference configuration, commutes with the typed/triadic projectors ($[\mathsf{A}_x, \Pi^{[\chi]}_{\Phi\Phi}] = [\mathsf{A}_x, \Pi_\alpha] = 0$).

Finally, the map $\mathsf{H}[\cdot]$ in Definition 9.278 denotes *Hermitian completion* and should not be confused with either the index A or the operator A_x.

In short: A (index) $\neq$ A_x (operator) $\neq$ H (map).

Proposition 9.275 (Conservation, Ward identities, and typed NG coupling)**.** *Assume the Gaiamiti action is G–invariant on the diagnostic realized reference configuration (law–symmetric case, i.e. QI/QII for the relevant types). Then on $\mathcal{H}_{\mathrm{phys}}$:*

(i) Bulk conservation

$\bar{\nabla}_\mu\, \mathcal{J}^\mu_A = 0$ *on* $\mathfrak{P}$. *Equivalently, each typed/triadic component satisfies* $\bar{\nabla}_\mu\, \mathcal{J}^{\mu,[\chi]}_{A,(\alpha)} = 0$.

(ii) Ward identity (typed form)

Let $\delta\Phi_{\mathrm{tang}} \in T_{\bar{\Phi}}\mathcal{M}_{\mathrm{vac}}$ *and* $\hat{h}^{(\alpha)}_{\mu\nu}$ *be the TT Goldstone metric deformation in channel* α *(Definition 9.263). In momentum space,*

$$i\,k_\mu \left\langle \mathcal{J}^{\mu,[\mathrm{TT}]}_{A,(\alpha)}(k)\ \cdots \right\rangle = \left\langle \delta_A \mathcal{O}_{\mathrm{TT}}(k)\ \cdots \right\rangle,$$

which implies an NG pole at $k^2 = 0$ *in the correlator* $\Pi_\alpha \Pi^{[\mathrm{TT}]}_{\Phi\Phi}\, G^{\mathrm{R}}_{\Phi\Phi,\mathrm{phys}}\, \Pi^{[\mathrm{TT}]}_{\Phi\Phi} \Pi_\alpha$ *with nonnegative residue (strictly positive in QII; Proposition 9.197).*

(iii) Explicit breaking and GMOR on $\mathfrak{P}$

If a small symmetry–breaking spurion deforms the law channel, the divergence obeys $\bar{\nabla}_\mu \mathcal{J}^\mu_A = \varepsilon_A\, \mathcal{X}_A$. *Typed/triadic SynTh sources then give a GMOR–type scaling for the TT pseudo–NG band on the plateau (QIV:* $\mathscr{H}_L^{[\Phi\Phi,\mathrm{TT}]} > 0$*; Definition 9.188 and Proposition 9.197).*

All statements are Nielsen–flat and BRST–safe by Propositions 9.191 and 9.207.

Definition 9.276 (Noether charge, flux, and edge class)**.** Let Σ_t be a constant–time slice with unit normal n_μ and induced measure $d\Sigma_\mu := n_\mu\, d\Sigma$. Define the physical Noether charge $Q_A(t) := \int_{\Sigma_t} d\Sigma_\mu\, \mathcal{J}^\mu_A$ and the boundary flux $\Phi_A(t) := \oint_{\partial\Sigma_t} dS_\mu\, \mathcal{J}^\mu_A$. On bulk diagnostic realized reference configuration with vanishing flux, $\dot{Q}_A(t) = 0$; with boundaries we classify the edge via the overlay of Definition 9.214 and record $\mathrm{Edge}^{[S,\chi]}$ in the ledger update (Corollary 9.218).

Corollary 9.277 (Quadrant semantics for currents)**.** *In the TT typed channel: QI ⇒ conserved current with no NG coupling; QII ⇒ conserved current sourcing an exact NG pole; QIV ⇒ nonzero divergence proportional to the typed law source* ($\mathscr{H}_L^{[\Phi\Phi,\mathrm{TT}]} > 0$) *and a pNG band with GMOR slope (Definitions 9.188 and 9.189 and Proposition 9.197). The trace (Apeiron) channel remains QI in the SSB–only regime.*

Definition 9.278 (Charge–generator convention and Hermitian completion)**.** Fix an internal label A and let the conserved charge $\hat{Q}_A$ act by adjoint on field operators so that

$$[\hat{Q}_A, \hat{\mathbf{\Phi}}] = T_A\,\hat{\mathbf{\Phi}}, \qquad \delta_A\hat{\mathbf{\Phi}} = i\,\epsilon\,T_A\hat{\mathbf{\Phi}} = i\,\epsilon\,[\hat{Q}_A, \hat{\mathbf{\Phi}}],$$

with T_A the (matrix) generator in the Gaiamiti representation and ϵ a constant parameter for global transformations. Define the Hermitian completion map $\mathsf{H}[X] := X + X^\dagger$. Assume the invariant internal metric contracts indices so that $\mathrm{Tr}\{AB\}$ implements the same bilinear as $\mathsf{H}[\cdot]$ componentwise.

Lemma 9.279 (Noether current bridge at the operator level)**.** *Let* $\mathcal{L}_\Phi(\hat{\mathbf{\Phi}}, \nabla\hat{\mathbf{\Phi}})$ *be the operator-valued Gaiamiti Lagrangian density. Set*

$$X^\mu_A \;:=\; \frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})}\,\big(i\,T_A\hat{\mathbf{\Phi}}\big).$$

Then the boxed current of Definition 9.273 and the "+ h.c." current of Definition 9.273 coincide under the invariant trace via

$$\boxed{\hat{\mathcal{J}}^\mu_A = \mathsf{H}\big[X^\mu_A\big] \equiv -i\,\mathrm{Tr}\left\{\frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})}\,[\hat{Q}_A, \hat{\mathbf{\Phi}}]\right\} =: \;\hat{J}^\mu_{(\Phi)}.} \tag{9.113}$$

Comment. *Equality is exact in the standard unitary representation where the internal trace implements the invariant bilinear; otherwise the two forms differ by an internally traceless anti-Hermitian commutator whose projection to* H^0 *vanishes on the diagnostic realized reference configuration.*

Definition 9.280 (Diagnostic realized reference configuration realization and projection map)**.** On the diagnostic realized reference configuration (Definition 9.185), replace $\nabla \to \bar{\nabla}(\bar{\Sigma})$ and apply the BRST–physical projector $\mathsf{P}_{\mathrm{phys}}$:

$$\mathfrak{B}^\mu_A[\,\cdot\,] \;:=\; \mathsf{P}_{\mathrm{phys}}\,\mathcal{U}_\Sigma\Big[\,(\cdot)\,\Big|_{\,\nabla\to\bar{\nabla}}\Big]\,\mathsf{P}_{\mathrm{phys}}.$$

For typed/triadic readings (Definitions 9.186 and 9.200) with $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, define

$$\mathfrak{B}^{\mu,[\chi]}_{A,(\alpha)}[\,\cdot\,] \;:=\; \Pi_\alpha\,\Pi^{[\chi]}_{\Phi\Phi}\,\mathfrak{B}^\mu_A[\,\cdot\,]\,\Pi^{[\chi]}_{\Phi\Phi}\,\Pi_\alpha.$$

Proposition 9.281 (Equivalence of the two currents on H^0 and in typed/triadic channels)**.** *With the conventions of Definition 9.278 and the map of Definition 9.280, the two definitions are the same current, realized on* H^0*:*

$$\mathcal{J}^\mu_A \;:=\; \mathfrak{B}^\mu_A\big[\hat{J}^\mu_{(\Phi)}\big] \;=\; \mathfrak{B}^\mu_A\big[\hat{\mathcal{J}}^\mu_A\big],$$

and, for every type $[\chi]$ *and triad label* α*,*

$$\boxed{\begin{aligned}\mathcal{J}^{\mu,[\chi]}_{A,(\alpha)} &= \Pi_\alpha\,\Pi^{[\chi]}_{\Phi\Phi}\,\mathcal{J}^\mu_A\,\Pi^{[\chi]}_{\Phi\Phi}\,\Pi_\alpha \\ &= \mathfrak{B}^{\mu,[\chi]}_{A,(\alpha)}\Big[\hat{J}^\mu_{(\Phi)}\Big] \\ &= \mathfrak{B}^{\mu,[\chi]}_{A,(\alpha)}\Big[\hat{\mathcal{J}}^\mu_A\Big].\end{aligned}} \tag{9.114}$$

Proof. *Apply Lemma 9.279 to identify the operator currents; then substitute* $\nabla \to \bar{\nabla}$*, apply* $\mathsf{P}_{\mathrm{phys}}$*, and commute the projectors* $\Pi^{[\chi]}_{\Phi\Phi}, \Pi_\alpha$ *with* $\mathsf{P}_{\mathrm{phys}}$ *(diagnostic realized reference configuration assumptions), yielding* (9.114). □

Corollary 9.282 (Conservation and improvements)**.** *If* S_Φ *is invariant under the* global *transformation (*$\epsilon = \text{const.}$*), then* $\bar{\nabla}_\mu\,\mathcal{J}^\mu_A = 0$ *on* H^0 *up to standard improvement terms and boundary contributions determined by* $\bar{\Sigma}$*; the same holds typewise and triadically for* $\mathcal{J}^{\mu,[\chi]}_{A,(\alpha)}$*.*

Remark 9.283 (Local parameter and anomalies)**.** For $\epsilon(x)$ (local variation) one obtains the Ward identity with source $\partial_\mu\epsilon(x)$; possible BRST or internal anomalies appear as usual in the divergence of $\mathcal{J}^\mu_A$ and are diagnosed in the triadic/typed channels by applying (9.114).

Interpretation. The expectation current $\bar{J}^\mu_{(\Phi)}(x) := \langle \mathring{\boldsymbol{\Psi}} \,|\, \hat{J}^\mu_{(\Phi)}(x) \,|\, \mathring{\boldsymbol{\Psi}} \rangle$ associated with the operator current of Definition 9.271 is a geometric conservation law: unlike Standard Model currents that transport *matter* charges, it transports conserved quantities tied to *symmetries of the geometric fabric* itself. When the generator $\hat{Q}$ implements a continuous motion on the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ (Definition 6.61), $\bar{J}^\mu_{(\Phi)}$ is the flow of the corresponding "geometric charge" [91, 100], ensuring compatibility between internal geometric symmetries and emergent dynamics.

On the diagnostic realized reference configuration, conservation appears in typed Ward form (Proposition 9.275):

$$\bar{\nabla}_\mu\,\mathcal{J}^\mu_A = 0 \quad\Longrightarrow\quad i\,k_\mu\,\Big\langle \mathcal{J}^{\mu,[\chi]}_{A,(\alpha)}(k)\,\cdots\Big\rangle = \Big\langle \delta_A\mathcal{O}^{[\chi]}_{(\alpha)}(k)\,\cdots\Big\rangle,$$

where $\mathcal{J}^{\mu,[\chi]}_{A,(\alpha)}$ is the typed/triadic projection of $\mathcal{J}^\mu_A$ defined in Definition 9.273 and linked to either current representation by eq. (9.114). In the TT channel this Ward identity enforces an exact NG pole at $k^2 = 0$ in QII (residue fixed by the TT Goldstone overlap; Proposition 9.197), whereas in QIV the pole remains as pNG with a GMOR slope set by the typed law source (Definition 9.188 and Proposition 9.197). Operationally, coupling a weak probe a^A_μ via $\delta S_\Phi = \int d^dx\, a^A_\mu\,\mathcal{J}^\mu_A$ promotes $\mathcal{J}^\mu_A$ to a susceptibility meter: the linear response

$$\chi^{[\chi]}_{AB,(\alpha)}(k) := i\,G^{\mathrm{R}}_{\mathcal{J}_A\mathcal{J}_B}\Big|_{[\chi],(\alpha)}(k)$$

reads the symmetry geometry; in the static, long-wavelength limit $\chi^{[\chi]}_{AB}(\omega\to 0, \mathbf{k}\to 0)$ measures the metric on the typed slice of $\mathcal{M}_{\mathrm{vac}}$.

The current inherits the triadic anatomy (Definition 9.263):

$$\mathcal{J}^\mu_A = \sum_{\alpha\in\{\mathrm{corr,vac,spec}\}} \Pi_\alpha\,\mathcal{J}^\mu_A\,\Pi_\alpha,$$

which separates correlational transport, vacuum–bundle, and spectral–carrier contributions. Their relative weights c_α coincide with those assembling the composite TT graviton on H^0 (Definition 9.265). With boundaries, Stokes' theorem relates bulk charge and boundary flow,

$$\dot{Q}_A(t) = -\Phi_A(t), \qquad Q_A(t) = \int_{\Sigma_t} d\Sigma_\mu \, \mathcal{J}_A^\mu, \quad \Phi_A(t) = \oint_{\partial\Sigma_t} dS_\mu \, \mathcal{J}_A^\mu$$

(Definition 9.276); comparing bulk vs. boundary typed meters fixes the edge class via the bulk/edge overlay and ledger update (Definition 9.214 and Corollary 9.218).

Scheme choices preserve physics: improvements $\mathcal{J}_A^\mu \to \mathcal{J}_A^\mu + \bar{\nabla}_\nu K_A^{[\mu\nu]}$ leave charges and typed Ward identities intact; BRST–exact additions vanish on H^0; and Nielsen/compatibility results guarantee gauge–parameter independence across the plateau $\mathfrak{P}$ (Propositions 9.191 and 9.207). Finally, the channel roles are complementary: in $(S, [\chi]) = (\Phi\Phi, \mathrm{Tr})$ the sector sits in QI—$\mathcal{J}_A^\mu$ diagnoses a *gapped* trace (Apeiron) channel with intrinsic scale m_A and correlation length $\xi_A \sim m_A^{-1}$ but no NG content—while the TT type carries the symmetry–breaking kinematics (QII/QIV). Conservation becomes operational at the typed onset $\mathrm{On}^{[S,\chi]}$ where SynTh meters stabilize (Definition 9.190); below onset, transient law–state mixing may occur without affecting plateau charges or residues.

The Geometric Charge as an Intrinsic Property of the Apeiron (augmented) The geometric charge is an intrinsic property of the *Apeiron* sector; this follows from the chain below.

(i) Provenance of the current (operator → DRCC, typed) The Noether current arises from a continuous internal symmetry of $S_\Phi[\hat{\mathbf{\Phi}}]$. Via the charge–generator bridge (Definition 9.278) and the operator identity (Lemma 9.279), the two operator forms $\hat{J}^\mu_{(\Phi)} = -i\,\mathrm{Tr}\{\partial\mathcal{L}_\Phi/\partial(\nabla_\mu\hat{\mathbf{\Phi}})\,[\hat{Q}, \hat{\mathbf{\Phi}}]\}$ and $\hat{\mathcal{J}}_A^\mu = \frac{\partial\mathcal{L}_\Phi}{\partial(\nabla_\mu\hat{\mathbf{\Phi}})}(i\,T_A\hat{\mathbf{\Phi}}) + \mathrm{h.c.}$ are equivalent. Realizing on the diagnostic realized reference configuration (DRCC) and projecting to H^0 with $\mathfrak{B}_A^\mu$ (Definition 9.280) yields $\mathcal{J}_A^\mu = \mathsf{P}_{\mathrm{phys}}\,\hat{\mathcal{J}}_A^\mu\,\mathsf{P}_{\mathrm{phys}}$, and the typed/triadic component $\mathcal{J}^{\mu,[\chi]}_{A,(\alpha)}$ as in Definition 9.273. Equivalence in each typed/triadic channel is *exact* by Proposition 9.281 and eq. (9.114). The conserved charge is $Q_A(t) = \int_{\Sigma_t} d\Sigma_\mu\,\mathcal{J}_A^\mu$ (Definition 9.276).

(ii) Action–quantum correspondence (Apeiron channel on $\mathfrak{P}$) The same action that defines the current also governs the *Apeiron*, i.e. the trace-typed quantum in $(S, [\chi]) = (\Phi\Phi, \mathrm{Tr})$ (Section 9.17.1). On a certified plateau $\mathfrak{P}$, the intrinsic scale is fixed by the typed curvature $m_A^2 = \mathrm{eig}_{\min}\big(\mathcal{K}^{[\mathrm{Tr}]}_{\Phi\Phi}\big)$ (Definition 9.242), so the correlation length behaves as $\xi_A \sim m_A^{-1}$. Let $\hat{a}^\dagger_{n,\mathrm{Tr}}$ create $\bar{\Sigma}$-orthonormal trace modes. Using the charge–generator convention (Definition 9.278),

$$[Q_A,\ \hat{a}^\dagger_{n,\mathrm{Tr}}] \;=\; q^{(\mathrm{Tr})}_{A,n}\,\hat{a}^\dagger_{n,\mathrm{Tr}} \;+\; \Big(\text{BRST-exact} \;\oplus\; \text{orthogonal-type pieces}\Big),$$

so the conserved quantum number $q^{(\mathrm{Tr})}_{A,n}$ is *carried* by Apeiron quanta on H^0.

(iii) Principle of charge attribution (typed/triadic semantics) Conserved charges extracted from S_Φ belong to the quanta of the field in the *relevant typed channel*. In the trace type the quadrant is $\mathrm{Quad}^{[\Phi\Phi,\mathrm{Tr}]} = \mathrm{QI}$ (Definition 9.189): the sector is gapped (no

NG/pNG), yet the charge is well-defined and measurable via (i) the equal-time commutator above, (ii) the static, long-wavelength limit of the typed current–current susceptibility $\chi^{[\mathrm{Tr}]}_{AB}(\omega\to 0,\mathbf{k}\to 0)$ (from the probe coupling in Proposition 9.275), and (iii) the ledgered **TLO** stamp recorded per Corollary 9.218.

Hence, because the Noether current and charge originate in the symmetry of the same action that defines the Apeiron, the associated conserved *geometric charge* is an intrinsic property of the Apeiron sector—consistent with QI (no NG content in this channel).

Elucidation on the Nature of Geometric Charge (augmented) It is crucial to distinguish "geometric charge'' from familiar matter charges.

1. An electron *possesses* electric charge as a property of a matter field; its current lives in a matter sector and counts matter quanta.

2. The Apeiron does not *possess* geometric charge in that ordinary sense; rather, it *is* the trace-typed quantum manifestation of a conserved property of the geometric vacuum, read from the diagnostic realized reference configuration-realized current $\mathcal{J}^{\mu}_{A}$ and its triadic anatomy $\mathcal{J}^{\mu}_{A}=\sum_{\alpha\in\{\mathrm{corr,vac,spec}\}}\Pi_{\alpha}\,\mathcal{J}^{\mu}_{A}\,\Pi_{\alpha}$ (Definition 9.273).

If the symmetry corresponds to a continuous rotation on $\mathcal{M}_{\mathrm{vac}}$ (Definition 6.61), the geometric charge is the conserved "orientation'' on $\mathcal{M}_{\mathrm{vac}}$; Apeiron quanta are its trace-typed carriers. By contrast, the TT type encodes symmetry breaking: the same current sources an NG (or pNG) pole (Proposition 9.197) whose residue feeds the composite graviton via triadic weights c_{α} (Definition 9.265), while the Apeiron remains gapped with scale m_{A} (Definition 9.242). Bulk–boundary overlays relate charge and flux by $\dot{Q}_{A}(t)=-\Phi_{A}(t)$ with Q_{A},Φ_{A} as in Definition 9.276; edge behavior is classified and ledgered via Definition 9.214 and Corollary 9.218. None of the admissible scheme choices—Belinfante improvements (Corollary 9.282), BRST-exact pieces (Proposition 9.207), or gauge-parameter changes (Nielsen flatness; Proposition 9.191)—alter charge attribution on H^{0} or the typed Ward identities across the plateau $\mathfrak{P}$.

9.17.9 The Noether Stress–Energy Tensor of the Gaiamiti Field

Within the framework of any physical theory, continuous symmetries of the action imply, via Noether's theorem, conserved currents. For the Gaiamiti field, invariance under infinitesimal spacetime translations yields the stress–energy tensor. In the IQR formalism this tensor—denoted $\hat{T}^{\mu\nu}_{(\Phi)}(x)$—is an operator–valued field encoding energy–momentum flux of *relational* geometric variations. Its expectation value $\bar{T}^{\mu\nu}_{(\Phi)}(x)$ plays the role of a classical stress–energy in GR, but sources the emergent, state–dependent geometry rather than a fixed background.

Definition 9.284 (Noether Stress–Energy Tensor of the Gaiamiti Field)**.** Let $\hat{\mathbf{\Phi}}(x)$ be the Gaiamiti field on $(\mathcal{X}_{q},\bar{\Sigma}_{\mu\nu})$ with action $S_{\Phi}[\hat{\mathbf{\Phi}}]$. The operator–valued Noether stress–energy tensor is

$$\boxed{\hat{T}^{\mu\nu}_{(\Phi)}(x):=\Big\{\big(\bar{\nabla}^{\mu}\hat{\mathbf{\Phi}}(x)\big)^{\dagger},\,\bar{\nabla}^{\nu}\hat{\mathbf{\Phi}}(x)\Big\}\;-\;\bar{\Sigma}^{\mu\nu}(x)\,\mathrm{Tr}\Big(\mathcal{L}_{\Phi}(x)\Big)\,\mathbb{I},}\tag{9.115}$$

Conventions.

(i) Relational Levi–Civita derivative
$\bar{\nabla}_\mu$ is the relational Levi–Civita derivative compatible with $\bar{\Sigma}_{\mu\nu}$ (Definition 6.7); indices are raised with $\bar{\Sigma}^{\mu\nu}$ so that $\bar{\nabla}^\mu := \bar{\Sigma}^{\mu\lambda}\bar{\nabla}_\lambda$ (Definition 6.184).

(ii) Anticommutator
$\{A, B\} := AB + BA$ is the anticommutator, ensuring Hermiticity and symmetry in (μ, ν).

(iii) Gaiamiti Lagrangian density
$\mathcal{L}_\Phi(x)$ is the operator–valued Gaiamiti Lagrangian *density* (Definition 6.172); on the diagnostic realized reference configuration it depends on $\bar{\Sigma}$ only through $\bar{\nabla}$-contractions and $\sqrt{-\det \bar{\Sigma}}$.

(iv) Internal trace
$\mathrm{Tr}(\cdot)$ traces over internal/operator fibers (not spacetime; Section 6.1.10), hence $\mathrm{Tr}(\mathcal{L}_\Phi)$ is a c–number density.

(v) Identity on the modal fiber
$\mathbb{I} \equiv \mathbb{I}_{\mathcal{H}_{\mathrm{mod}}^{(\mathfrak{B}_x)}}$ is the identity on the local modal fiber (eq. (6.131)).

Hilbert–Noether equivalence. For minimally coupled $\mathcal{L}_\Phi$,

$$\hat{T}^{\mu\nu}_{(\Phi)}(x) = \frac{2}{\sqrt{-\det \bar{\Sigma}(x)}} \frac{\delta S_\Phi}{\delta \bar{\Sigma}_{\mu\nu}(x)} \quad \text{(up to standard improvement terms).}$$

Expectation on the diagnostic realized reference configuration Taking the expectation value in the Quantum Holo–State $|\mathring{\boldsymbol{\Psi}}\rangle$ defines the classical (expectation–level) stress–energy:

$$\boxed{\bar{T}^{\mu\nu}_{(\Phi)}(x) := \Big\langle \mathring{\boldsymbol{\Psi}} \Big| \mathsf{P}_{\mathrm{phys}}\, \hat{T}^{\mu\nu}_{(\Phi)}(x)\, \mathsf{P}_{\mathrm{phys}} \Big| \mathring{\boldsymbol{\Psi}} \Big\rangle \equiv \langle \mathring{\boldsymbol{\Psi}} | \hat{T}^{\mu\nu}_{(\Phi)}(x) | \mathring{\boldsymbol{\Psi}} \rangle,} \tag{9.116}$$

where the equivalence holds whenever $|\mathring{\boldsymbol{\Psi}}\rangle \in \mathcal{H}_{\mathrm{phys}}$. On the diagnostic realized reference configuration we regard $\hat{T}^{\mu\nu}_{(\Phi)}$ as band–limited/IR–windowed and properly normal–ordered so that $\bar{T}^{\mu\nu}_{(\Phi)}$ is finite on the certified plateau $\mathfrak{P}$.
Typed/triadic expectation. For $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ and $[\chi] \in \{\mathrm{TT}, \mathrm{Tr}\}$, set

$$\bar{T}^{\mu\nu\,[\chi]}_{(\Phi),(\alpha)}(x) := \Big\langle \mathring{\boldsymbol{\Psi}} \Big| \Pi_\alpha \Pi^{[\chi]}_{\Phi\Phi}\, \hat{T}^{\mu\nu}_{(\Phi)}(x)\, \Pi^{[\chi]}_{\Phi\Phi} \Pi_\alpha \Big| \mathring{\boldsymbol{\Psi}} \Big\rangle. \tag{9.117}$$

It inherits symmetry $\bar{T}^{\mu\nu} = \bar{T}^{\nu\mu}$ and transforms covariantly with $\bar{\nabla}$. With (9.116)–(9.117) in place, the conservation law of Proposition 9.285 follows.

Proposition 9.285 (Conservation of the Noether Stress–Energy Tensor)**.** *If the Gaiamiti field $\hat{\boldsymbol{\Phi}}(x)$ satisfies its Euler–Lagrange equation (Definition 9.268), then the expectation–level stress–energy tensor is covariantly conserved with respect to the relational Levi–Civita connection:*

$$\boxed{\bar{\nabla}_\mu\, \bar{T}^{\mu\nu}_{(\Phi)}(x) = 0.} \tag{9.118}$$

Proof of Proposition 9.285. The conservation of the Noether stress–energy tensor follows from diffeomorphism invariance of the Gaiamiti action S_Φ together with the field equations.

Step 1: Diffeomorphism invariance and total variation. Write the action as an integral of a scalar density,

$$S_\Phi = \int_{\mathcal{X}_q} d^d x \, \mathcal{L}_\Phi,$$

and consider an infinitesimal diffeomorphism $x^\mu \mapsto x'^\mu = x^\mu - \xi^\mu(x)$ with $\xi^\mu|_{\partial\mathcal{X}_q} = 0$. The total variation splits into field and geometry parts:

$$\delta S_\Phi = \int_{\mathcal{X}_q} \left[\frac{\delta S_\Phi}{\delta \hat{\mathbf{\Phi}}} \, \delta\hat{\mathbf{\Phi}} + \frac{\delta S_\Phi}{\delta \bar{\Sigma}_{\mu\nu}} \, \delta\bar{\Sigma}_{\mu\nu} \right] d^d x = 0.$$

Step 2: On–shell reduction. Assuming the Euler–Lagrange equations hold (Definition 9.268), we have $\delta S_\Phi / \delta\hat{\mathbf{\Phi}} = 0$, hence

$$\delta S_\Phi = \int_{\mathcal{X}_q} \frac{\delta S_\Phi}{\delta \bar{\Sigma}_{\mu\nu}} \, \delta\bar{\Sigma}_{\mu\nu} \, d^d x = 0.$$

Step 3: Metric variation and Hilbert–Noether identity. Under the diffeomorphism,

$$\delta\bar{\Sigma}_{\mu\nu} = \mathcal{L}_\xi \bar{\Sigma}_{\mu\nu} = \bar{\nabla}_\mu \xi_\nu + \bar{\nabla}_\nu \xi_\mu,$$

with $\bar{\nabla}$ the Levi–Civita derivative of $\bar{\Sigma}$. Using the Hilbert form (equivalent to the boxed Noether definition in (9.115) up to standard improvement terms),

$$\frac{\delta S_\Phi}{\delta \bar{\Sigma}_{\mu\nu}} = \frac{\sqrt{-\det \bar{\Sigma}}}{2} \, \hat{T}^{\mu\nu}_{(\Phi)},$$

we obtain

$$\delta S_\Phi = \int_{\mathcal{X}_q} \sqrt{-\det \bar{\Sigma}} \; \hat{T}^{\mu\nu}_{(\Phi)} \, \bar{\nabla}_\mu \xi_\nu \, d^d x = 0,$$

where symmetry $\hat{T}^{\mu\nu}_{(\Phi)} = \hat{T}^{\nu\mu}_{(\Phi)}$ was used to combine the two terms.

Step 4: Integration by parts and operator identity. Integrating by parts and dropping the boundary term (since ξ^μ vanishes on $\partial\mathcal{X}_q$),

$$0 = \int_{\mathcal{X}_q} \sqrt{-\det \bar{\Sigma}} \left[\bar{\nabla}_\mu\big(\hat{T}^{\mu\nu}_{(\Phi)} \xi_\nu\big) - \big(\bar{\nabla}_\mu \hat{T}^{\mu\nu}_{(\Phi)}\big)\xi_\nu \right] d^d x = - \int_{\mathcal{X}_q} \sqrt{-\det \bar{\Sigma}} \, \big(\bar{\nabla}_\mu \hat{T}^{\mu\nu}_{(\Phi)}\big) \, \xi_\nu \, d^d x.$$

Because ξ_ν is arbitrary, we conclude the operator-level conservation law:

$$\bar{\nabla}_\mu \hat{T}^{\mu\nu}_{(\Phi)}(x) = 0.$$

Step 5: Expectation-level conservation. Taking the expectation in the Quantum Holo–State $|\overset{\circ}{\mathbf{\Psi}}\rangle$ and using linearity of $\bar{\nabla}$ on spacetime indices yields

$$\bar{\nabla}_\mu \, \bar{T}^{\mu\nu}_{(\Phi)}(x) = \bar{\nabla}_\mu \, \langle \overset{\circ}{\mathbf{\Psi}} | \hat{T}^{\mu\nu}_{(\Phi)}(x) | \overset{\circ}{\mathbf{\Psi}} \rangle = 0,$$

which is (9.118). □

Corollary 9.286 (Typed/triadic conservation on the diagnostic realized reference configuration)**.** *For* $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ *and* $[\chi] \in \{\mathrm{TT}, \mathrm{Tr}\}$*, define the* operator-level *typed/triadic tensor*

$$\hat{T}^{\mu\nu\,[\chi]}_{(\Phi),(\alpha)} := \Pi_\alpha\, \Pi^{[\chi]}_{\Phi\Phi}\, \hat{T}^{\mu\nu}_{(\Phi)}\, \Pi^{[\chi]}_{\Phi\Phi}\, \Pi_\alpha,$$

and its expectation-level *version* $\bar{T}^{\mu\nu\,[\chi]}_{(\Phi),(\alpha)} := \langle \overset{\circ}{\boldsymbol{\Psi}} | \hat{T}^{\mu\nu\,[\chi]}_{(\Phi),(\alpha)} | \overset{\circ}{\boldsymbol{\Psi}} \rangle$*. On the certified plateau* $\mathfrak{P}$ *(diagnostic realized reference configuration projectors commuting with* $\bar{\nabla}$ *within tolerances),*

$$\bar{\nabla}_\mu\, \bar{T}^{\mu\nu\,[\chi]}_{(\Phi),(\alpha)} = 0.$$

Remark 9.287 (Scope and improvements)**.** (i) Belinfante–Rosenfeld improvements $T^{\mu\nu} \to T^{\mu\nu} + \bar{\nabla}_\lambda K^{[\lambda\mu]\nu}$, with $K^{[\lambda\mu]\nu} = -K^{[\mu\lambda]\nu}$, preserve (9.118) ([462, 463, 464]). (ii) If $\mathcal{L}_\Phi$ contains explicit (nonminimal) metric dependence beyond $\bar{\nabla}$-contractions and $\sqrt{-\det \bar{\Sigma}}$, additional terms appear in $\bar{\nabla}_\mu T^{\mu\nu}$ proportional to that breaking; potential anomalies would modify the divergence in the standard way (cf. [301, 300]).

Interpretation and Physical Significance

The stress–energy tensor $\hat{T}^{\mu\nu}_{(\Phi)}(x)$ is a fundamentally geometric object. By construction in (9.115) (and equivalently by the Hilbert–Noether identity stated under that definition), it is Hermitian and symmetric,

$$\hat{T}^{\mu\nu}_{(\Phi)} = \hat{T}^{\nu\mu}_{(\Phi)},$$

with symmetry preserved under Belinfante–Rosenfeld improvements (see Remark 9.287). When the field equations hold, its expectation is covariantly conserved on the diagnostic realized reference configuration,

$$\bar{\nabla}_\mu\, \bar{T}^{\mu\nu}_{(\Phi)} = 0,$$

as proved in Proposition 9.285; typed/triadic slices obey the same conservation law by Corollary 9.286. The expectation $\bar{T}^{\mu\nu}_{(\Phi)}$ is defined in (9.116).

At the Quantum Level. The operator $\hat{T}^{\mu\nu}_{(\Phi)}(x)$ captures the local energy–momentum flux of the relational degrees of freedom of quantum geometry encoded by the Gaiamiti field $\hat{\boldsymbol{\Phi}}$ (see Definition 6.172 and §6.1.10). In the band-limited, BRST-physical setting on the certified plateau $\mathfrak{P}$, its typed/triadic projections

$$\hat{T}^{\mu\nu\,[\chi]}_{(\Phi),(\alpha)} = \Pi_\alpha\, \Pi^{[\chi]}_{\Phi\Phi}\, \hat{T}^{\mu\nu}_{(\Phi)}\, \Pi^{[\chi]}_{\Phi\Phi}\, \Pi_\alpha, \qquad \alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\},\ [\chi] \in \{\mathrm{TT}, \mathrm{Tr}\}$$

(Corollary 9.286 and Definitions 9.186 and 9.200) resolve:

(i) Kinetic flux Kinetic flux from relational propagation across $\mathcal{X}_q$ (the covariant-derivative term in (9.115)).

(ii) Potential energy Potential energy of internal deformations tied to the Gaiamiti potential (cf. Definition 9.235 and the typed curvature drivers Definition 9.220).

This decomposition is the energy–momentum analogue of the current's typed/triadic anatomy used in Definition 9.273 and Proposition 9.275.

At the Classical Level. The expectation $\bar{T}^{\mu\nu}_{(\Phi)}(x)$ (eq. (9.116)) functions as the effective source for the realized chronogeometry through the Hilbert–Noether equivalence just below (9.115):

$$\frac{\delta S_\Phi}{\delta \bar{\Sigma}_{\mu\nu}} = \frac{\sqrt{-\det \bar{\Sigma}}}{2}\, \hat{T}^{\mu\nu}_{(\Phi)} \quad \text{(up to improvements)}.$$

In an IQR gravity closure, this provides the right–hand side of a relational Einstein-like equation in which $\bar{\Sigma}_{\mu\nu}$ is state-dependent and dynamical rather than a fixed background.

The Self-Sourcing Nature of Geometry

The principle is *geometry sources itself*: the energy–momentum of relational fluctuations governs the evolution of the very geometry that supports them. Concretely, the structure of $\hat{T}^{\mu\nu}_{(\Phi)}$ in (9.115) shows:

(i) Flux transport term The $\{(\bar{\nabla}^\mu \hat{\mathbf{\Phi}})^\dagger, \bar{\nabla}^\nu \hat{\mathbf{\Phi}}\}$ term encodes local transport of quantum-geometric flux across $\mathcal{X}_q$.

(ii) Background-independent subtraction The subtraction $\bar{\Sigma}^{\mu\nu}\,\mathrm{Tr}(\mathcal{L}_\Phi)\,\mathbb{I}$ enforces compatibility with relational background independence and yields the Hilbert source via the metric variation just cited.

Remark 9.288 (Relation to the graviton and typed symmetry breaking)**.** When $\bar{T}^{\mu\nu}_{(\Phi)}$ is sourced by excitations of the Apeiron (trace type) about its certified background (Definition 9.242), the trace channel remains gapped and law-symmetric (QI), while the TT channel carries symmetry-breaking kinematics. In the TT type, the Noether current's Ward identity (Proposition 9.275) enforces an NG (or pNG, in QIV) pole whose residue feeds the composite graviton; the corresponding energy–momentum coupling is isolated by the TT projector on $T^{\mu\nu}$ (cf. the metric-response line under (9.115)). This mirrors the phonon analogy in condensed matter ([461, 14, 393]) but with geometry's TT Goldstone as the graviton; onset/location and edge behavior are recorded through the typed ledger (Definitions 9.190 and 9.198 and Corollary 9.286).

9.17.10 Projection Operators and Geometric Duality

Definition 9.289 (Projection Operators for Geometric and Matter Sectors)**.** Let $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$ be the local modal Hilbert space at $x \in \mathcal{X}_q$, with local vacuum $|\Omega(x)\rangle \in \mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$, and let $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}} \subset \mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$ denote the (assumed closed) tangent space to the vacuum manifold at $|\Omega(x)\rangle$.

Conventions. $g^{(x)}_{\mathrm{mod}}(\cdot,\cdot)$ is the relational inner product on $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$; orthogonality $(\cdot)^\perp$ is taken w.r.t. $g^{(x)}_{\mathrm{mod}}$. The identity on the fiber is $\mathbb{I}_x \equiv \mathbb{I}_{\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}}$. Bras $\langle\cdot|$ denote the $g^{(x)}_{\mathrm{mod}}$–Riesz duals. If $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ is infinite–dimensional, operator sums below are understood in the strong–operator topology.

(i) Geometric projector

For any $g^{(x)}_{\mathrm{mod}}$–orthonormal basis $\{|\delta\Omega_i(x)\rangle\}_{i=1}^{r}$ of $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ ($r = \dim T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$, finite or countable), define

$$\hat{P}_T(x) \;:=\; \sum_{i=1}^{r} |\delta\Omega_i(x)\rangle\langle\delta\Omega_i(x)|, \tag{9.119}$$

which is basis–independent and satisfies $\hat{P}_T(x)^2 = \hat{P}_T(x) = \hat{P}_T(x)^\dagger$. Its image is the geometric excitation space

$$\mathcal{E}_{\mathrm{geo}}(x) \;:=\; \mathrm{Im}\,\hat{P}_T(x) \;=\; T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}. \tag{9.120}$$

This space supports the dynamical Gaiamiti field $\hat{\mathbf{\Phi}}(x)$; in particular, its *trace–typed* quanta are the Apeiron (Definition 9.242).

(ii) Matter projector

The orthogonal–complement projector is

$$\hat{P}_{\mathrm{exc}}(x) \;:=\; \mathbb{I}_x - \hat{P}_T(x), \tag{9.121}$$

with $\hat{P}_{\mathrm{exc}}(x)^2 = \hat{P}_{\mathrm{exc}}(x) = \hat{P}_{\mathrm{exc}}(x)^\dagger$ and $\hat{P}_{\mathrm{exc}}(x)\hat{P}_T(x) = 0$. Its image is the excitation fiber

$$\mathcal{E}_{\mathrm{exc}}(x) \;:=\; \mathrm{Im}\,\hat{P}_{\mathrm{exc}}(x) \;=\; \big(T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}\big)^{\perp}, \tag{9.122}$$

which supports the Tantrakyma field $\hat{\mathbf{\Theta}}(x)$; its quantized excitations are the kymons.

Consequently, $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}} = \mathcal{E}_{\mathrm{geo}}(x) \oplus \mathcal{E}_{\mathrm{exc}}(x)$ and $\hat{P}_T(x) + \hat{P}_{\mathrm{exc}}(x) = \mathbb{I}_x$.

Remark 9.290 (Orthogonal decomposition of modal degrees of freedom)**.** With the projectors of Definition 9.289, the fiber $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$ splits $g^{(x)}_{\mathrm{mod}}$–orthogonally as

$$\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}} = \mathcal{E}_{\mathrm{geo}}(x) \oplus \mathcal{E}_{\mathrm{exc}}(x), \qquad \hat{P}_T(x) + \hat{P}_{\mathrm{exc}}(x) = \mathbb{I}_x, \quad \hat{P}_T(x)\hat{P}_{\mathrm{exc}}(x) = 0.$$

This partition is *canonical* relative to the choice of vacuum $|\Omega(x)\rangle$ and relational inner product $g^{(x)}_{\mathrm{mod}}$, and it is basis–independent: for any $g^{(x)}_{\mathrm{mod}}$–orthonormal basis of $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$, the series in (9.119) (finite or countable) converges in the strong–operator topology to the same $\hat{P}_T(x)$.

Regularity. Assume $x \mapsto \hat{P}_T(x)$ is C^1 on the diagnostic realized reference configuration. Then $\mathcal{E}_{\mathrm{geo}} := \mathrm{Im}\,\hat{P}_T$ and $\mathcal{E}_{\mathrm{exc}} := \mathrm{Im}\,\hat{P}_{\mathrm{exc}}$ assemble into smooth subbundles of $\mathcal{H}_{\mathrm{mod}}$ over $x \in \mathcal{X}_q$. Moreover, we assume compatibility with the typed/triadic structure of the $\Phi\Phi$ sector:

$$[\hat{P}_T(x), \Pi^{[\chi]}_{\Phi\Phi}] = 0, \qquad [\hat{P}_T(x), \Pi_\alpha] = 0,$$

so typed/triadic readings (Definitions 9.186 and 9.200) respect the geometric–matter split fiberwise.

Parallel transport of the split. If, in addition, $\bar{\nabla}_\mu \hat{P}_T(x) = 0$ (with $\bar{\nabla}$ from Definition 6.7), the decomposition is *parallel*: covariant transport preserves $\mathcal{E}_{\mathrm{geo}}$ and $\mathcal{E}_{\mathrm{exc}}$ along $\mathcal{X}_q$. More generally, the off–diagonal operator $\bar{\nabla}_\mu \hat{P}_T(x)$ measures any residual leakage between the two subbundles; on the certified plateau $\mathfrak{P}$ this is taken to vanish within diagnostic realized reference configuration tolerances, ensuring the conservation statements and typed Ward identities apply slice–wise (cf. Corollary 9.286).

Definition 9.291 (Diagnostic realized reference configuration–compatibility assumptions)**.** **Setting.** Work on the instrumented diagnostic realized reference configuration (Definition 9.185) on a certified plateau $\mathfrak{P}$. Use the geometric/matter split of Definition 9.289 and Remark 9.290 and the typed/triadic projectors $\Pi_{\Phi\Phi}^{[\chi]}$ and Π_α ($\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$; Definitions 9.186 and 9.200).

Smoothness. The fiber maps $x \mapsto \hat{P}_T(x)$, $\Pi_{\Phi\Phi}^{[\chi]}(x)$, $\Pi_\alpha(x)$ are C^1 in $x \in \mathcal{X}_q$. When used, $x \mapsto J^{(x)}$ (Kähler branch) and $x \mapsto \mathsf{A}_x$ (Legendre branch) are also C^1.

Commutation (diagnostic realized reference configuration tolerances). Projectors and diagnostic realized reference configuration structures commute within plateau tolerances:

$$[\hat{P}_T(x), \Pi_{\Phi\Phi}^{[\chi]}] = [\hat{P}_T(x), \Pi_\alpha] = 0, \qquad [\mathsf{P}_{\mathrm{phys}}, \Pi_{\Phi\Phi}^{[\chi]}] = [\mathsf{P}_{\mathrm{phys}}, \Pi_\alpha] = 0.$$

In the Kähler branch, $[J^{(x)}, \Pi_{\Phi\Phi}^{[\chi]}] = [J^{(x)}, \Pi_\alpha] = 0$; in the Legendre branch, $[\mathsf{A}_x, \Pi_{\Phi\Phi}^{[\chi]}] = [\mathsf{A}_x, \Pi_\alpha] = 0$. Band tags commute with these projectors ($P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$; Chapter 8).

Parallel transport (optional strengthening). Either $\bar{\nabla}_\mu \hat{P}_T(x) = 0$ (parallel split) or the leakage operator $\bar{\nabla}_\mu \hat{P}_T(x)$ is negligible on $\mathfrak{P}$, ensuring typed/triadic Ward and conservation statements apply slice-wise (cf. Corollary 9.286).

Functional–analytic regularity. $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ is closed in $\mathcal{H}_{\mathrm{mod}}^{(\mathfrak{B}_x)}$; sums like $\sum_i |\delta\Omega_i\rangle\langle\delta\Omega_i|$ converge in the strong-operator topology (Definition 9.289).

Proposition 9.292 (Vacuum duality and geometric identification)**.** *Let the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ carry the metric induced from the relational inner product on $\mathcal{H}_{\mathrm{mod}}$ at $|\Omega(x)\rangle$, so that $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ is a Hilbert space with inner product $g_T^{(x)}$. Assume, in addition to Definition 9.289 and Remark 9.290, one of the following sufficient structures at each $x \in \mathcal{X}_q$:*

(i) (A) Kähler duality
Assume that $\mathcal{H}_{\mathrm{mod}}^{(\mathfrak{B}_x)}$ admits a Kähler triple $\big(g_{\mathrm{mod}}^{(x)}, J^{(x)}, \omega^{(x)}\big)$ with $J^{(x)}\big(T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}\big) = \mathcal{E}_{\mathrm{exc}}(x)$, $\omega^{(x)}(\cdot,\cdot) = g_{\mathrm{mod}}^{(x)}(\cdot, J^{(x)}\cdot)$, and, on the diagnostic realized reference configuration, $J^{(x)}$ commutes with the typed/triadic projectors: $[J^{(x)}, \Pi_{\Phi\Phi}^{[\chi]}] = [J^{(x)}, \Pi_\alpha] = 0$.

(ii) (B) Legendre nondegeneracy (diagnostic realized reference configuration Lagrangian)
The $\Phi\Phi$-sector kinetic term is strictly nondegenerate on the diagnostic realized reference configuration, $\mathcal{L}_{\Phi,\mathrm{kin}} = \frac{1}{2} g_T^{(x)}(\dot{\Phi}, \mathsf{A}_x\dot{\Phi})$, with $\mathsf{A}_x : T_{|\Omega}\mathcal{M}_{\mathrm{vac}} \to T_{|\Omega}\mathcal{M}_{\mathrm{vac}}$ positive and boundedly invertible, and $[\mathsf{A}_x, \Pi_{\Phi\Phi}^{[\chi]}] = [\mathsf{A}_x, \Pi_\alpha] = 0$. The fiberwise Legendre/Riesz map $\mathcal{R}_x^{(\mathsf{A})} : v \mapsto g_T^{(x)}(\mathsf{A}_x v, \cdot)$ is an isometric isomorphism $T_{|\Omega}\mathcal{M}_{\mathrm{vac}} \xrightarrow{\cong} T_{|\Omega}^*\mathcal{M}_{\mathrm{vac}}$. Furthermore, the Tantrakyma fiber is the canonical momentum *fiber at $|\Omega(x)\rangle$: $\mathcal{E}_{\mathrm{exc}}(x) \cong T_{|\Omega(x)\rangle}^*\mathcal{M}_{\mathrm{vac}}$ via the canonical one–form pairing.*

Then there exists a canonical, fiberwise isometric isomorphism

$$\Psi_x : \ \mathcal{E}_{\mathrm{exc}}(x) \ \xrightarrow{\cong}\ T_{|\Omega(x)\rangle}^*\mathcal{M}_{\mathrm{vac}},$$

natural in x, commuting with the typed/triadic projectors on the $\Phi\Phi$ sector, $[\Psi_x, \Pi^{[\chi]}_{\Phi\Phi}] = [\Psi_x, \Pi_\alpha] = 0$, and unique up to unitaries within $\mathcal{E}_{\mathrm{exc}}(x)$ that commute with $\hat{P}_T(x)$ and with the typed/triadic projectors. Consequently,

$$\mathcal{E}_{\mathrm{exc}}(x) \;\simeq\; T^*_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}, \tag{9.123}$$

and the Tantrakyma field $\hat{\boldsymbol{\Theta}}(x)$ defines a covector on $\mathcal{M}_{\mathrm{vac}}$ at $|\Omega(x)\rangle$.

Remark 9.293 (Kinetic–symplectic meaning of A_x and compatibility of the two identifications)**.** In case (B), the operator $\mathsf{A}_x : T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}} \to T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ is the fiberwise *kinetic metric/inertia* associated to the diagnostic realized reference configuration Lagrangian

$$\mathcal{L}_{\Phi,\mathrm{kin}} = \tfrac{1}{2}\, g_T^{(x)}\Big(\dot{\Phi},\, \mathsf{A}_x\dot{\Phi}\Big),$$

hence positive, boundedly invertible, and $g_T^{(x)}$–self–adjoint. The Legendre/Riesz map

$$\mathcal{R}^{(\mathsf{A})}_x : \; v \longmapsto \Big[w \mapsto g_T^{(x)}(\mathsf{A}_x v, w)\Big]$$

is therefore an isometric isomorphism $T_{|\Omega}\mathcal{M}_{\mathrm{vac}} \xrightarrow{\cong} T^*_{|\Omega}\mathcal{M}_{\mathrm{vac}}$, and the momentum fiber at $|\Omega(x)\rangle$ identifies canonically with $\mathcal{E}_{\mathrm{exc}}(x)$, cf. Definitions 6.104 and 9.289, Remark 9.290, and Proposition 9.292. If, in addition, the Kähler structure in (A) is available and commutes with the typed/triadic projectors, then there exists a unitary $U_x : \mathcal{E}_{\mathrm{exc}}(x) \to \mathcal{E}_{\mathrm{exc}}(x)$ commuting with $\hat{P}_T(x)$, $\Pi^{[\chi]}_{\Phi\Phi}$ and Π_α such that

$$\Psi^{(\mathrm{A})}_x \;=\; \Psi^{(\mathrm{B})}_x \circ U_x.$$

Hence the two constructions agree up to the intrinsic ambiguity already recorded in Proposition 9.292. In diagnostic realized reference configuration–normal coordinates for which $g_T^{(x)} = \mathbf{1}$ and the projectors are diagonal, one has the coordinate-level Legendre pairing $p_i = (\mathsf{A}_x)_{ij}\,\dot{\phi}^j$, while the Kähler construction reads $\Psi_x(u)[v] = g^{(x)}_{\mathrm{mod}}(u, J^{(x)}v)$ with $J^{(x)}(T_{|\Omega}\mathcal{M}_{\mathrm{vac}}) = \mathcal{E}_{\mathrm{exc}}(x)$; these coincide precisely when A_x matches the $J^{(x)}$–induced kinetic metric on $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$.

Proof. We give two sufficient constructions of the canonical isomorphism $\Psi_x : \mathcal{E}_{\mathrm{exc}}(x) \xrightarrow{\cong} T^*_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$, each compatible with the diagnostic realized reference configuration split of Definition 9.289 and Remark 9.290. Throughout, $g_T^{(x)}$ denotes the inner product on $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ induced from $g^{(x)}_{\mathrm{mod}}$, and $\mathcal{R}_x : T_{|\Omega}\mathcal{M}_{\mathrm{vac}} \to T^*_{|\Omega}\mathcal{M}_{\mathrm{vac}}$ is the fiberwise Riesz isomorphism (Definition 6.104; cf. [253]).

Preliminaries (orthogonal split). By Definition 9.289 and Remark 9.290, $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}} = \mathcal{E}_{\mathrm{geo}}(x) \oplus \mathcal{E}_{\mathrm{exc}}(x)$ with $\mathcal{E}_{\mathrm{geo}}(x) = T_{|\Omega}\mathcal{M}_{\mathrm{vac}}$ and $\mathcal{E}_{\mathrm{exc}}(x) = \big(T_{|\Omega}\mathcal{M}_{\mathrm{vac}}\big)^{\perp}$. Typed/triadic compatibility holds on the diagnostic realized reference configuration: $[\hat{P}_T(x), \Pi^{[\chi]}_{\Phi\Phi}] = [\hat{P}_T(x), \Pi_\alpha] = 0$.

Construction (A): Kähler duality. Assume the existence of a Kähler triple $\big(g^{(x)}_{\mathrm{mod}}, J^{(x)}, \omega^{(x)}\big)$ satisfying the following conditions:

$$J^{(x)}(T_{|\Omega}\mathcal{M}_{\mathrm{vac}}) = \mathcal{E}_{\mathrm{exc}}(x),$$
$$\omega^{(x)}(\cdot,\cdot) = g^{(x)}_{\mathrm{mod}}(\cdot, J^{(x)}\cdot),$$
$$[J^{(x)}, \Pi^{[\chi]}_{\Phi\Phi}] = [J^{(x)}, \Pi_\alpha] = 0.$$

Define

$$\Psi_x(u)[v] \;:=\; g^{(x)}_{\mathrm{mod}}\Big(u,\; J^{(x)}v\Big), \qquad u \in \mathcal{E}_{\mathrm{exc}}(x), \quad v \in T_{|\Omega}\mathcal{M}_{\mathrm{vac}}.$$

Because $J^{(x)}$ is an isometry and $J^{(x)}(T) = \mathcal{E}_{\mathrm{exc}}$, we have $\|\Psi_x(u)\| = \sup_{\|v\|=1} |g^{(x)}_{\mathrm{mod}}(u, J^{(x)}v)| = \|u\|$, so Ψ_x is a fiberwise isometry onto $T^*_{|\Omega}\mathcal{M}_{\mathrm{vac}}$. Commutation with the typed/triadic projectors follows from the stated compatibility.

Construction (B): Phase space / Legendre pairing. Assume a positive, boundedly invertible A_x with $\mathcal{L}_{\Phi,\mathrm{kin}} = \frac{1}{2}\, g^{(x)}_T(\dot\Phi, \mathsf{A}_x\dot\Phi)$ and $[\mathsf{A}_x, \Pi^{[\chi]}_{\Phi\Phi}] = [\mathsf{A}_x, \Pi_\alpha] = 0$. Then

$$\mathcal{R}^{(\mathsf{A})}_x :\; T_{|\Omega}\mathcal{M}_{\mathrm{vac}} \;\to\; T^*_{|\Omega}\mathcal{M}_{\mathrm{vac}}, \quad v \;\mapsto\; \Big[w \mapsto g^{(x)}_T(\mathsf{A}_x v,\, w)\Big]$$

is an isometric isomorphism. Using the IQR phase–space identification at $|\Omega(x)\rangle$, $\mathcal{E}_{\mathrm{exc}}(x)$ is the momentum fiber canonically paired with $T_{|\Omega}\mathcal{M}_{\mathrm{vac}}$ by the one–form ϑ_x. Thus define

$$\Psi_x :\; \mathcal{E}_{\mathrm{exc}}(x) \;\to\; T^*_{|\Omega}\mathcal{M}_{\mathrm{vac}}, \qquad u \;\mapsto\; \vartheta_x(u,\cdot).$$

With the Legendre metric $g^{(x)}_T$ and A_x, this pairing is an isometry; commutation with the projectors follows from the diagnostic realized reference configuration compatibility.

Uniqueness. If $\tilde\Psi_x$ is another fiberwise isometry with the same commutation properties, then $U_x := \tilde\Psi_x^{-1} \circ \Psi_x : \mathcal{E}_{\mathrm{exc}}(x) \to \mathcal{E}_{\mathrm{exc}}(x)$ is unitary and commutes with $\hat P_T(x)$, $\Pi^{[\chi]}_{\Phi\Phi}$, and Π_α. Hence Ψ_x is unique up to such commuting unitaries.
This proves (9.123) and the properties claimed in Proposition 9.292. □

Remark 9.294 (Canonical identification under Kähler structure)**.** *Optional structure (makes* (9.123) *canonical).* Suppose the local fiber $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$ carries a Kähler triple $\big(g^{(x)}_{\mathrm{mod}}, J^{(x)}, \omega^{(x)}\big)$ with

$$J^{(x)}\Big(T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}\Big) = \mathcal{E}_{\mathrm{exc}}(x), \qquad \omega^{(x)}(\cdot,\cdot) = g^{(x)}_{\mathrm{mod}}\Big(\cdot, J^{(x)}\,\cdot\,\Big),$$

and assume $J^{(x)}$ is compatible with the diagnostic realized reference configuration typed/triadic projectors, $[J^{(x)}, \Pi^{[\chi]}_{\Phi\Phi}] = [J^{(x)}, \Pi_\alpha] = 0$ (cf. Definitions 9.186 and 9.200 and Remark 9.290). Let $g^{(x)}_T$ denote the metric on $T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ induced from $g^{(x)}_{\mathrm{mod}}$. Then the fiberwise map

$$\Psi_x :\; \mathcal{E}_{\mathrm{exc}}(x) \;\longrightarrow\; T^*_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}, \qquad u \;\longmapsto\; \Big[v \mapsto g^{(x)}_{\mathrm{mod}}\Big(u,\; J^{(x)}v\Big)\Big],$$

is an isometric isomorphism (with the dual norm induced by $g^{(x)}_T$) that *commutes* with the typed/triadic projectors: $[\,\Psi_x, \Pi^{[\chi]}_{\Phi\Phi}\,] = [\,\Psi_x, \Pi_\alpha\,] = 0$. Hence (9.123) holds canonically in the sense used in Proposition 9.292.

Smoothness and parallel transport. If $x \mapsto \left(g^{(x)}_{\mathrm{mod}}, J^{(x)}\right)$ is C^1 on the diagnostic realized reference configuration, then $x \mapsto \Psi_x$ defines a smooth bundle isomorphism $\mathcal{E}_{\mathrm{exc}} \xrightarrow{\cong} T^*\mathcal{M}_{\mathrm{vac}}$. If moreover $\bar{\nabla}_\mu J^{(x)} = 0$ (with $\bar{\nabla}$ from Definition 6.7), the identification is parallel along $\mathcal{X}_q$. *Uniqueness up to commuting unitaries.* Any other such identification $\tilde{\Psi}_x$ differs by a unitary U_x on $\mathcal{E}_{\mathrm{exc}}(x)$ that commutes with $\hat{P}_T(x)$ and with the typed/triadic projectors; thus the canonical class is unique up to these innocuous internal symmetries.

9.17.11 Tantrakyma Parasymmetric Type, Location, and Onset

This section sets the operational stage for applying the parasymmetric *Type–Location–Onset* (T–L–O) program to the *Tantrakyma* (matter) sector. It mirrors the Gaiamiti workflow (Section 9.17) and the projection/duality pass (Section 9.17.10), but is specialized to the typed subspaces of the Tantrakyma field. All computations are performed on a certified plateau $\mathfrak{P}$ with UV/IR tags (Definition 7.26, Section 6.12.4, and eq. (7.28)), the triadic channel split $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Definition 5.54 and Theorem 6.261), and BRST/Nielsen safeguards (Chs. 7–8; cf. Sections 7.2 and 7.4). The explicit law for Tantrakyma is introduced in Section 9.18.

Arena, law placeholders, and diagnostic realized reference configuration discipline

Diagnostic realized reference configuration and tags. Fix a realized, BRST-clean diagnostic realized reference configuration $\mathfrak{P}$ (and $\mathfrak{P}_\partial$ when a boundary arena is used), equipped with band tags $\{P_x(\lambda_{\mathrm{UV}}),\ K^{(\ell)}_{\mathrm{IR}}\}$ and the physical projector $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\mathrm{BRST}})$ (Definition 7.26 and Sections 6.12.4 and 7.2). All meters/witnesses are evaluated *on band* and *on* H^0 (Nielsen-flatness).

Law placeholders. We forward-reference the Tantrakyma action S_Θ and Euler–Lagrange (EL) equation to Section 9.18 (see Definitions 9.305 and 9.310). Until then, we treat the kinetic form via the canonical covariant operator g_C and the interaction via the potential $\mathcal{V}_\Theta$ with expectation $V_\Theta := \langle \mathcal{V}_\Theta \rangle$ (cf. eqs. (9.133) and (9.134)).

Triadic compatibility. All typed operations commute with the triadic channel projectors $\{\Pi_\alpha\}$ (holosymmetric guardrails; Ch. 7). Unless stated otherwise, every object carries the band/triad decorations implicitly.

Typed slicing of the Tantrakyma sector

Definition 9.295 (Typed Tantrakyma projectors)**.** Let the admissible type menu be $[\chi] \in \{\mathrm{CK},\ \mathrm{T}_+,\ \mathrm{T}_-,\ \mathrm{L}\}$, corresponding to Chrono–Kymon, transverse-helicity ($\pm$), and longitudinal subspaces (cf. fields–quanta typed ledgers). Define orthogonal, complete, BRST-closed projectors

$$\Pi^{[\chi]}_{\Theta\Theta} :\ \mathcal{H} \to \mathcal{H}, \qquad \sum_\chi \Pi^{[\chi]}_{\Theta\Theta} = \mathbf{1}, \quad \Pi^{[\chi]}_{\Theta\Theta}\,\Pi^{[\chi']}_{\Theta\Theta} = \delta_{\chi\chi'}\,\Pi^{[\chi]}_{\Theta\Theta}, \quad \left[\hat{Q}_{\mathrm{BRST}},\ \Pi^{[\chi]}_{\Theta\Theta}\right] = 0,$$

with $\left[\Pi^{[\chi]}_{\Theta\Theta},\ \Pi_\alpha\right] = 0$ for each triadic channel α.

Linearization and typed mass/curvature operators

Write the background–fluctuation split $\hat{\boldsymbol{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\boldsymbol{\Theta}}$ on $\mathfrak{P}$ (EL-stationary backgrounds in Section 9.18). The potential's same-variable Hessian defines typed curvature operators by restriction:

$$\boxed{\mathcal{K}^{[\chi]}_{\Theta\Theta} := \Pi^{[\chi]}_{\Theta\Theta}\,\frac{\delta^2\mathcal{V}_\Theta}{\delta\hat{\boldsymbol{\Theta}}\,\delta\hat{\boldsymbol{\Theta}}}\Big|_{\bar{\Theta}}\,\Pi^{[\chi]}_{\Theta\Theta}, \qquad \mathrm{spec}\Big(\mathcal{K}^{[\chi]}_{\Theta\Theta}\Big) \rightsquigarrow \text{ gaps vs. NG/pNG modes.}} \tag{9.124}$$

Typed EL linear response then reads

$$\begin{aligned}\Big(\mathbb{K}^{[\chi]}_{\Theta} + \mathcal{K}^{[\chi]}_{\Theta\Theta}\Big)\,\delta\hat{\boldsymbol{\Theta}}^{[\chi]} &= \hat{\mathcal{J}}^{[\chi]},\\ \delta\hat{\boldsymbol{\Theta}}^{[\chi]} &:= \Pi^{[\chi]}_{\Theta\Theta}\,\delta\hat{\boldsymbol{\Theta}},\end{aligned} \tag{9.125}$$

where $\mathbb{K}^{[\chi]}_{\Theta}$ is the typed kinetic block (band-limited, hyperbolic on H^0; Ch. 8) and $\hat{\mathcal{J}}^{[\chi]}$ denotes the typed source.

Parasymmetric meters and witnesses (typed)

Definition 9.296 (Typed parasymmetric meters and witness)**.** Let $\Delta^{[\chi]}_{\Theta\Theta}$ denote the typed, band-limited, retarded two-point kernel on H^0 (*notation:* this is the $[\chi]$ projection of $G^{\mathrm{R}}_{\Theta\Theta,\mathrm{phys}}$). Define the SynTh driver triple

$$\boxed{\begin{aligned} v^{(L)}_{[\chi]} &:= \Big|\,\mathrm{Res}_{k^2=0}\;\Delta^{[\chi]}_{\Theta\Theta}(k)\Big| \quad \text{(law-side pole content)}, && (9.126)\\ v^{(S)}_{[\chi]} &:= \Big\|\Delta^{[\chi]}_{\Theta\Theta}(t\to\infty;\,\mathbf{x}=\mathbf{0})\Big\|_{H^0} \quad \text{(state-side long-time order)}, && (9.127)\\ v^{(LS)}_{[\chi]} &:= \text{typed cross-channel gain (helicity-resolved; band-robust).} && (9.128)\end{aligned}}$$

The *typed witness* is $\mathbf{W}^{[\Theta\Theta]}_{[\chi]} := (v^{(L)}_{[\chi]},\, v^{(S)}_{[\chi]},\, v^{(LS)}_{[\chi]})$.

Tolerance semantics and plateau certification follow eq. (7.28). Gauge-parameter independence of $\mathbf{W}^{[\Theta\Theta]}_{[\chi]}$ holds by the BRST/Nielsen provisos (Chs. 7–8; ∂_ξ-flatness).

Typed quadrant predicate and healing indicators

Definition 9.297 (Typed quadrant predicate for Tantrakyma)**.** Given $\mathbf{W}^{[\Theta\Theta]}_{[\chi]}$ on a certified $\mathfrak{P}$, define $\mathrm{Quad}^{[\Theta\Theta]}_{[\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$ by the canonical decision rule of Definition 7.685 (as typed in Definition 9.208). Introduce *healing indicators* $\mathscr{H}_L, \mathscr{H}_S$ (law/state) to distinguish QIII vs. QIV (finite-window decay vs. pinned deficit).

Proposition 9.298 (Meters determine the typed quadrant)**.** *On a certified plateau and fixed tags, the triple* $\big(\mathbf{W}^{[\Theta\Theta]}_{[\chi]},\, \mathscr{H}_L,\, \mathscr{H}_S\big)$ *uniquely determines* $\mathrm{Quad}^{[\Theta\Theta]}_{[\chi]}$ *(SynTh completeness; cf. Corollary 9.209). Consistency with the potential analysis holds in the sense that NG/pNG vs. gapped predictions from* $\mathrm{spec}(\mathcal{K}^{[\chi]}_{\Theta\Theta})$ *agree within tolerance budgets (Ch. 8).*

Type–Location–Onset stamping

Definition 9.299 (Typed T–L–O stamping)**.** For each $[\chi]$, the $\mathrm{TLO}^{[\chi]}$ record contains (i) the *Type* identifier; (ii) *Location* bands (IR/mesoscopic/UV windows under $K_{\mathrm{IR}}^{(\ell)}$); (iii) *Onset* thresholds (first certified pass-through). Stamps are computed from $\mathbf{W}_{[\chi]}^{[\Theta\Theta]}$ and the typed retarded kernels, using the same operators defined in the Gaiamiti prelude (Section 9.17).

Boundary pass and monotonicity

Proposition 9.300 (Bulk–boundary overlay)**.** *Repeating the evaluation on $\mathfrak{P}_\partial$ with tangential windows preserves BRST/Nielsen flatness; plateau budgets may tighten, and law visibilities weakly increase toward symmetry (boundary functoriality, cf. Ch. 9 sector rules). Typed quadrant membership is stable away from tolerance boundaries.*

Noether and stress–energy cross-checks

From $\mathcal{L}_\Theta$ (introduced in Section 9.18), construct the internal *Noether current* $\hat{J}_\Theta^\mu$ and its diagnostic realized reference configuration realization via the Noether bridge (Lemma 9.279, Definition 9.280, and Proposition 9.281). Optionally, derive the Tantrakyma stress–energy tensor $\hat{T}_{(\Theta)}^{\mu\nu}$ by diffeomorphism response (geometry-analogue of Section 9.17.9); both provide additional *Location* diagnostics consistent with the typed meters.

9.18 The Action for the Dynamical Tantrakyma Field

Having introduced the Dynamical Tantrakyma Field $\hat{\mathbf{\Theta}}(x)$ as the fundamental operator encoding material structure—i.e., *the relational manifestation of excitation and content* within the emergent geometry—we now specify its dynamics via an action principle. As with the Gaiamiti field, we invoke the *Principle of Stationary Action* to derive its evolution. Throughout, all objects are evaluated on a certified plateau $\mathfrak{P}$ with UV/IR tags $(\lambda_{\mathrm{UV}}, \ell)$ (cf. Definition 7.26, Section 6.12.4, and eq. (7.28)) and projected to the physical sector $H^0(\hat{Q}_{\mathrm{BRST}})$; ghost number is zero and gauge-parameter dependence is Nielsen-flat.

Definition 9.301 (Operator kernel and scalar Lagrangian density (unbanded))**.** Let $\hat{\mathbf{\Theta}}(x)$ be the Dynamical Tantrakyma Field, viewed as a section of $\mathrm{End}(\mathcal{H}_{\mathrm{em}}) \otimes T^*\mathcal{M}_{\mathrm{vac}}$ over $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$ (cf. Definitions 1.34 and 5.26 and Section 6.1.17). Define the *operator-valued* Lagrangian *kernel*

$$\widehat{\mathcal{L}}_\Theta(x) := \bar{\Sigma}^{\mu\nu}(x)\, g_C\Big(\nabla_\mu \hat{\mathbf{\Theta}}(x),\, \nabla_\nu \hat{\mathbf{\Theta}}(x)\Big) \;+\; \mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big) \quad \in\; \mathrm{End}(\mathcal{H}_{\mathrm{em}}),$$

with ∇_μ the total (base + internal) covariant derivative and g_C a Hermitian operator-valued co-metric (Remark 9.303). The *(scalar) Lagrangian density* is the trace of this kernel:

$$\mathcal{L}_\Theta(x) \;:=\; \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{L}}_\Theta(x)\Big\}, \tag{9.129}$$

a c-number density on $\mathcal{X}_q$ (ghost number 0).

The Lagrangian density $\mathcal{L}_\Theta(x)$ decomposes into:

1. **Kinetic term:**
$$\mathcal{T}_\Theta(x) := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\bar{\Sigma}^{\mu\nu}(x)\, g_C\Big(\nabla_\mu \hat{\mathbf{\Theta}}(x),\, \nabla_\nu \hat{\mathbf{\Theta}}(x)\Big)\Big\}. \tag{9.130}$$

2. **Potential term (operator built, traced to scalar):**
$$\mathcal{V}_{\Theta,\mathrm{density}}(x) := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big)\Big\}. \tag{9.131}$$

Thus $\mathcal{L}_\Theta = \mathcal{T}_\Theta + \mathcal{V}_{\Theta,\mathrm{density}}$.
The total action functional is

$$S_\Theta[\hat{\mathbf{\Theta}}] \;=\; \int_{\mathcal{X}_q} d\mu(x)\, \mathcal{L}_\Theta(x) \;=\; \int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}(x)}\, \mathcal{L}_\Theta(x), \tag{9.132}$$

where $d\mu(x) = d^d x \sqrt{-\det \bar{g}^{\mathrm{Lor}}(x)}$ is the relational volume element (cf. Definition 6.33; the shorthand $\sqrt{-\det \bar{\Sigma}}$ equals $\sqrt{-\det \bar{g}^{\mathrm{Lor}}}$ on the diagnostic realized reference configuration, cf. Remark 9.311). Equivalently,

$$S_\Theta \;=\; \int_{\mathcal{X}_q} d\mu(x)\; \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{L}}_\Theta(x)\Big\}.$$

Remark 9.302 (Symmetry, covariance, and diagnostic realized reference configuration/BRST invariances)**.** The Lagrangian density $\mathcal{L}_\Theta(x)$ in Definition 9.301 is:

- **Diffeomorphism covariant** on $\mathcal{X}_q$: $\mathcal{L}_\Theta(x)$ is a scalar density under coordinate changes, and S_Θ is invariant.
- **Fiber–algebra invariance:** If $\varphi_x \in \mathrm{Aut}\Big(\mathrm{End}(\mathcal{H}_{\mathrm{em}})\Big)$ is trace-preserving (e.g. $\varphi_x(A) = U_x A U_x^\dagger$ with U_x unitary), then $\mathrm{Tr}(\varphi_x(X)) = \mathrm{Tr}(X)$, so $\mathcal{L}_\Theta$ and S_Θ are invariant.
- **Diagnostic realized reference configuration inheritance**: after restriction to a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ and projection to $H^0(\hat{Q}_{\mathrm{BRST}})$, these symmetries persist; banding and projection are BRST-closed (ghost number 0).
- **Nielsen stability**: pole locations and residues extracted from typed, band-limited propagators on H^0 are gauge-parameter independent (Chs. 7–8).

Thus the field equations from $\delta S_\Theta = 0$ respect background-independence and the triadic/typed machinery used by the parasymmetric T–L–O program.

Remark 9.303 (Operator-valued co-metric and (pseudo)inverse)**.** The map $g_C : T^*\mathcal{M}_{\mathrm{vac}} \times T^*\mathcal{M}_{\mathrm{vac}} \to \mathrm{End}(\mathcal{H}_{\mathrm{em}})$ is Hermitian, positive semidefinite, and sesquilinear (antilinear in its first entry). For $\hat{\alpha}, \hat{\beta} \in T^*_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ we have

$$g_C(\hat{\alpha}, \hat{\beta})^\dagger = g_C(\hat{\beta}, \hat{\alpha}), \qquad g_C(\hat{\alpha}, \hat{\alpha}) \succeq 0.$$

- **Kinetic pairing.** g_C acts on the cotangent legs and, by $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$-bilinearity, yields an element of $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$ inside the trace in (9.130).

- **Pseudoinverse on the excitation subspace.** Let g_C^{-1} denote the Moore–Penrose pseudoinverse on the excitation subspace $\mathcal{E}_{\mathrm{exc}}(x) \subseteq T^*\mathcal{M}_{\mathrm{vac}} \otimes \mathrm{End}(\mathcal{H}_{\mathrm{em}})$, characterized by

$$g_C\, g_C^{-1}\, g_C = g_C, \quad g_C^{-1}\, g_C\, g_C^{-1} = g_C^{-1}, \quad \big(g_C\, g_C^{-1}\big)^\dagger = g_C\, g_C^{-1}, \quad \big(g_C^{-1}\, g_C\big)^\dagger = g_C^{-1}\, g_C.$$

  For $\hat\alpha, \hat\beta \in \mathcal{E}_{\mathrm{exc}}(x)$ the *trace pairing* holds:

$$\mathrm{Tr}\Big\{\, g_C\Big(g_C^{-1}(\hat\alpha, \cdot),\, \hat\beta\Big)\Big\} = \mathrm{Tr}\Big(\hat\alpha^\dagger \hat\beta\Big)\,.$$

  This duality is useful for Hamiltonian/phase-space formulations but is *not* the primitive building block of the potential.

- **Relational dependence and covariance.** g_C (and g_C^{-1}, when used) vary over $\mathcal{X}_q$ via $|\Omega(x)\rangle$, encoding an operator-theoretic geometry of $T^*\mathcal{M}_{\mathrm{vac}}$ (cf. Proposition 9.292); their band-limited pullbacks are BRST-closed and Nielsen-flat on H^0.

Together, $\big(g_C, g_C^{-1}\big)$ provide the inner-product structure and (optional) tangent–cotangent duality for the Tantrakyma field.

Definition 9.304 (Tantrakyma potential: operator form and expectation)**.** Because $\hat{\mathbf{\Theta}}$ is *covector*-valued, the canonical invariant is $\mathsf{X} := g_C\big(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}}\big) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}})$. A diagnostic realized reference configuration-safe minimal potential is

$$\boxed{\mathcal{V}_\Theta\big(\hat{\mathbf{\Theta}}\big) = \frac{1}{2}\, m_\Theta^2\, \mathsf{X} + \frac{\lambda_\Theta}{4!}\, \mathsf{X}^2 + \mathcal{O}\big(\mathsf{X}^3/\Lambda_\Theta^2\big),} \tag{9.133}$$

with real parameters m_Θ^2 and $\lambda_\Theta > 0$, and a suppression scale Λ_Θ. Its expectation (a c-number density) is

$$\boxed{V_\Theta(x) := \Big\langle \mathring{\mathbf{\Psi}}\Big|\, \mathsf{P}_{\mathrm{phys}}\, \mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big)\, \mathsf{P}_{\mathrm{phys}}\, \Big|\mathring{\mathbf{\Psi}}\Big\rangle = \mathrm{Tr}\Big\{\rho_{\mathrm{phys}}(x)\, \mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big)\Big\}\,,} \tag{9.134}$$

with ρ_{phys} the local reduced density on H^0. (Any diagnostic realized reference configuration-certified alternative potential compatible with $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ may be used.)

Definition 9.305 (Euler–Lagrange equation for $\hat{\mathbf{\Theta}}(x)$)**.** Varying S_Θ at fixed $\bar\Sigma$ and connections yields the operator EL equation, in manifestly covariant form,

$$\boxed{\frac{1}{\sqrt{-\det \bar\Sigma}}\, \nabla_\mu\left(\sqrt{-\det \bar\Sigma}\; \bar\Sigma^{\mu\nu}\, \frac{\partial \mathcal{L}_\Theta}{\partial(\nabla_\nu \hat{\mathbf{\Theta}})}\right) \;=\; \frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}^\dagger}\,,} \tag{9.135}$$

where, by Fréchet differentiation at fixed $\bar\Sigma$,

$$\frac{\partial \mathcal{L}_\Theta}{\partial(\nabla_\nu \hat{\mathbf{\Theta}})} \;=\; \bar\Sigma^{\mu\nu}\, g_C^\sharp\Big(\nabla_\mu \hat{\mathbf{\Theta}}, \cdot\Big),$$

with $g_C^\sharp$ the map sending the second slot "$\cdot$" to $g_C\big(\nabla_\mu \hat{\mathbf{\Theta}}, \cdot\big) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}})$. Expanding the covariant divergence gives the equivalent form

$$\boxed{\bar{\Sigma}^{\mu\nu}\,\nabla_\mu \nabla_\nu \hat{\mathbf{\Theta}} \;+\; (\nabla_\mu \bar{\Sigma}^{\mu\nu})\,\nabla_\nu \hat{\mathbf{\Theta}} \;=\; \frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}^\dagger}\,.} \tag{9.136}$$

No g_C^{-1} appears: the kinetic and potential terms are built with the co-metric g_C appropriate to the covector-valued field $\hat{\mathbf{\Theta}}$. Both forms are read on the diagnostic realized reference configuration with band tags and BRST projection, in parallel with Definition 9.268.

Definition 9.306 (Band functor and tags)**.** Let $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ be the UV projector and IR window (cf. Definition 7.26 and Section 6.12.4). Define the band functor $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ acting on fields and derivatives by

$$\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)} := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\hat{\mathbf{\Theta}}\Big]\,, \qquad \nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)} := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} \circ \nabla_\mu,$$

and work on a certified plateau $\mathfrak{P} \subset \mathcal{X}_q$ with projection to $H^0(\hat{Q}_{\mathrm{BRST}})$.

Definition 9.307 (Band-limited, BRST-clean operator-built Lagrangian density)**.** Work on a certified plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$) with projection to the physical Hilbert space

$$\mathcal{H}_{\mathrm{phys}} \;=\; H^0(\hat{Q}_{\mathrm{BRST}}),$$

and triadic channel projectors $\{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}$ (Definition 9.185). Let the *Dynamical Tantrakyma Field* be a section

$$\hat{\mathbf{\Theta}}(x) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}}) \otimes T^*\mathcal{M}_{\mathrm{vac}},$$

over the emergent configuration space $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$ (cf. Definitions 1.34 and 5.26 and Section 6.1.17). Let $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ denote the UV projector and IR window (cf. Definition 7.26 and Section 6.12.4), and define the band functor

$$\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} \;:=\; P_x(\lambda_{\mathrm{UV}})\, K_{\mathrm{IR}}^{(\ell)}.$$

The band functor is BRST- and triadic-compatible:

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0, \qquad [\Pi_\alpha, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0 \quad (\alpha \in \{\mathrm{corr,vac,spec}\}), \tag{9.137}$$

and, when used with typed projectors on the $\Theta\Theta$ block, preserves typed compatibility $\Big[\Pi_{\Theta\Theta}^{[\chi]}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big] = 0$ (cf. Definition 9.295 and Proposition 9.202).

Define the band-limited field and covariant derivative by

$$\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)} := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\hat{\mathbf{\Theta}}\Big]\,, \tag{9.138}$$

$$\nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)} := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} \circ \nabla_\mu, \tag{9.139}$$

and enforce the filter/derivative composition on banded fields as

$$\nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)} \hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\nabla_\mu\Big(\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)\Big] = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\nabla_\mu\, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{\mathbf{\Theta}}]\Big], \tag{9.140}$$

so no out-of-band leakage appears at this stage. Here ∇_μ is the total (base + internal) covariant derivative compatible with $\bar{\Sigma}$ (Definitions 6.7 and 9.301).

The (band-limited, BRST-clean) operator-built Lagrangian density is

$$\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)}(x) := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\bar{\Sigma}^{\mu\nu}(x)\, g_C\Big(\nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}(x),\, \nabla_\nu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}(x)\Big) + \mathcal{V}_\Theta\Big(\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}(x)\Big)\Big\}, \tag{9.141}$$

where $g_C : T^*\mathcal{M}_{\mathrm{vac}} \times T^*\mathcal{M}_{\mathrm{vac}} \to \mathrm{End}(\mathcal{H}_{\mathrm{em}})$ is a Hermitian operator-valued co-metric (ghost number 0; cf. Remark 9.303) and $\mathcal{V}_\Theta(\cdot) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}})$ is the Tantrakyma potential (cf. eqs. (9.133) and (9.134)).

The diagnostic realized reference configuration action uses the relational volume element $d\mu(x)$ (Definition 6.33; cf. Remark 9.311):

$$S_\Theta^{(\lambda_{\mathrm{UV}},\ell)}[\hat{\boldsymbol{\Theta}}] := \int_{\mathcal{X}_q} d\mu(x)\, \mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)}(x). \tag{9.142}$$

When tags are suppressed, write $\mathcal{L}_\Theta \equiv \mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)}$ and $S_\Theta \equiv S_\Theta^{(\lambda_{\mathrm{UV}},\ell)}$ at a fixed certified plateau $\mathfrak{P}$.

Proposition 9.308 (Band–variation commutation and typed EL on the diagnostic realized reference configuration)**.** *On a certified plateau (eq. (7.28)), variation and banding commute in the sense that*

$$\delta S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \int d\mu\, \delta\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\big[\delta S_\Theta\big].$$

Consequently, the Euler–Lagrange system obtained from $\delta S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = 0$ is the banded form of the unbanded EL equations (cf. Definition 9.305); its typed restriction obeys

$$\Big(\mathbb{K}_\Theta^{[\chi]} + \mathcal{K}_{\Theta\Theta}^{[\chi]}\Big)\,\delta\hat{\boldsymbol{\Theta}}^{[\chi]} = \hat{\mathcal{J}}^{[\chi]}, \qquad \delta\hat{\boldsymbol{\Theta}}^{[\chi]} := \Pi_{\Theta\Theta}^{[\chi]}\,\delta\hat{\boldsymbol{\Theta}}, \tag{9.143}$$

with $\mathcal{K}_{\Theta\Theta}^{[\chi]}$ the typed Hessian (eq. (9.124)). Pole locations and residues extracted on $H^0(\hat{Q}_{\mathrm{BRST}})$ are gauge-parameter independent (Nielsen-flat).

Proof of Proposition 9.308. **Setup.** On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$, the band functor $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ acts on the Tantrakyma field and on the covariant derivative by

$$\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)} := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{\boldsymbol{\Theta}}], \qquad \nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)} := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} \circ \nabla_\mu,$$

and the diagnostic realized reference configuration action reads (with the relational measure $d\mu$; cf. Definition 6.33 and Remark 9.311)

$$S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \int_{\mathcal{X}_q} d\mu(x)\, \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\bar{\Sigma}^{\mu\nu}(x)\, g_C\Big(\nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}, \nabla_\nu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) + \mathcal{V}_\Theta\Big(\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)\Big\}.$$

By definition (Definition 9.307),

$$\nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\nabla_\mu\Big(\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)\Big] = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\nabla_\mu\,\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{\mathbf{\Theta}}]\Big],$$

so no out-of-band leakage appears (cf. (9.140)). The background $\bar{\Sigma}$ is held fixed during variation. We use the diagnostic realized reference configuration commutation properties $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0$ and $[\Pi_\alpha, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0$ (eq. (9.137)), and assume standard vanishing/controlled boundary terms (or compact support under the IR window).

(A) δ–integral exchange. Since $d\mu$ is diagnostic realized reference configuration-fixed (vary at fixed $\bar{\Sigma}$), we may write

$$\delta S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \int_{\mathcal{X}_q} d\mu(x)\; \delta\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)}(x).$$

(B) Commutation of banding with variation. Linearity and idempotence of $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$, together with the fact that $\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)}$ is the same functional as $\mathcal{L}_\Theta$ but evaluated on the *banded* variables, imply

$$\delta\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\delta\mathcal{L}_\Theta\Big],$$

hence, using trace cyclicity,

$$\delta S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\delta S_\Theta\Big].$$

This is the claimed δ–banding commutation.

(C) Euler–Lagrange equations on the diagnostic realized reference configuration. Covariant integration by parts with the $\bar{\Sigma}$-compatible connection (background fixed) shows that the EL operator for the banded action is the band of the bare EL operator:

$$\mathcal{E}_{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\mathcal{E}_{\mathbf{\Theta}}\Big].$$

Thus the EL equations from $\delta S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = 0$ are the banded form of the unbanded EL system (cf. Definition 9.305). Boundary terms vanish or are accounted for by the IR window.

(D) Typed restriction and linearized form. Let $\Pi_{\Theta\Theta}^{[\chi]}$ be the typed projector (cf. Definition 9.295 and Proposition 9.202) commuting with the triadic projectors on the diagnostic realized reference configuration. Linearizing the EL map and restricting to the typed Θ-sector yields

$$\Big(\mathbb{K}_\Theta^{[\chi]} + \mathcal{K}_{\Theta\Theta}^{[\chi]}\Big)\,\delta\hat{\mathbf{\Theta}}^{[\chi]} = \hat{\mathcal{J}}^{[\chi]}, \qquad \delta\hat{\mathbf{\Theta}}^{[\chi]} := \Pi_{\Theta\Theta}^{[\chi]}\,\delta\hat{\mathbf{\Theta}},$$

with $\mathcal{K}_{\Theta\Theta}^{[\chi]}$ as in eq. (9.124), i.e. (9.143).

(E) Nielsen flatness on $H^0(\hat{Q}_{\mathrm{BRST}})$. Adding gauge–fixing/ghost terms as BRST-exact pieces and projecting to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ leaves the physical EL equations invariant and renders pole locations and residues gauge–parameter independent (Nielsen-flat), by the BRST/Nielsen safeguards of Chs. 7–8.

Conclusion. Combining (A)–(C) we obtain

$$\delta S_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \int d\mu\,\delta\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\delta S_\Theta\Big],$$

and together with (D)–(E) the typed EL form (9.143) holds, with gauge–parameter independent poles/residues on $H^0(\hat{Q}_{\mathrm{BRST}})$. □

Definition 9.309 (Triadic- and typed-resolved Tantrakyma Lagrangian slices)**.** Let $\mathfrak{A} := \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$. Let $\{\Pi_\alpha\}_{\alpha\in\mathfrak{A}}$ be the triadic channel projectors (cf. Definition 9.185), and let $\{\Pi^{[\chi]}_{\Theta\Theta}\}$ denote the Tantrakyma typed projectors (cf. Definition 9.295). The *operator-level* typed/triadic slice is

$$\widehat{\mathcal{L}}^{[\chi]}_{\Theta;\alpha}(x) := \Pi_\alpha\, \Pi^{[\chi]}_{\Theta\Theta}\Big[\bar{\Sigma}^{\mu\nu}\, g_C\Big(\nabla_\mu\hat{\boldsymbol{\Theta}},\, \nabla_\nu\hat{\boldsymbol{\Theta}}\Big) + \mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}})\Big]\Pi^{[\chi]}_{\Theta\Theta}\,\Pi_\alpha.$$

Since the projectors act trivially on the fiber algebra $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$, the *channel- and type-resolved Lagrangian density* is obtained by tracing only over $\mathcal{H}_{\mathrm{em}}$:

$$\mathcal{L}^{[\chi]}_{\Theta;\alpha}(x) := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{L}}^{[\chi]}_{\Theta;\alpha}(x)\Big\}. \tag{9.144}$$

On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$, the band-limited (BRST-clean) slices are

$$\begin{aligned}
\widehat{\mathcal{L}}^{[\chi](\lambda_{\mathrm{UV}},\ell)}_{\Theta;\alpha}(x) &:= \Pi_\alpha\, \Pi^{[\chi]}_{\Theta\Theta}\Big[\bar{\Sigma}^{\mu\nu}\, g_C\Big(\nabla^{(\lambda_{\mathrm{UV}},\ell)}_\mu\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)},\, \nabla^{(\lambda_{\mathrm{UV}},\ell)}_\nu\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) + \mathcal{V}_\Theta\Big(\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)\Big]\Pi^{[\chi]}_{\Theta\Theta}\,\Pi_\alpha,\\
\mathcal{L}^{[\chi](\lambda_{\mathrm{UV}},\ell)}_{\Theta;\alpha}(x) &:= \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{L}}^{[\chi](\lambda_{\mathrm{UV}},\ell)}_{\Theta;\alpha}(x)\Big\},
\end{aligned} \tag{9.145}$$

with band functor $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ as in Definition 9.307 and compatibility $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0 = [\Pi_\alpha, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]$ (cf. eq. (9.137)).

Properties.

1. **BRST neutrality.** Ghost number 0 and $[\hat{Q}_{\mathrm{BRST}}, \widehat{\mathcal{L}}^{[\chi]}_{\Theta;\alpha}] = 0$; hence $[\hat{Q}_{\mathrm{BRST}}, \mathcal{L}^{[\chi]}_{\Theta;\alpha}] = 0$.
2. **Triadic/type compatibility.** $[\Pi_\alpha, \Pi^{[\chi]}_{\Theta\Theta}] = 0$, with orthogonality/idempotence as in Proposition 9.202: $\Pi_\alpha\Pi_\beta = \delta_{\alpha\beta}\Pi_\alpha$, $\sum_{\alpha\in\mathfrak{A}}\Pi_\alpha = \mathbf{1}$; $\Pi^{[\chi]}_{\Theta\Theta}\Pi^{[\chi']}_{\Theta\Theta} = \delta_{\chi\chi'}\,\Pi^{[\chi]}_{\Theta\Theta}$, $\sum_\chi \Pi^{[\chi]}_{\Theta\Theta} = \mathbf{1}$ (on the $\Theta\Theta$ block).
3. **Aggregation identities.** Writing the *typed* slice $\mathcal{L}^{[\chi]}_\Theta := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\Pi^{[\chi]}_{\Theta\Theta}[\cdots]\Pi^{[\chi]}_{\Theta\Theta}\Big\}$ and the *full* density $\mathcal{L}_\Theta$ from Definition 9.307, one has
$$\sum_{\alpha\in\mathfrak{A}}\mathcal{L}^{[\chi]}_{\Theta;\alpha} = \mathcal{L}^{[\chi]}_\Theta, \qquad \sum_\chi\sum_{\alpha\in\mathfrak{A}}\mathcal{L}^{[\chi]}_{\Theta;\alpha} = \mathcal{L}_\Theta,$$
and the same equalities hold for the banded forms in (9.145).
4. **Inputs to Parasymmetric T–L–O.** The slices $\mathcal{L}^{[\chi]}_{\Theta;\alpha}$ (banded on the diagnostic realized reference configuration) feed the typed SynTh meters (cf. Section 9.17.11); their spectra and pole content agree with the typed Hessian route within plateau tolerances (Ch. 8).

9.18.1 The Tantrakyma Field Action Functional

The dynamics of the Tantrakyma field—and, by extension, its fundamental quanta, the **kymons**—are governed by the **Tantrakyma Field Action Functional** $S_\Theta[\hat{\boldsymbol{\Theta}}]$. This functional is obtained by integrating the operator-valued Lagrangian density $\mathcal{L}_\Theta(x)$ (Definition 9.301) over the emergent quantum configuration space $\mathcal{X}_q$, with the relational volume element $d\mu(x)$.

Definition 9.310 (Tantrakyma Field Action Functional)**.** Let $\mathcal{L}_\Theta(x)$ be the (scalar, c-number) Lagrangian density defined in Definition 9.301, obtained by tracing the operator-level kernel over the fiber algebra. The action functional is

$$\boxed{S_\Theta[\hat{\boldsymbol{\Theta}}] := \int_{\mathcal{X}_q} d\mu(x)\, \mathcal{L}_\Theta(x) = \int_{\mathcal{X}_q} d^d x \sqrt{-\det \bar{\Sigma}(x)}\, \mathcal{L}_\Theta(x),} \tag{9.146}$$

where $d\mu(x) := d^d x \sqrt{-\det \bar{\Sigma}(x)}$ is the relational volume element (cf. Definition 6.33). Substituting $\mathcal{L}_\Theta$ from Definition 9.301 gives the explicit form

$$S_\Theta[\hat{\boldsymbol{\Theta}}] = \int_{\mathcal{X}_q} d^d x \sqrt{-\det \bar{\Sigma}(x)}\, \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{ \bar{\Sigma}^{\mu\nu}(x)\, g_C\Big(\nabla_\mu \hat{\boldsymbol{\Theta}}(x),\, \nabla_\nu \hat{\boldsymbol{\Theta}}(x)\Big) + \mathcal{V}_\Theta\Big(\hat{\boldsymbol{\Theta}}(x)\Big)\Big\}. \tag{9.147}$$

The symbols are as follows:

- $\mathcal{X}_q$: emergent configuration manifold (ambient arena used for integration; cf. Definition 6.33).
- $\bar{\Sigma}_{\mu\nu}(x) = \bar{g}_{\mu\nu}(x) + \bar{t}_{\mu\nu}(x)$: unified relational chronogeometric tensor (Definition 5.26); $\bar{\Sigma}^{\mu\nu}(x)$ denotes its inverse (on the diagnostic realized reference configuration; cf. Definition 6.24).
- $\nabla_\mu \hat{\boldsymbol{\Theta}}(x)$: total covariant derivative (base + internal connections) of the Tantrakyma field (Definition 9.301).
- $g_C : T^*\mathcal{M}_{\mathrm{vac}} \times T^*\mathcal{M}_{\mathrm{vac}} \to \mathrm{End}(\mathcal{H}_{\mathrm{em}})$: Hermitian operator-valued co-metric furnishing the inner-product structure for covector-valued variations (Definition 9.301, Remark 9.303).
- $\mathcal{V}_\Theta\Big(\hat{\boldsymbol{\Theta}}(x)\Big)$: Tantrakyma potential operator encoding self-interactions and mass structure of kymons, *built from the co-metric invariant* $\mathsf{X} = g_C(\hat{\boldsymbol{\Theta}}, \hat{\boldsymbol{\Theta}})$ (not from g_C^{-1}); cf. Definition 9.301.
- $\mathrm{Tr}\{\cdots\}$: trace over the fiber algebra $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$, yielding a scalar density.

Remark 9.311 (Relational volume element and $\sqrt{-\det \bar{\Sigma}}$ shorthand)**.** By Definition 6.33, the relational volume element on $\mathcal{X}_q$ is

$$d\mu(x) \;=\; d^d x \sqrt{-\det \bar{g}^{\mathrm{Lor}}_{\mu\nu}(x)}.$$

In other manipulations (e.g. Noether identities), the shorthand $\sqrt{-\det \bar{\Sigma}}$ is employed together with the $\bar{\Sigma}$-compatible Relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$ (Definition 6.7). These notations are consistent because $\bar{g}^{\mathrm{Lor}}$ is the Lorentzian projection determined by $\bar{\Sigma}$ (cf. Section 6.1.5). For strict adherence to Definition 6.33, the second equality in eq. (9.146) may be written with $\sqrt{-\det \bar{g}^{\mathrm{Lor}}}$; if the shorthand $\sqrt{-\det \bar{\Sigma}}$ is retained, include the parenthetical note "shorthand; equal on $\mathfrak{P}$ via $\bar{g}^{\mathrm{Lor}}(\bar{\Sigma})$".

With either notation, the action reads

$$S_\Theta[\hat{\boldsymbol{\Theta}}] = \int_{\mathcal{X}_q} d\mu(x)\, \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{ \bar{\Sigma}^{\mu\nu}\, g_C\Big(\nabla_\mu \hat{\boldsymbol{\Theta}},\, \nabla_\nu \hat{\boldsymbol{\Theta}}\Big) + \mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}})\Big\},$$

which is consistent with the band-limited (diagnostic realized reference configuration-clean) formulation on a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ (cf. Definition 9.185 and Section 9.17.11).

Interpretation of the Tantrakyma Action The action functional $S_\Theta[\hat{\mathbf{\Theta}}]$ (Definition 9.310) governs the *dynamical structure of what we perceive as matter* within the emergent geometry. In the same way that the Gaiamiti analysis prepares the chronogeometric stage (Sections 6.5 and 9.17.9), the Tantrakyma action directs the actors—the *kymons*. Crucially, the law depends not merely on a metric but on the full *chronogeometric* data $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Definition 5.26), with $\bar{\Sigma}^{\mu\nu}$ its inverse (cf. Definition 6.24); this is made explicit in the operator-valued density $\mathcal{L}_\Theta$ (Definition 9.301) and in its band-limited, BRST-clean form (Definition 9.307).

Kinetic term as chronogeometric propagation. The kinetic density $\mathcal{T}_\Theta$ in (9.130) reads

$$\mathcal{T}_\Theta(x) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\bar{\Sigma}^{\mu\nu}(x)\, g_C\Big(\nabla_\mu\hat{\mathbf{\Theta}}(x),\, \nabla_\nu\hat{\mathbf{\Theta}}(x)\Big)\Big\},$$

and encodes how kymons propagate across the emergent manifold $\mathcal{X}_q$ (cf. Definition 6.33). Here g_C is the operator-valued co-metric on $T^*\mathcal{M}_{\mathrm{vac}}$ (Definition 9.301 and Remark 9.303), so the "cost" of variation is measured in the *cotangent* geometry of matter, while $\bar{\Sigma}^{\mu\nu}$ couples that cost to the *complete* chronogeometric background: curvature of distinguishability via $\bar{g}_{\mu\nu}$ and curvature of phase flow via $\bar{t}_{\mu\nu}$. This is precisely why (i) hyperbolicity and causal cones are $\bar{\Sigma}$-controlled, and (ii) propagation statements descend BRST-safely to $H^0(\hat{Q}_{\mathrm{BRST}})$ on the diagnostic realized reference configuration (Ch. 8; cf. Definition 9.307).

Potential term as identity and self-interaction. The potential density $\mathcal{V}_{\Theta,\mathrm{density}}$ in (9.131),

$$\mathcal{V}_{\Theta,\mathrm{density}}(x) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big)\Big\},$$

governs the *identity* of the kymons: emergent masses, spectra, and internal symmetry-breaking patterns (Definition 9.301). Linearizing around a realized background yields the typed Hessians $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ (eq. (9.124)) and the typed EL response (eq. (9.143)), which determine NG/pNG versus gapped behavior in each Tantrakyma type $[\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}$ (Definition 9.295). These are the inputs consumed by the Parasymmetric T–L–O meters (Section 9.17.11) to populate the typed quadrant ledger (Section 9.17.11). In keeping with the covector nature of $\hat{\mathbf{\Theta}}$, the scalar invariant used in the potential is built from the *co-metric* g_C, mirroring the Gaiamiti (vector) case that uses the tangent metric g_T; the pseudoinverse g_C^{-1} is reserved for dualizations/Legendre maps, not for the mass/quartic primitive.

Hierarchy and coupling of the two fundamental sectors. The Gaiamiti field generates the chronogeometric landscape $\bar{\Sigma}_{\mu\nu}$ (Section 6.5), while the Tantrakyma field—and its kymonic excitations—*live within and respond to this complete structure* through $\mathcal{L}_\Theta$ (Definition 9.301). Hence matter dynamics are richer than in metric-only theories: they are inextricably coupled to both geometric and temporal textures of emergence (via $\bar{g}_{\mu\nu}$ and $\bar{t}_{\mu\nu}$), and are diagnosed operationally through the typed, triadic T–L–O pipeline on the certified plateau (Definition 9.307 and Sections 9.17 and 9.17.11).

Proposition 9.312 (Euler–Lagrange equations on the diagnostic realized reference configuration)**.** *For admissible variations $\delta\hat{\mathbf{\Theta}}$ with compact support (diagnostic realized reference configuration boundary terms suppressed by the plateau budget), stationarity $\delta S_\Theta = 0$ yields the operator EL system*

$$\bar{\Sigma}^{\mu\nu}\,\nabla_\mu\nabla_\nu\,\hat{\mathbf{\Theta}} \;+\; (\nabla_\mu\bar{\Sigma}^{\mu\nu})\,\nabla_\nu\hat{\mathbf{\Theta}} \;=\; \frac{\delta\mathcal{V}_\Theta}{\delta\hat{\mathbf{\Theta}}}\,, \tag{9.148}$$

with the companion adjoint equation obtained by varying $\hat{\mathbf{\Theta}}^\dagger$ *when* $\hat{\mathbf{\Theta}}$ *is not Hermitian. Its typed restriction and linearization read*

$$\begin{aligned}\left(\mathbb{K}_\Theta^{[\chi]} + \mathcal{K}_{\Theta\Theta}^{[\chi]}\right)\delta\hat{\mathbf{\Theta}}^{[\chi]} &= \hat{\mathcal{J}}^{[\chi]},\\ \delta\hat{\mathbf{\Theta}}^{[\chi]} &:= \Pi_{\Theta\Theta}^{[\chi]}\,\delta\hat{\mathbf{\Theta}},\end{aligned} \tag{9.149}$$

which is the same statement as (9.143)*, with* $\mathcal{K}_{\Theta\Theta}^{[\chi]}$ *the typed Hessian of the potential (cf. eq.* (9.124)*).*

Remark 9.313 (Symmetry, covariance, and Nielsen stability)**.** The density $\mathcal{L}_\Theta$ is covariant under diffeomorphisms of $\mathcal{X}_q$ and invariant under local automorphisms of $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$. On $H^0(\hat{Q}_{\mathrm{BRST}})$ the pole locations and residues extracted from the typed, band-limited propagators are gauge-parameter independent (Nielsen-flat), and the principal symbol of $\mathbb{K}_\Theta$ is $\bar{\Sigma}$-hyperbolic (Ch. 8), ensuring well-posedness and Kugo–Ojima positivity of realized modes used by T–L–O. In particular, the mass/quartic potential is built from the co-metric invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ (not g_C^{-1}), mirroring the Gaiamiti (tangent-metric) construction.

Diagnostic realized reference configuration usage. On a certified plateau $\mathfrak{P}$, we use the band-limited density $\mathcal{L}_\Theta^{(\lambda_{\mathrm{UV}},\ell)}$ and action $S_\Theta^{(\lambda_{\mathrm{UV}},\ell)}$ (cf. Definition 9.307 and eq. (9.142)), and the typed/triadic instrumentation from Section 9.17.11.

9.18.2 Holosymmetric Wordwise Tantrakyma Field

In the holosymmetric wordwise (HS) formulation, the Tantrakyma field is treated entirely within the words–dressed bundle framework (Section 6.4.1), with kinematics governed by the operator-bundle connection (Section 6.6.1) and the Relational Levi–Civita geometry induced by the unified chronogeometric tensor (Definition 6.7).

Definition 9.314 (HS Tantrakyma field as a words–dressed section)**.** The Tantrakyma field is a words–dressed section

$$\hat{\mathbf{\Theta}}(x) \in \Gamma\left(\mathcal{E}_\Theta^{\mathrm{HS}}\right),$$

where $\mathcal{E}_\Theta^{\mathrm{HS}} \to \mathcal{X}_q$ is the HS operator bundle for the Tantrakyma sector with fibres contained in $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$, expressed in holosymmetric frames (Section 6.4.1). Frame changes act by HS–unitaries and are mediated by the operator bundle connection one–form in Section 6.6.1.

Definition 9.315 (HS total covariant derivative for $\hat{\mathbf{\Theta}}$)**.** The HS covariant derivative acting on $\hat{\mathbf{\Theta}}$ is the tripartite operator

$$\boxed{\mathcal{D}_\mu^{\mathrm{HS}}\hat{\mathbf{\Theta}} \;:=\; \left(\nabla_\mu^{(\mathrm{rel})} + \nabla_\mu^{(T)} + \mathcal{D}_\mu\right)\hat{\mathbf{\Theta}}\,, \quad \text{as in (6.259)}\,,} \tag{9.150}$$

combining the $\bar{\Sigma}$–compatible Relational Levi–Civita piece, the vacuum–tangent pullback, and the operator–bundle adjoint connection, respectively (Definition 6.7 and Sections 6.4.1 and 6.6.1).

Definition 9.316 (HS co–metric for Tantrakyma variations)**.** The HS co–metric is a Hermitian operator–valued bilinear form

$$g_C^{\mathrm{HS}} : T^*\mathcal{M}_{\mathrm{vac}} \times T^*\mathcal{M}_{\mathrm{vac}} \longrightarrow \mathrm{End}(\mathcal{H}_{\mathrm{em}}) ,$$

obtained by words–dressing the standard co–metric g_C (Definition 9.301). It is invariant under HS frame changes and compatible with the operator–bundle connection (Section 6.6.1).

Definition 9.317 (HS fundamental invariant for the Tantrakyma potential)**.** The basic HS invariant for the Tantrakyma potential is

$$\boxed{\mathsf{X}^{\mathrm{HS}}(x) \;:=\; g_C^{\mathrm{HS}}\Big(\hat{\boldsymbol{\Theta}}(x), \hat{\boldsymbol{\Theta}}(x)\Big) ,} \tag{9.151}$$

a fibrewise Hermitian scalar operator built from the HS co–metric. Any admissible HS potential density must be a real functional of X^{HS}:

$$\boxed{\mathcal{V}_\Theta^{\mathrm{HS}}(x) \;=\; F_\Theta\Big(\mathsf{X}^{\mathrm{HS}}(x)\Big) , \quad F_\Theta : \mathbb{R}_{\geq 0} \to \mathbb{R} .} \tag{9.152}$$

Definition 9.318 (HS Tantrakyma Lagrangian density)**.** Let $\boldsymbol{g}_{\mu\nu}^{\mathrm{Lor}}$ be the HS effective Lorentzian tensor and $\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}$ its inverse in holosymmetric frames (Section 5.3.7 and Definition 6.34). The HS Lagrangian density is the c–number obtained by the field–dialectic trace (Definition 6.45):

$$\boxed{\mathcal{L}_\Theta^{\mathrm{HS}}(x) \;:=\; \mathrm{Tr}_{\mathrm{FD}}\Big\{\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}(x)\, g_C^{\mathrm{HS}}\Big(\mathcal{D}_\mu^{\mathrm{HS}}\hat{\boldsymbol{\Theta}}(x),\, \mathcal{D}_\nu^{\mathrm{HS}}\hat{\boldsymbol{\Theta}}(x)\Big) \;+\; \mathcal{V}_\Theta^{\mathrm{HS}}\Big(\hat{\boldsymbol{\Theta}}(x)\Big)\Big\} .} \tag{9.153}$$

Definition 9.319 (HS Tantrakyma action functional)**.** With the HS relational volume element $d\boldsymbol{\mu}(x) = d^d x\, \boldsymbol{\varpi}(x)$, $\boldsymbol{\varpi}(x) = \Big(\det_{\mathrm{HS}}(-\boldsymbol{g}^{\mathrm{Lor}}(x))\Big)^{1/2}$ (Definition 6.34), the HS action is

$$\boxed{\hat{\boldsymbol{S}}_\Theta\,[\hat{\boldsymbol{\Theta}}] \;:=\; \int_{\mathcal{X}_q} d\boldsymbol{\mu}(x)\; \mathcal{L}_\Theta^{\mathrm{HS}}(x) .} \tag{9.154}$$

This formulation is words–only (HS) and reduces to the standard presentation under the expectation/volume push–throughs (Remark 6.35 and eqs. (6.99) and (6.110)).

Proposition 9.320 (HS symmetry properties and positivity)**.** *The density $\mathcal{L}_\Theta^{\mathrm{HS}}$ in (9.153) is:*

(i) gauge–invariant under HS frame transformations generated by the operator–bundle connection (Section 6.6.1);

(ii) covariant under base diffeomorphisms compatible with the Relational Levi–Civita connection (Definition 6.7);

(iii) positive–semidefinite in its kinetic part whenever g_C^{HS} is positive and $\boldsymbol{g}^{\mathrm{Lor}}$ has the standard Lorentzian signature on the certified plateau.

Proof. We prove (1)–(3) for the holosymmetric wordwise Lagrangian density

$$\mathcal{L}^{\mathrm{HS}}_{\Theta}(x) \;=\; \mathrm{Tr}_{\mathrm{FD}}\Big\{\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}(x)\, g^{\mathrm{HS}}_{C}\Big(\mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}}(x),\, \mathcal{D}^{\mathrm{HS}}_{\nu}\hat{\boldsymbol{\Theta}}(x)\Big) \;+\; \mathcal{V}^{\mathrm{HS}}_{\Theta}\Big(\hat{\boldsymbol{\Theta}}(x)\Big)\Big\} \quad (\text{cf. } eq.\ (9.153)), \tag{9.155}$$

where $\mathcal{D}^{\mathrm{HS}}_{\mu} = \nabla^{(\mathrm{rel})}_{\mu} + \nabla^{(T)}_{\mu} + \mathcal{D}_{\mu}$ (eq. (9.150) and Definition 9.327), the HS co-metric g^{HS}_{C} is Hermitian (Definition 9.316), and $\mathrm{Tr}_{\mathrm{FD}}$ is the field–dialectic trace (Definition 6.45).

(1) Gauge invariance under HS frame transformations. Let $U(x)$ be an HS frame change generated by the operator–bundle connection (Section 6.6.1), acting by conjugation on bundle fibres:

$$\hat{\boldsymbol{\Theta}} \mapsto \hat{\boldsymbol{\Theta}}' = U\,\hat{\boldsymbol{\Theta}}\,U^{\dagger}, \qquad \mathcal{A}_{\mu} \mapsto \mathcal{A}'_{\mu} = U\mathcal{A}_{\mu}U^{\dagger} - (\partial_{\mu}U)U^{\dagger}.$$

By standard gauge-covariance of the connection, the HS total derivative transforms *equivariantly* (eq. (9.150)):

$$\mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}} \;\mapsto\; \mathcal{D}^{\mathrm{HS}\,\prime}_{\mu}\hat{\boldsymbol{\Theta}}' \;=\; U\Big(\mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}}\Big)U^{\dagger}. \tag{9.156}$$

By construction, g^{HS}_{C} is invariant under HS frame changes in the sense that

$$g^{\mathrm{HS}}_{C}\Big(UXU^{\dagger},\, UYU^{\dagger}\Big) \;=\; U\, g^{\mathrm{HS}}_{C}(X,Y)\,U^{\dagger}, \tag{9.157}$$

and the potential is built from the HS invariant $\mathsf{X}^{\mathrm{HS}} = g^{\mathrm{HS}}_{C}(\hat{\boldsymbol{\Theta}},\hat{\boldsymbol{\Theta}})$ (Definition 9.317 and eqs. (9.151) and (9.152)), so that $\mathcal{V}^{\mathrm{HS}}_{\Theta}(\hat{\boldsymbol{\Theta}}) \mapsto U\,\mathcal{V}^{\mathrm{HS}}_{\Theta}(\hat{\boldsymbol{\Theta}})\,U^{\dagger}$. Since $\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}$ is a base tensor (gauge-blind), inserting (9.156)–(9.157) into (9.155) and using the cyclicity of $\mathrm{Tr}_{\mathrm{FD}}$ (Definition 6.45 and eq. (6.99)) gives

$$\mathcal{L}^{\mathrm{HS}}_{\Theta}(x) \;\mapsto\; \mathrm{Tr}_{\mathrm{FD}}\Big\{U(\cdots)U^{\dagger}\Big\} = \mathcal{L}^{\mathrm{HS}}_{\Theta}(x).$$

Hence (1).

(2) Covariance under base diffeomorphisms compatible with $\nabla^{(\mathrm{rel})}$. Let $\varphi : \mathcal{X}_q \to \mathcal{X}_q$ be a diffeomorphism and denote the Jacobian by $J^{\mu}{}_{\alpha} = \partial x^{\mu}/\partial x'^{\alpha}$. The Relational Levi–Civita connection is $\bar{\Sigma}$–compatible (Definition 6.7), hence $\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}$ transforms as a contravariant $(2,0)$ tensor and $\mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}}$ as a covector–valued operator:

$$\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu} \mapsto \boldsymbol{g}^{\mathrm{Lor}\,\alpha\beta}\, J^{\mu}{}_{\alpha} J^{\nu}{}_{\beta}, \qquad \mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}} \mapsto J^{\alpha}{}_{\mu}\,(\mathcal{D}^{\mathrm{HS}}_{\alpha}\hat{\boldsymbol{\Theta}}) \circ \varphi^{-1}.$$

Therefore the contraction $\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}\, g^{\mathrm{HS}}_{C}(\mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}}, \mathcal{D}^{\mathrm{HS}}_{\nu}\hat{\boldsymbol{\Theta}})$ is a scalar (operator) on the base, and $\mathrm{Tr}_{\mathrm{FD}}$ yields a scalar c–number density. Consequently $\mathcal{L}^{\mathrm{HS}}_{\Theta}$ transforms as a scalar under such diffeomorphisms, proving (2).

(3) Positivity of the kinetic part on the certified plateau. Write the HS kinetic operator at x as

$$\mathcal{K}^{\mathrm{HS}}(x) \;:=\; \mathrm{Tr}_{\mathrm{FD}}\Big\{\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu}(x)\, g^{\mathrm{HS}}_{C}\Big(\mathcal{D}^{\mathrm{HS}}_{\mu}\hat{\boldsymbol{\Theta}}(x),\, \mathcal{D}^{\mathrm{HS}}_{\nu}\hat{\boldsymbol{\Theta}}(x)\Big)\Big\}.$$

Assume g^{HS}_{C} is positive in the sense that $g^{\mathrm{HS}}_{C}(X,X) \succeq 0$ as an operator for all X (Definition 9.316). On a certified plateau, choose a time orientation and let u_{μ} be a future unit covector; decompose the co-metric as

$$\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu} \;=\; u^{\mu}u^{\nu} \;-\; h^{\mu\nu},$$

with $h^{\mu\nu}$ the induced positive–definite spatial co-metric (standard Lorentzian signature). Let $W_\mu := \mathcal{D}^{\mathrm{HS}}_\mu \hat{\boldsymbol{\Theta}}$. By cone–gating on the plateau, W_μ is supported in the dual causal cone (cf. the effective light–cone structure and causal gating: Section 5.4.2 and Proposition 9.108), hence

$$u^\mu u^\nu \, g^{\mathrm{HS}}_C(W_\mu, W_\nu) \;\succeq\; 0, \qquad h^{\mu\nu} \, g^{\mathrm{HS}}_C(W_\mu, W_\nu) \;\succeq\; 0,$$

as operator inequalities. Therefore

$$\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu} \, g^{\mathrm{HS}}_C(W_\mu, W_\nu) \;=\; u^\mu u^\nu \, g^{\mathrm{HS}}_C(W_\mu, W_\nu) \;-\; h^{\mu\nu} \, g^{\mathrm{HS}}_C(W_\mu, W_\nu) \;\succeq\; 0,$$

where the last inequality follows because dual–cone support guarantees the time–like contribution dominates the spatial one (standard Minkowski inequality inside the cone). Taking the (positive) field–dialectic trace preserves the ordering, hence $\mathcal{K}^{\mathrm{HS}}(x) \geq 0$. This shows that the kinetic part of $\mathcal{L}^{\mathrm{HS}}_\Theta$ is positive–semidefinite on the certified plateau when g^{HS}_C is positive and $\boldsymbol{g}^{\mathrm{Lor}}$ has standard Lorentzian signature, establishing (3).

Items (1)–(3) together prove the proposition. □

Definition 9.321 (HS Euler–Lagrange equation for $\hat{\boldsymbol{\Theta}}$)**.** Varying (9.154) with respect to $\hat{\boldsymbol{\Theta}}$ (holding HS frames fixed) yields the covariant field equation

$$\boxed{\mathcal{D}^{\mathrm{HS}}_\mu \left(\boldsymbol{g}^{\mathrm{Lor}\,\mu\nu} \frac{\delta}{\delta(\mathcal{D}^{\mathrm{HS}}_\nu \hat{\boldsymbol{\Theta}})} \mathrm{Tr}_{\mathrm{FD}}\Big\{ g^{\mathrm{HS}}_C(\mathcal{D}^{\mathrm{HS}}_\nu \hat{\boldsymbol{\Theta}}, \cdot) \Big\} \right) \;-\; \frac{\delta}{\delta \hat{\boldsymbol{\Theta}}} \mathrm{Tr}_{\mathrm{FD}}\Big\{ \mathcal{V}^{\mathrm{HS}}_\Theta(\hat{\boldsymbol{\Theta}}) \Big\} \;=\; 0\,,} \tag{9.158}$$

with all derivatives understood as in (9.150). The operator functional derivatives are taken inside the $\mathrm{Tr}_{\mathrm{FD}}$; contractions use $\boldsymbol{g}^{\mathrm{Lor}}$.

Remark 9.322 (Reduction to standard variables)**.** Applying the expectation/volume push–throughs (Remark 6.35) to (9.154) recovers the standard action in Section 9.18.1, with the identifications $\boldsymbol{g}^{\mathrm{Lor}} \mapsto \bar{g}^{\mathrm{Lor}}$, $g^{\mathrm{HS}}_C \mapsto g_C$, and $\mathcal{D}^{\mathrm{HS}}_\mu \mapsto \nabla_\mu$, consistent with the Chapter VI HS↔standard equivalence (Definition 6.45 and eqs. (6.99), (6.110) and (6.259)).

9.18.3 Covariant Derivative of the Tantrakyma Field

The Tantrakyma field $\hat{\boldsymbol{\Theta}}(x)$ is a section of the operator-valued cotangent bundle $\mathrm{End}(\mathcal{H}_{\mathrm{em}}) \otimes T^*\mathcal{M}_{\mathrm{vac}}$ over the emergent configuration space $\mathcal{X}_q$ (cf. Definition 9.301). To define its dynamics as used in the action $\mathcal{L}_\Theta$ and S_Θ (Definitions 9.301 and 9.310), the derivative must capture variations along the base manifold and transformations in the internal fiber. Accordingly, the total covariant derivative ∇_μ unifies general covariance with local gauge covariance.

Definition 9.323 (Covariant derivative of the Tantrakyma field)**.** Let $\hat{\boldsymbol{\Theta}}(x)$ be the Dynamical Tantrakyma Field. Define

$$\boxed{\nabla_\mu \hat{\boldsymbol{\Theta}} := \nabla^{(\mathrm{rel})}_\mu \hat{\boldsymbol{\Theta}} \;+\; D_\mu \hat{\boldsymbol{\Theta}},} \tag{9.159}$$

where:

1. **Relational Levi–Civita derivative** $\nabla_\mu^{(\mathrm{rel})}$ is the torsion-free, $\bar{\Sigma}$-compatible connection associated with the chronogeometric tensor $\bar{\Sigma}_{\alpha\beta}$ ($\nabla_\mu^{(\mathrm{rel})}\bar{\Sigma}_{\alpha\beta}=0$), defined in Definition 6.7, built from $\bar{\Sigma}_{\alpha\beta}=\bar{g}_{\alpha\beta}+\bar{t}_{\alpha\beta}$ (Definition 5.26). It acts on the cotangent indices of $\hat{\boldsymbol{\Theta}}$.
2. **Gauge-covariant derivative** D_μ acts on the operator-valued fiber via the operator-bundle connection $\mathcal{A}_\mu(x)$ (cf. Definition 6.192):

$$D_\mu\hat{\boldsymbol{\Theta}}(x):=\partial_\mu\hat{\boldsymbol{\Theta}}(x)+i\big[\mathcal{A}_\mu(x),\,\hat{\boldsymbol{\Theta}}(x)\big].$$

The field strength is $\mathcal{F}_{\mu\nu}:=\partial_\mu\mathcal{A}_\nu-\partial_\nu\mathcal{A}_\mu-i[\mathcal{A}_\mu,\mathcal{A}_\nu]$. Under a local unitary U_x (inner automorphism), $\hat{\boldsymbol{\Theta}}\mapsto U_x\hat{\boldsymbol{\Theta}}U_x^\dagger$, $\mathcal{A}_\mu\mapsto U_x\mathcal{A}_\mu U_x^\dagger-i(\partial_\mu U_x)U_x^\dagger$, and $D_\mu\hat{\boldsymbol{\Theta}}$ transforms covariantly.

In a local basis $\{\mathbf{e}_\nu(x)\}$ of $T^*_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ with $\hat{\boldsymbol{\Theta}}(x)=\hat{\boldsymbol{\Theta}}^\nu(x)\,\mathbf{e}_\nu(x)$, the component form is

$$\boxed{(\nabla_\mu\hat{\boldsymbol{\Theta}})_\lambda(x):=\partial_\mu\hat{\boldsymbol{\Theta}}_\lambda(x)-\Gamma^\nu_{\mu\lambda}\big[\bar{\Sigma}\big]\,(x)\,\hat{\boldsymbol{\Theta}}_\nu(x)+i\big[\,\mathcal{A}_\mu(x),\,\hat{\boldsymbol{\Theta}}_\lambda(x)\,\big],}\tag{9.160}$$

where $\Gamma^\nu_{\mu\lambda}[\bar{\Sigma}]$ are the Christoffel symbols of $\nabla^{(\mathrm{rel})}$.

Diagnostic realized reference configuration / band-limited form and BRST compatibility. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}},\ell)$ and projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definition 9.307 and eq. (9.137)), we use the band-limited derivative

$$\nabla_\mu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}:=\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\big[\nabla_\mu\hat{\boldsymbol{\Theta}}\big]=\nabla_\mu^{(\mathrm{rel})(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}+D_\mu^{(\lambda_{\mathrm{UV}},\ell)}\hat{\boldsymbol{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}.\tag{9.161}$$

This is BRST-closed (ghost number 0) and compatible with the typed/triadic filters used in T–L–O: on $\mathfrak{P}$ we choose connections so that $[\Pi_\alpha,\nabla_\mu]=0$ and $[\Pi^{[\chi]}_{\Theta\Theta},D_\mu]=0$ (or commute up to BRST-exact terms) (cf. Definition 9.295 and Proposition 9.202).

Proposition 9.324 (Compatibility with $\bar{\Sigma}$ and g_C; Leibniz rule)**.** *The total derivative* $\nabla_\mu=\nabla_\mu^{(\mathrm{rel})}+D_\mu$ *satisfies:*

(i) $\nabla_\mu^{(\mathrm{rel})}\bar{\Sigma}_{\alpha\beta}=0$ *(metric compatibility) and torsion-freeness (Definition 6.7).*

(ii) Co-metric compatibility on all legs: $\nabla_\mu^{(\mathrm{rel})}g_C=0$ *on the cotangent slots and* $D_\mu g_C=0$ *on the operator (fiber) slot; equivalently,* $\nabla_\mu g_C=0$ *(cf. Remark 9.303).*

(iii) The Leibniz rule for operator-valued tensors and trace cyclicity under $\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}$*, ensuring covariant integration by parts in* S_Θ *(Definition 9.310).*

These properties guarantee that the kinetic term in $\mathcal{L}_\Theta$ *is well-defined (with the co-metric* g_C *contracting the covector legs) and variationally compatible with the Euler–Lagrange system (Definition 9.305 and eq. (9.143)).*

Remark 9.325 (Curvatures and identities)**.** The relational Riemann tensor $R^\rho{}_{\sigma\mu\nu}[\bar{\Sigma}]$ and the bundle field strength $\mathcal{F}_{\mu\nu}$ obey their respective Bianchi identities. On the diagnostic realized reference configuration, the typed/triadic projections of $\nabla_\mu\hat{\boldsymbol{\Theta}}$ provide inputs to the Parasymmetric meters (Section 9.17.11), feeding the quadrant decision and T–L–O stamps (Section 9.17.11). In keeping with the covector nature of $\hat{\boldsymbol{\Theta}}$, scalar invariants for the *potential* are built with the co-metric g_C (not g_C^{-1}), mirroring the Gaiamiti (vector, metric) construction.

Interpretation of the Composite Derivative The dual structure of the covariant derivative ∇_μ in (9.159) is the natural consequence of the dual identity of the Tantrakyma field: $\hat{\boldsymbol{\Theta}}$ is simultaneously a geometric covector and an operator on the fiber algebra (cf. Definition 9.301). Accordingly, ∇_μ splits into a *relational* (base-manifold) part and a *gauge* (fiber) part, each with a clear operational meaning and symmetry transformation law (Definition 9.323 and eq. (9.160)).

Relational part (geometric covariance). The relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$ is torsion-free and $\bar{\Sigma}$-compatible ($\nabla^{(\mathrm{rel})}_\mu \bar{\Sigma}_{\alpha\beta} = 0$; Definitions 5.26 and 6.7), hence it transports the covector indices of $\hat{\boldsymbol{\Theta}}$ consistently with the full chronogeometric structure $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$. In components this yields the Christoffel-symbol correction $-\Gamma^\nu_{\mu\lambda}[\bar{\Sigma}]\,\hat{\boldsymbol{\Theta}}_\nu$ in (9.160), which ties the *propagation of kymons* to both (i) curvature of distinguishability ($\bar{g}$) and (ii) curvature of quantum phase flow ($\bar{t}$). Through the kinetic density $\mathcal{T}_\Theta$ (eq. (9.130)) this relational coupling governs the causal cones and hyperbolicity of the EL system (eqs. (9.148) and (9.149)).

Gauge part (fiber covariance). The operator–bundle connection $\mathcal{A}_\mu$ (cf. Definition 6.192) implements local unitary changes of basis in the fiber $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$. Under a unitary U_x,

$$\hat{\boldsymbol{\Theta}} \;\mapsto\; U_x\,\hat{\boldsymbol{\Theta}}\,U_x^\dagger, \qquad \mathcal{A}_\mu \;\mapsto\; U_x\,\mathcal{A}_\mu\,U_x^\dagger - i(\partial_\mu U_x)\,U_x^\dagger,$$

so the commutator term $i[\mathcal{A}_\mu, \hat{\boldsymbol{\Theta}}]$ in $D_\mu\hat{\boldsymbol{\Theta}}$ enforces covariant transport. The associated field strength is $\mathcal{F}_{\mu\nu} := \partial_\mu\mathcal{A}_\nu - \partial_\nu\mathcal{A}_\mu - i[\mathcal{A}_\mu, \mathcal{A}_\nu]$, and the full derivative $\nabla_\mu = \nabla^{(\mathrm{rel})}_\mu + D_\mu$ appears in eqs. (9.159) and (9.160). Because $\mathcal{L}_\Theta$ uses trace functionals (Definition 9.301), fiber $*$-automorphisms preserve the action (fiber–algebra invariance; cf. Remark 9.313).

Unification and diagnostic realized reference configuration readiness. Taken together, $\nabla_\mu = \nabla^{(\mathrm{rel})}_\mu + D_\mu$ unifies general covariance with local gauge covariance in a way compatible with the chronogeometric background and the operator-valued fiber structure. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$, the band-limited derivative $\nabla^{(\lambda_{\mathrm{UV}},\ell)}_\mu$ of (9.161) is BRST-closed and (by construction of the diagnostic realized reference configuration instrumentation) commutes with the triadic and typed filters $(\Pi_\alpha, \Pi^{[\chi]}_{\Theta\Theta})$ (cf. Definitions 9.185, 9.295, 9.306 and 9.307 and eq. (9.137)). This ensures that the kinetic term remains variationally well-posed, g_C-compatible (Proposition 9.324 and Remark 9.303), and ready for Parasymmetric T–L–O diagnostics (Section 9.17.11).

In essence, the composite derivative ∇_μ is the correct and complete tool to describe the dynamics of a matter-representing quantum field in a self-consistently generated, relational spacetime: it makes the law $\mathcal{L}_\Theta$ and action S_Θ (Definitions 9.301 and 9.310) simultaneously faithful to the base chronogeometry and to the internal quantum gauge structure.

9.18.4 Holosymmetric Wordwise Tantrakyma Covariant Derivative

We formulate the covariant derivative of the Tantrakyma field entirely in the holosymmetric wordwise (HS) framework, mirroring the Gaiamiti construction in Section 6.5.4. The bundle background and gauge data are those of Sections 6.4.1 and 6.6.1; chronogeometry is governed by the Relational Levi–Civita structure of Definition 6.7.

Definition 9.326 (HS Tantrakyma field as a words–dressed cotangent section)**.** The Tantrakyma field is a words–dressed section

$$\hat{\boldsymbol{\Theta}}(x) \;\in\; \Gamma\Big(\mathcal{E}_{\Theta}^{\mathrm{HS}}\Big) \;\subset\; \Gamma\Big(\mathrm{End}(\mathcal{H}_{\mathrm{em}}) \otimes T^{*}\mathcal{M}_{\mathrm{vac}}\Big),$$

expressed in holosymmetric frames (Section 6.4.1). HS frame changes act by unitary conjugation on the operator slot and by orthogonal transformations on $T^{*}\mathcal{M}_{\mathrm{vac}}$, mediated by the operator bundle connection of Section 6.6.1.

Definition 9.327 (Total HS covariant derivative for $\hat{\boldsymbol{\Theta}}$)**.** The total HS covariant derivative combines base, vacuum–tangent, and operator connections (cf. eq. (6.259)):

$$\boxed{\mathcal{D}_{\mu}^{\mathrm{HS}}\hat{\boldsymbol{\Theta}} \;:=\; \underbrace{\nabla_{\mu}^{(\mathrm{rel})}\hat{\boldsymbol{\Theta}}}_{\text{base (Levi–Civita on } \bar{\Sigma})} \;+\; \underbrace{\nabla_{\mu}^{(T)}\hat{\boldsymbol{\Theta}}}_{\text{pullback on } T^{*}\mathcal{M}_{\mathrm{vac}}} \;+\; \underbrace{\mathcal{D}_{\mu}\hat{\boldsymbol{\Theta}}}_{\text{operator (adjoint) connection}} .} \tag{9.162}$$

Here $\nabla_{\mu}^{(\mathrm{rel})}\bar{\Sigma}_{\alpha\beta} = 0$ (torsion-free), $\nabla_{\mu}^{(T)}$ is induced by $x \mapsto |\Omega(x)\rangle$ and g_T on $T^{*}\mathcal{M}_{\mathrm{vac}}$, and $\mathcal{D}_{\mu} = \partial_{\mu} + [A_{\mu},\,\cdot\,]$ acts on the $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$ slot (Definition 6.185 and Section 6.6.1).

Definition 9.328 (HS component forms (cotangent-valued field))**.** Let $\{\mathbf{e}^{i}(x)\}_{i=1}^{r}$ be a g_T–orthonormal local frame of $T^{*}_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ with dual $\{\mathbf{e}_{i}(x)\}$. Write $\hat{\boldsymbol{\Theta}} = \hat{\Theta}_{i}\,\mathbf{e}^{i}$. Then

$$\boxed{(\mathcal{D}_{\mu}^{\mathrm{HS}}\hat{\boldsymbol{\Theta}})_{i} = \partial_{\mu}\hat{\Theta}_{i} \;-\; \omega_{\mu\,i}{}^{j}\,\hat{\Theta}_{j} \;+\; [A_{\mu},\hat{\Theta}_{i}],} \tag{9.163}$$

where $\omega_{\mu\,i}{}^{j}$ are the coefficients of the pullback connection on $T^{*}\mathcal{M}_{\mathrm{vac}}$. If a base index is used instead, $\hat{\boldsymbol{\Theta}} = \hat{\boldsymbol{\Theta}}_{\lambda}\,dx^{\lambda}$ and

$$\boxed{(\mathcal{D}_{\mu}^{\mathrm{HS}}\hat{\boldsymbol{\Theta}})_{\lambda} = \partial_{\mu}\hat{\boldsymbol{\Theta}}_{\lambda} \;-\; \Gamma_{\mu\lambda}^{\nu}[\bar{\Sigma}]\,\hat{\boldsymbol{\Theta}}_{\nu} \;+\; [A_{\mu},\hat{\boldsymbol{\Theta}}_{\lambda}].} \tag{9.164}$$

Remark 9.329 (Leibniz and SOT regularity)**.** $\mathcal{D}_{\mu}$ is an inner derivation, so $\mathcal{D}_{\mu}(XY) = (\mathcal{D}_{\mu}X)Y + X(\mathcal{D}_{\mu}Y)$. All derivatives are taken in the strong–operator topology on band–limited fibres (Remark 6.187).

Definition 9.330 (Total HS curvature acting on $\hat{\boldsymbol{\Theta}}$)**.** The commutator of HS covariant derivatives yields

$$\boxed{[\mathcal{D}_{\mu}^{\mathrm{HS}},\mathcal{D}_{\nu}^{\mathrm{HS}}]\hat{\boldsymbol{\Theta}} \;=\; \mathcal{R}_{\mu\nu}\cdot\hat{\boldsymbol{\Theta}} \;+\; [\mathcal{F}_{\mu\nu},\hat{\boldsymbol{\Theta}}], \qquad \mathcal{F}_{\mu\nu} = \partial_{[\mu}A_{\nu]} + [A_{\mu},A_{\nu}],} \tag{9.165}$$

where $\mathcal{R}_{\mu\nu}$ collects the base Riemann curvature $R[\bar{\Sigma}]$ and the vacuum–tangent curvature $\Omega_{\mu\nu} = \partial_{[\mu}\omega_{\nu]} + [\omega_{\mu},\omega_{\nu}]$, acting on the corresponding cotangent indices of $\hat{\boldsymbol{\Theta}}$.

Proposition 9.331 (Gauge/frame covariance of $\mathcal{D}_{\mu}^{\mathrm{HS}}\hat{\boldsymbol{\Theta}}$)**.** *Under modal frame changes $g(x) \in U(n)$ and tangent rotations $R(x) \in O(r)$,*

$$\hat{\Theta}_{i} \mapsto \mathrm{Ad}_{g}(\hat{\Theta}_{j})\,(R^{-1})^{j}{}_{i}, \qquad A_{\mu} \mapsto gA_{\mu}g^{\dagger} - (\partial_{\mu}g)\,g^{\dagger}, \qquad \omega_{\mu} \mapsto R\omega_{\mu}R^{-1} + (\partial_{\mu}R)R^{-1},$$

and $(\mathcal{D}_{\mu}^{\mathrm{HS}}\hat{\boldsymbol{\Theta}})_{i}$ transforms covariantly in the same way. If $\hat{\boldsymbol{\Theta}}$ carries a base index, $\Gamma[\bar{\Sigma}]$ transforms as the Levi–Civita connection.

Proof idea. Working in the g_T–orthonormal frame of Definition 9.328, apply the same steps as in Proposition 6.188 (Gaiamiti case), noting the cotangent sign in (9.163) and the action of $R \in O(r)$ on covector indices. The inhomogeneous pieces in A'_μ and ω'_μ cancel by the same conjugation and frame-rotation identities; the result is the stated covariance.

Holosymmetric wordwise proof (expanded). Work in the g_T–orthonormal coframe of Definition 9.328, writing $\hat{\mathbf{\Theta}} = \hat{\Theta}_i\, \mathbf{e}^i$ so that

$$(\mathcal{D}^{\mathrm{HS}}_\mu \hat{\mathbf{\Theta}})_i = \partial_\mu \hat{\Theta}_i \;-\; \omega_{\mu\, i}{}^{j}\, \hat{\Theta}_j \;+\; [A_\mu, \hat{\Theta}_i] \qquad \text{(cf. eq. (9.163))}. \tag{9.166}$$

Let a *modal frame change* $g(x) \in U(n)$ act by the adjoint $\mathrm{Ad}_g(X) = gXg^\dagger$ on the operator slot, and let a *tangent rotation* $R(x) \in O(r)$ act on the coframe by $\mathbf{e}^i \mapsto \mathbf{e}'^i = (R^{-1})^i{}_j\, \mathbf{e}^j$. Since $\hat{\mathbf{\Theta}}$ is a *covector*-valued field, its components transform as

$$\hat{\Theta}_i \;\longmapsto\; \hat{\Theta}'_i := \mathrm{Ad}_g(\hat{\Theta}_j)\, (R^{-1})^j{}_i. \tag{9.167}$$

The connections transform as

$$A'_\mu = gA_\mu g^\dagger - (\partial_\mu g)\, g^\dagger, \qquad \omega'_\mu = R\omega_\mu R^{-1} + (\partial_\mu R)\, R^{-1}. \tag{9.168}$$

Step 1: Differentiate the transformed field. Using the product rule, the adjunct derivative identity $\partial_\mu(\mathrm{Ad}_g X) = \mathrm{Ad}_g(\partial_\mu X) + [(\partial_\mu g)g^\dagger, \mathrm{Ad}_g X]$, and $\partial_\mu(R^{-1}) = -R^{-1}(\partial_\mu R)R^{-1}$,

$$\begin{aligned} \partial_\mu \hat{\Theta}'_i &= \partial_\mu\Big(\mathrm{Ad}_g(\hat{\Theta}_j)(R^{-1})^j{}_i\Big) \\ &= \mathrm{Ad}_g(\partial_\mu \hat{\Theta}_j)(R^{-1})^j{}_i + [(\partial_\mu g)g^\dagger, \mathrm{Ad}_g(\hat{\Theta}_j)](R^{-1})^j{}_i \\ &\quad - \mathrm{Ad}_g(\hat{\Theta}_j)(R^{-1})^j{}_k (\partial_\mu R)^k{}_m (R^{-1})^m{}_i. \end{aligned} \tag{9.169}$$

Step 2: Act with the transformed pullback connection. Using (9.166) with ω'_μ and $\hat{\Theta}'_i$,

$$-\,\omega'_{\mu\, i}{}^{k}\, \hat{\Theta}'_k = -\left(R\omega_\mu R^{-1}\right)_i^{\,k}\; \mathrm{Ad}_g(\hat{\Theta}_\ell)\, (R^{-1})^\ell{}_k \;-\; \left((\partial_\mu R)R^{-1}\right)_i^{\,k}\; \mathrm{Ad}_g(\hat{\Theta}_\ell)\, (R^{-1})^\ell{}_k. \tag{9.170}$$

Step 3: Act with the transformed operator connection. From A'_μ in (9.168) and (9.167),

$$\begin{aligned} [\, A'_\mu, \hat{\Theta}'_i\,] &= [\, gA_\mu g^\dagger - (\partial_\mu g)g^\dagger,\; \mathrm{Ad}_g(\hat{\Theta}_j)\, (R^{-1})^j{}_i\,] \\ &= \underbrace{[\, gA_\mu g^\dagger,\; \mathrm{Ad}_g(\hat{\Theta}_j)\,]}_{=\; \mathrm{Ad}_g([A_\mu, \hat{\Theta}_j])} (R^{-1})^j{}_i \;-\; [\,(\partial_\mu g)g^\dagger,\; \mathrm{Ad}_g(\hat{\Theta}_j)\,]\, (R^{-1})^j{}_i. \end{aligned} \tag{9.171}$$

Step 4: Assemble $(\mathcal{D}^{\mathrm{HS}}_\mu \hat{\mathbf{\Theta}})'_i$. By definition,

$$(\mathcal{D}^{\mathrm{HS}}_\mu \hat{\mathbf{\Theta}})'_i = \partial_\mu \hat{\Theta}'_i \;-\; \omega'_{\mu\, i}{}^{k}\, \hat{\Theta}'_k \;+\; [\, A'_\mu, \hat{\Theta}'_i\,].$$

Insert (9.169), (9.170), (9.171). Two cancellations occur:

- The terms proportional to $(\partial_\mu g)g^\dagger$ cancel *exactly* between $[(\partial_\mu g)g^\dagger, \mathrm{Ad}_g(\hat{\Theta}_j)](R^{-1})^j{}_i$ in (9.169) and $-[\,(\partial_\mu g)g^\dagger, \mathrm{Ad}_g(\hat{\Theta}_j)\,](R^{-1})^j{}_i$ in (9.171).

- The terms containing $(\partial_\mu R)R^{-1}$ cancel between the third term of (9.169) and the second term of (9.170) upon relabeling indices and using $-(R^{-1})^j{}_k(\partial_\mu R)^k{}_m(R^{-1})^m{}_i = -\big((\partial_\mu R)R^{-1}\big)_i{}^k(R^{-1})^j{}_k$.

What remains is

$$\begin{aligned}(\mathcal{D}^{\mathrm{HS}}_\mu\hat{\boldsymbol{\Theta}})'_i &= \mathrm{Ad}_g(\partial_\mu\hat\Theta_j)(R^{-1})^j{}_i - (R\omega_\mu R^{-1})_i{}^k\ \mathrm{Ad}_g(\hat\Theta_\ell)(R^{-1})^\ell{}_k + \mathrm{Ad}_g([A_\mu,\hat\Theta_j])(R^{-1})^j{}_i\\ &= \mathrm{Ad}_g\Big(\partial_\mu\hat\Theta_j - \omega_\mu{}_j{}^\ell\hat\Theta_\ell + [A_\mu,\hat\Theta_j]\Big)(R^{-1})^j{}_i\end{aligned}$$

(using $R\omega_\mu R^{-1}$ on the covector index)

$$= \mathrm{Ad}_g\Big((\mathcal{D}^{\mathrm{HS}}_\mu\hat{\boldsymbol{\Theta}})_j\Big)(R^{-1})^j{}_i.$$

This is precisely the claimed *covariant* transformation law of the HS derivative: it transforms by inner automorphism on the operator slot and by R^{-1} on the covector index.

Step 5 (optional): Inclusion of a base index. If $\hat{\boldsymbol{\Theta}} = \hat{\boldsymbol{\Theta}}_\lambda\, dx^\lambda$, then

$$(\mathcal{D}^{\mathrm{HS}}_\mu\hat{\boldsymbol{\Theta}})_\lambda = \partial_\mu\hat{\boldsymbol{\Theta}}_\lambda - \Gamma^\nu_{\mu\lambda}[\bar\Sigma]\,\hat{\boldsymbol{\Theta}}_\nu + [A_\mu,\hat{\boldsymbol{\Theta}}_\lambda] \qquad \text{(cf. eq. (9.164))}.$$

Under a diffeomorphism or base frame change, $\Gamma^\nu_{\mu\lambda}[\bar\Sigma]$ transforms as the Levi–Civita connection (Definition 6.7), so the same calculation goes through with an additional covector index λ carried along; covariance persists componentwise.

Conclusion. Therefore, under the HS modal frame $g \in U(n)$ and tangent rotation $R \in O(r)$,

$$(\mathcal{D}^{\mathrm{HS}}_\mu\hat{\boldsymbol{\Theta}})_i \;\longmapsto\; (\mathcal{D}^{\mathrm{HS}}_\mu\hat{\boldsymbol{\Theta}})'_i = \mathrm{Ad}_g\Big((\mathcal{D}^{\mathrm{HS}}_\mu\hat{\boldsymbol{\Theta}})_j\Big)\,(R^{-1})^j{}_i,$$

and, when present, base indices transform by the Levi–Civita rule. This proves Proposition 9.331. □

Remark 9.332 (Insertion into the HS Tantrakyma dynamics)**.** Substituting (9.150) and the component forms (9.163)–(9.164) into the HS Lagrangian and action (Definitions 9.318 and 9.319) yields the wordwise dynamics used in Proposition 9.320. The HS→standard reduction follows Remark 9.322, identifying $\boldsymbol{g}^{\mathrm{Lor}} \mapsto \bar g^{\mathrm{Lor}}$, $g^{\mathrm{HS}}_C \mapsto g_C$, and $\mathcal{D}^{\mathrm{HS}}_\mu \mapsto \nabla^{(\mathrm{rel})}_\mu + D_\mu$ as in Section 9.18.3 and Definition 9.323.

9.18.5 Tantrakyma Field Potential and the Origin of the Kymon

While the kinetic term governs propagation (eq. (9.130)), the *potential term* $\mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}})$ fixes the self-interaction and selects energetically preferred backgrounds for the matter sector (eq. (9.131)). It is the proximate source of the kymon's intrinsic properties (masses, symmetry patterns), and it is the matter-sector analogue of the Gaiamiti potential discussed in Section 9.17.

Invariant Construction of the Tantrakyma Potential

The Tantrakyma field is an operator-valued *covector* on the vacuum manifold, $\hat{\mathbf{\Theta}}(x) \in T^*_{|\Omega(x)\rangle}\mathcal{M}_{\text{vac}} \otimes \text{End}(\mathcal{H}_{\text{em}})$ (cf. Proposition 9.292 and Definitions 6.142 and 9.301). To build scalar (operator-valued) invariants from covectors one uses the operator-valued *co-metric* g_C (cf. Remark 9.303). The basic invariant is therefore the "amplitude"

$$\mathsf{X}(x) := g_C\Big(\hat{\mathbf{\Theta}}(x),\, \hat{\mathbf{\Theta}}(x)\Big) \;\in\; \text{End}(\mathcal{H}_{\text{em}}),$$

which plays for Tantrakyma the role that $g_T(\cdot,\cdot)$ plays for Gaiamiti. (The pseudoinverse g_C^{-1} is useful for dualizations/Legendre maps but is *not* the primitive building block of the mass/quartic potential.)

Definition 9.333 (Tantrakyma field potential)**.** The minimal, Hermitian, symmetry-respecting operator potential built from $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ is

$$\boxed{\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) = \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X} \;+\; \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 \;+\; \mathcal{O}\Big(\mathsf{X}^3/\Lambda_\Theta^2\Big),} \tag{9.172}$$

with real parameters m_Θ^2 and $\lambda_\Theta > 0$, and a suppression scale Λ_Θ for higher operators. The scalar potential density used in $\mathcal{L}_\Theta$ is

$$\mathcal{V}_{\Theta,\text{density}}(x) = \text{Tr}_{\mathcal{H}_{\text{em}}}\{\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}(x))\}. \tag{9.173}$$

Diagnostic realized reference configuration usage. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\text{UV}}, \ell)$, the same form holds with $\hat{\mathbf{\Theta}} \to \hat{\mathbf{\Theta}}^{(\lambda_{\text{UV}},\ell)}$ (cf. Definitions 9.306 and 9.307). Expectation values define the effective potential

$$V_\Theta \;:=\; \Big\langle \mathcal{V}_\Theta \Big\rangle_{\mathfrak{P}} \;=\; \text{Tr}_{\mathcal{H}_{\text{em}}}\Big\langle \tfrac{1}{2} m_\Theta^2\, \mathsf{X} \;+\; \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 \Big\rangle_{\mathfrak{P}} \;+\; \cdots, \tag{9.174}$$

to be minimized over admissible backgrounds $\bar{\Theta}$ consistent with the EL equations (eq. (9.148)).

1. Field content and representation in the dual space

The covector character of $\hat{\mathbf{\Theta}}$ (Ch. 7) forces the invariant building block to use the *co-metric* g_C (rather than the Gaiamiti pairing g_T); see Remark 9.303. Thus the fundamental scalar operator is

$$\mathsf{X} \;:=\; g_C\Big(\hat{\mathbf{\Theta}},\, \hat{\mathbf{\Theta}}\Big) \;\in\; \text{End}(\mathcal{H}_{\text{em}}),$$

from which all polynomial invariants follow via the trace.

2. Constraints of stability, symmetry, and minimality

Stability. Boundedness from below requires $\lambda_\Theta > 0$ and, for the quartic truncation, fixes the sign structure of the extrema in V_Θ.

Symmetry. A $\mathbb{Z}_2$ invariance $\hat{\mathbf{\Theta}} \mapsto -\hat{\mathbf{\Theta}}$ and, more generally, invariance under local fiber inner $*$-automorphisms (cf. Definitions 6.192 and 9.301) restrict $\mathcal{V}_\Theta$ to depend only on the invariant X.

Minimality/Universality. Retaining operators up to mass dimension four yields the quartic form in eq. (9.133), the lowest-order choice capable of nontrivial vacuum structure (cf. Ch. 8 discussion of universality classes).

3. Vacuum structure and kymon origin (typed view)

Let $x := \left\langle \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}} \mathsf{X} \right\rangle_{\mathfrak{P}}$ be the invariant amplitude. Minimizing the quartic part of eq. (9.174) gives

$$\frac{d}{dx}\left(\tfrac{1}{2}m_\Theta^2 x + \tfrac{\lambda_\Theta}{4!}x^2\right) = 0 \implies x_\star = \begin{cases} 0, & m_\Theta^2 > 0, \\ -\dfrac{6\,m_\Theta^2}{\lambda_\Theta}, & m_\Theta^2 < 0 \text{ (SSB)}. \end{cases}$$

About any realized background $\bar{\Theta}$ solving the EL equations (eq. (9.148)), the typed mass/curvature operators are obtained from the potential Hessian restricted by the Tantrakyma projectors (Definition 9.295):

$$\boxed{\mathcal{K}^{[\chi]}_{\Theta\Theta} := \Pi^{[\chi]}_{\Theta\Theta}\, \frac{\delta^2 \mathcal{V}_\Theta}{\delta\hat{\boldsymbol{\Theta}}\,\delta\hat{\boldsymbol{\Theta}}}\bigg|_{\bar{\Theta}} \Pi^{[\chi]}_{\Theta\Theta}, \qquad [\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}.} \tag{9.175}$$

The eigenstructure of $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ determines the kymon content: zero/pseudo-zero modes indicate NG/pNG directions; positive eigenvalues signal gapped modes. These predictions cross-check the SynTh meters and typed quadrant outcomes in the T–L–O pipeline (eqs. (9.126) to (9.128) and Section 9.17.11).

Remark 9.334 (Coupling to chronogeometry and diagnostic realized reference configuration readiness)**.** Although $\mathcal{V}_\Theta$ depends only on X, the *realization* of vacua and spectra is diagnostic realized reference configuration- and channel-dependent through the kinetic pairing with $\bar{\Sigma}^{\mu\nu}$ in $\mathcal{T}_\Theta$ (eq. (9.130)) and the typed/triadic evaluation on $\mathfrak{P}$ (Definition 9.307 and Section 9.17.11). BRST/Nielsen hygiene ensures gauge-parameter independence of pole data on $H^0(\hat{Q}_{\mathrm{BRST}})$.

Summary. The potential eq. (9.133) is the unique minimal operator-valued choice consistent with stability, symmetry, and universality. Its Hessian eq. (9.175) seeds the typed mass operators that generate the kymon spectrum; together with the chronogeometric kinetic pairing, it yields a complete, diagnostic realized reference configuration-certified account of matter dynamics that mirrors the Gaiamiti story while living on the cotangent side of the vacuum geometry.

Invariant Construction of the Tantrakyma Potential

It is necessary to demonstrate that the specific form of the Tantrakyma potential—as given in Definition 9.333 and eq. (9.133)—arises as the unique, minimal choice consistent with the IQR principles (stability, symmetry, and minimality) and with the operator–geometric structure of the matter sector (Definition 9.301 and Remark 9.303).

1. Field content and representation in the dual space

The Tantrakyma field is an operator-valued *covector* on the vacuum manifold, $\hat{\boldsymbol{\Theta}}(x) \in T^*_{|\Omega(x))}\mathcal{M}_{\mathrm{vac}} \otimes \mathrm{End}(\mathcal{H}_{\mathrm{em}})$ (cf. Proposition 9.292 and Definitions 6.142 and 9.301). Accordingly,

scalar operator invariants must be built using the cotangent *co-metric* g_C (with g_C^{-1} its pseudoinverse; cf. Remark 9.303). The fundamental invariant is

$$\mathsf{X}(x) \;:=\; g_C\Big(\hat{\mathbf{\Theta}}(x),\, \hat{\mathbf{\Theta}}(x)\Big) \;\in\; \mathrm{End}(\mathcal{H}_{\mathrm{em}}),$$

which plays for Tantrakyma the role that $g_T(\cdot,\cdot)$ plays for the Gaiamiti sector (Section 9.17). Scalar *densities* for the action are then obtained by tracing over the fiber algebra, as in $\mathcal{V}_{\Theta,\mathrm{density}} = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathcal{V}_\Theta\}$ (eq. (9.131) and Definition 9.310). (The pseudoinverse g_C^{-1} is useful for dualizations/Legendre maps but is *not* the primitive building block for the mass/quartic potential.)

2. Constraints of stability, symmetry, and minimality

Stability. Boundedness from below requires the highest-order coefficient to be positive and, for a quartic truncation, $\lambda_\Theta > 0$. In particular, the X^2 coefficient controls large-amplitude behavior in the effective potential $V_\Theta = \langle \mathcal{V}_\Theta \rangle$ (eq. (9.134)).

Symmetry. To permit spontaneous (rather than explicit) symmetry breaking, the potential must respect the internal fiber symmetries (trace-preserving $*$-automorphisms; cf. Remark 9.313) and any discrete matter symmetries such as $\mathbb{Z}_2 : \hat{\mathbf{\Theta}} \mapsto -\hat{\mathbf{\Theta}}$. These conditions enforce that $\mathcal{V}_\Theta$ is a function only of the invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$.

Minimality and universality. Keeping operators up to mass-dimension four (QFT renormalizability; universality of the quartic Landau functional) selects the quartic polynomial in X as the lowest-order choice able to produce a nontrivial vacuum structure and mass generation, in precise analogy with the Gaiamiti construction (Section 9.17).

Putting these together, the most general operator-valued potential consistent with the symmetries is

$$\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) \;=\; f(\mathsf{X}), \qquad f(\mathsf{X}) = \sum_{n\geq 0} d_{2n}\, \mathsf{X}^{2n},$$

with $d_{2n} \in \mathbb{R}$ and $d_{2N} > 0$ at the highest retained order. The *minimal* (dimension ≤ 4) choice is precisely the quartic polynomial displayed in eq. (9.133).

Conclusion: the unique minimal potential for the matter sector

The unique, minimal, Hermitian and symmetry-respecting form is (cf. Definition 9.333)

$$\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) = \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X} \;+\; \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 \;+\; \mathcal{O}\Big(\mathsf{X}^3/\Lambda_\Theta^2\Big), \qquad \mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}}).$$

On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$, this feeds the effective potential V_Θ (eq. (9.134)) whose minima $\bar{\Theta}$ solve the EL system (eq. (9.148)). Linearizing about $\bar{\Theta}$ produces the typed mass/curvature operators via the Hessian restriction (eqs. (9.124) and (9.175)), which in turn predict NG/pNG versus gapped kymons by type $[\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}$ (Definition 9.295). These predictions are cross-checked by the parasymmetric meters and the typed quadrant decision in the T–L–O pipeline (Section 9.17.11).

The Tantrakyma Field Potential

Definition 9.335 (Tantrakyma Field Potential)**.** Let $\hat{\mathbf{\Theta}}(x) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}}) \otimes \mathcal{E}_{\mathrm{exc}}(x)$ be the operator-valued Tantrakyma field, where $\mathcal{E}_{\mathrm{exc}}(x) \subseteq T^*_{|\Omega(x))}\mathcal{M}_{\mathrm{vac}}$ denotes the excitation subspace of the cotangent fiber (cf. Remark 9.303, Proposition 9.292, and Definition 9.307). The *operator-valued potential* $\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}(x))$ is a Hermitian functional built from the cotangent invariant

$$\mathsf{X}(x) := g_C\Big(\hat{\mathbf{\Theta}}(x), \hat{\mathbf{\Theta}}(x)\Big) \;\in\; \mathrm{End}(\mathcal{H}_{\mathrm{em}})$$

(cf. Remark 9.303), namely

$$\boxed{\mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big) := \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X}(x) \;+\; \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}(x)^2 \;+\; \mathcal{O}\Big(\mathsf{X}(x)^3/\Lambda_\Theta^2\Big),} \tag{9.176}$$

with real m_Θ^2 and $\lambda_\Theta > 0$. The scalar density that enters the Lagrangian (cf. eq. (9.131) and Definition 9.301) is obtained by tracing over the fiber algebra:

$$\mathcal{V}_{\Theta,\mathrm{density}}(x) \;=\; \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}(x))\Big\}.$$

Physical Interpretation: from potential to particle properties The phenomenologically relevant potential is the scalar function obtained by taking the diagnostic realized reference configuration expectation value (cf. Definitions 9.307 and 9.310):

$$V_\Theta(x) \;:=\; \Big\langle \mathcal{V}_\Theta\Big(\hat{\mathbf{\Theta}}(x)\Big)\Big\rangle_{\mathfrak{P}}, \qquad \mathcal{L}_\Theta(x) = \mathcal{T}_\Theta(x) + \mathcal{V}_{\Theta,\mathrm{density}}(x), \quad \mathcal{V}_{\Theta,\mathrm{density}} = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathcal{V}_\Theta\}. \tag{9.177}$$

Minima of V_Θ determine realized backgrounds $\bar{\Theta}$ satisfying the Euler–Lagrange system (eq. (9.148)); linearizing about $\bar{\Theta}$ yields typed mass/curvature operators via the potential Hessian restricted to the Tantrakyma projectors (Definition 9.295 and eq. (9.124)), which in turn set the kymon spectrum used by Parasymmetric T–L–O (Section 9.17.11).

- **Mass parameter m_Θ^2.** The sign controls vacuum structure in V_Θ: $m_\Theta^2 > 0 \Rightarrow \bar{\Theta} = 0$ (symmetric phase); $m_\Theta^2 < 0 \Rightarrow \bar{\Theta} \neq 0$ (SSB). In the linearized EL equation (eq. (9.143)) it sources the quadratic (mass) block of $\mathcal{K}^{[\chi]}_{\Theta\Theta}$.
- **Quartic coupling λ_Θ.** With $\lambda_\Theta > 0$ the potential is bounded below and provides the leading self-interaction controlling kymon–kymon scattering and the curvature of V_Θ at the minima (typed gaps).
- **Symmetry breaking.** A "Mexican-hat" profile ($m_\Theta^2 < 0$, $\lambda_\Theta > 0$) realizes spontaneous symmetry breaking consistent with fiber $*$-automorphisms (trace-preserving) and discrete $\mathbb{Z}_2$ symmetry ($\hat{\mathbf{\Theta}} \mapsto -\hat{\mathbf{\Theta}}$) (cf. Remark 9.313). NG/pNG versus gapped outcomes by type follow from $\mathrm{spec}\Big(\mathcal{K}^{[\chi]}_{\Theta\Theta}\Big)$ and are cross-checked by T–L–O meters.

In summary, $\mathcal{V}_\Theta$ is the engine of matter phenomenology in the IQR framework: together with the chronogeometric kinetic pairing (eq. (9.130)) it determines the realized vacuum, typed mass operators, and thus the spectrum and interactions of kymons in a diagnostic realized reference configuration-certified, BRST/Nielsen-safe manner.

Holosymmetric Wordwise Tantrakyma Field Potential

We now dress the standard Tantrakyma potential (Section 9.18.5) in the *holosymmetric wordwise* (HS) framework developed in Chapter VI, using the HS co–metric and bundle data (Definition 9.316 and Sections 6.4.1 and 6.6.1) and the Relational Levi–Civita compatibility on the base (Definition 6.7).

Definition 9.336 (HS fundamental invariant for Tantrakyma)**.** The HS invariant attached to the covector field $\hat{\boldsymbol{\Theta}}$ is

$$\boxed{\mathsf{X}^{\mathrm{HS}}(x) \;:=\; g_C^{\mathrm{HS}}\Big(\hat{\boldsymbol{\Theta}}(x),\, \hat{\boldsymbol{\Theta}}(x)\Big) \in \mathrm{End}(\mathcal{H}_{\mathrm{em}}),} \tag{9.178}$$

as introduced in Definition 9.316 and eq. (9.151). Here g_C^{HS} is the HS words–dressed co–metric on $T^*\mathcal{M}_{\mathrm{vac}}$.

Definition 9.337 (HS Tantrakyma potential operator and scalar density)**.** The *HS operator potential* is any Hermitian functional of X^{HS}; in particular, the quartic (plus higher) form reads (cf. eqs. (9.152) and (9.172))

$$\boxed{\mathcal{V}_\Theta^{\mathrm{HS}}(\hat{\boldsymbol{\Theta}}) \;:=\; \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X}^{\mathrm{HS}} \;+\; \tfrac{\lambda_\Theta}{4!}\, (\mathsf{X}^{\mathrm{HS}})^2 \;+\; \sum_{k\geq 3} \frac{d_k}{k!}\, (\mathsf{X}^{\mathrm{HS}})^k, \qquad \lambda_\Theta > 0,} \tag{9.179}$$

with real couplings $m_\Theta^2, \lambda_\Theta, d_k$. The corresponding *HS scalar potential density* is the field–dialectic trace (Definition 6.45 and eq. (6.99)):

$$\boxed{\mathcal{V}^{\mathrm{HS}}_{\Theta,\mathrm{density}}(x) \;:=\; \mathrm{Tr}_{\mathrm{FD}}\Big\{\mathcal{V}_\Theta^{\mathrm{HS}}(\hat{\boldsymbol{\Theta}}(x))\Big\}.} \tag{9.180}$$

Remark 9.338 (HS action contribution and reduction to standard)**.** The potential sector of the HS action uses the HS invariant measure $d\boldsymbol{\mu} = d^d x\, \boldsymbol{\varpi}$, $\boldsymbol{\varpi} = (\det_{\mathrm{HS}}(-\boldsymbol{g}^{\mathrm{Lor}}))^{1/2}$ (Definition 6.34):

$$\boxed{\widehat{\boldsymbol{S}}_{\Theta,\mathrm{pot}} \;:=\; \int_{\mathcal{X}_q} d\boldsymbol{\mu}(x)\; \mathcal{V}^{\mathrm{HS}}_{\Theta,\mathrm{density}}(x).} \tag{9.181}$$

Applying the expectation/volume push–throughs (Remark 6.35) recovers the standard scalar density $\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathcal{V}_\Theta\}$ in Section 9.18.5.

Proposition 9.339 (HS gauge/frame invariance and diffeo covariance (Tantrakyma))**.** *Under HS modal frame changes $g(x) \in U(n)$ and vacuum–tangent rotations $R(x) \in O(r)$ acting on covectors by $\hat{\Theta}_i \mapsto \mathrm{Ad}_g(\hat{\Theta}_j)(R^{-1})^j{}_i$ (cf. Proposition 9.331),*

$$g_C^{\mathrm{HS}}(\mathrm{Ad}_g\, X \cdot R^{-1},\, \mathrm{Ad}_g\, Y \cdot R^{-1}) \;=\; g_C^{\mathrm{HS}}(X, Y),$$

hence X^{HS} and $\mathcal{V}_\Theta^{\mathrm{HS}}$ are invariant. Moreover, $\mathcal{V}^{\mathrm{HS}}_{\Theta,\mathrm{density}}$ is a base scalar density for diffeomorphisms compatible with $\nabla^{(\mathrm{rel})}$ (Definition 6.7).

Proof. g_C^{HS} is a fibrewise Hermitian bilinear preserved by HS unitaries and orthogonal coframe rotations (Definition 9.316). For covector indices the orthogonal action is by R^{-1} (cf. Definition 9.328 and Proposition 9.331); invariance then gives $\mathsf{X}^{\mathrm{HS}} \mapsto \mathsf{X}^{\mathrm{HS}}$. Any real functional of X^{HS} is therefore invariant, proving gauge/frame invariance. The field–dialectic trace produces a c–number and carries no free base index (Definition 6.45 and eq. (6.99)); compatibility of $\nabla^{(\mathrm{rel})}$ with $\bar{\Sigma}$ ensures that $\mathcal{V}^{\mathrm{HS}}_{\Theta,\mathrm{density}}$ transforms as a scalar density under the allowed diffeomorphisms. □

Lemma 9.340 (First variation and stationarity (Tantrakyma, HS))**.** *Let $\delta\hat{\boldsymbol{\Theta}}$ be a compactly supported variation in the HS cotangent fibre. Then*

$$\boxed{\delta\,\mathcal{V}^{\mathrm{HS}}_{\Theta,\mathrm{density}} = \mathrm{Tr}_{\mathrm{FD}}\left\{\left(\tfrac{1}{2}m_\Theta^2 + \tfrac{\lambda_\Theta}{3!}\,\mathsf{X}^{\mathrm{HS}} + \sum_{k\geq 3}\tfrac{d_k}{(k-1)!}\,(\mathsf{X}^{\mathrm{HS}})^{k-1}\right)\delta\mathsf{X}^{\mathrm{HS}}\right\},} \tag{9.182}$$

with

$$\boxed{\delta\mathsf{X}^{\mathrm{HS}} = g_C^{\mathrm{HS}}(\delta\hat{\boldsymbol{\Theta}},\hat{\boldsymbol{\Theta}}) + g_C^{\mathrm{HS}}(\hat{\boldsymbol{\Theta}},\delta\hat{\boldsymbol{\Theta}}) = 2\,\mathrm{Re}\,g_C^{\mathrm{HS}}(\hat{\boldsymbol{\Theta}},\delta\hat{\boldsymbol{\Theta}})\,.} \tag{9.183}$$

Proof. Use $\mathcal{V}^{\mathrm{HS}}_\Theta = F(\mathsf{X}^{\mathrm{HS}})$ with $F'(s) = \frac{1}{2}m_\Theta^2 + \frac{\lambda_\Theta}{3!}s + \sum_{k\geq 3}\frac{d_k}{(k-1)!}s^{k-1}$ and the chain rule inside $\mathrm{Tr}_{\mathrm{FD}}$ (cf. Definition 6.45 and Remark 6.187). Treat g_C^{HS} as fixed under field variation; bilinearity and Hermiticity of g_C^{HS} (Definition 9.316) give (9.183). □

Corollary 9.341 (Boundedness and vacuum types (Tantrakyma, HS))**.** *If $\lambda_\Theta > 0$ and the higher d_k satisfy standard positivity/coercivity bounds, then $\mathcal{V}^{\mathrm{HS}}_\Theta$ is bounded below. For $m_\Theta^2 > 0$ the symmetric vacuum $\hat{\boldsymbol{\Theta}} = 0$ is stationary; for $m_\Theta^2 < 0$ a "Mexican-hat" structure arises in the HS covector norm X^{HS}, with symmetry breaking analyzed by the HS vacuum manifold tools of Chapter VI (Section 6.1.9).*

Proof. Identical to the Gaiamiti argument in Corollary 9.241, with $s = \mathsf{X}^{\mathrm{HS}} \geq 0$ and $F(s)$ from (9.179). Coercivity (highest even power positive) gives boundedness. At $\hat{\boldsymbol{\Theta}} = 0$, $\delta\mathsf{X}^{\mathrm{HS}} = 0$ so stationarity is automatic; the second variation is $m_\Theta^2\,\mathrm{Tr}_{\mathrm{FD}}\{\,g_C^{\mathrm{HS}}(\delta\hat{\boldsymbol{\Theta}},\delta\hat{\boldsymbol{\Theta}})\} \geq 0$ for $m_\Theta^2 > 0$, and negative for $m_\Theta^2 < 0$, implying a nonzero minimizing radius determined by $F'(s_\star) = 0$ as in the Gaiamiti case, now with $s_\star = \mathsf{X}^{\mathrm{HS}}$. □

Proposition 9.342 (HS $\leftrightarrow$ standard equivalence for the Tantrakyma potential)**.** *Let $\mathsf{X}^{\mathrm{HS}} := g_C^{\mathrm{HS}}(\hat{\boldsymbol{\Theta}},\hat{\boldsymbol{\Theta}})$ (Definition 9.316 and eq. (9.178)) and $\mathsf{X} := g_C(\hat{\boldsymbol{\Theta}},\hat{\boldsymbol{\Theta}})$ (Section 9.18.5). Then, on a certified plateau and after the HS expectation/volume push–through (Definition 6.45, eq. (6.99), and Remark 6.35),*

$$\boxed{\langle\mathsf{X}^{\mathrm{HS}}\rangle \;=\; \mathsf{X}, \qquad \langle\mathrm{Tr}_{\mathrm{FD}}\{(\mathsf{X}^{\mathrm{HS}})^k\}\rangle \;=\; \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathsf{X}^k\}}$$

and the HS operator potential (Definition 9.337 and eq. (9.179))

$$\mathcal{V}^{\mathrm{HS}}_\Theta(\hat{\boldsymbol{\Theta}}) = \tfrac{1}{2}m_\Theta^2\,\mathsf{X}^{\mathrm{HS}} + \tfrac{\lambda_\Theta}{4!}(\mathsf{X}^{\mathrm{HS}})^2 + \sum_{k\geq 3}\frac{d_k}{k!}(\mathsf{X}^{\mathrm{HS}})^k$$

reduces to the standard operator potential (Definition 9.335 and eq. (9.176))

$$\boxed{\langle \mathcal{V}_\Theta^{\mathrm{HS}} \rangle \;=\; \mathcal{V}_\Theta \;=\; \tfrac{1}{2} m_\Theta^2\, \mathsf{X} + \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 + \mathcal{O}(\mathsf{X}^3/\Lambda_\Theta^2)}$$

with the same parameters $m_\Theta^2, \lambda_\Theta$ (and $d_k \leftrightarrow$ higher–order Wilson coefficients). Moreover, the HS scalar density $\mathcal{V}^{\mathrm{HS}}_{\Theta,\mathrm{density}} = \mathrm{Tr}_{\mathrm{FD}}\{\mathcal{V}_\Theta^{\mathrm{HS}}\}$ (Definition 9.337 and eq. (9.180)) pushes through to the standard density $\mathcal{V}_{\Theta,\mathrm{density}} = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathcal{V}_\Theta\}$ used in Section 9.18.5.

Sketch. (i) By construction g_C^{HS} words–dresses g_C and is preserved by HS unitaries and $O(r)$ coframe rotations (Definition 9.316 and Proposition 9.331); thus X^{HS} is the HS counterpart of X. (ii) The FD trace reduces to the fibre trace under the expectation/volume push–through (Definition 6.45, eq. (6.99), and Remark 6.35), yielding the displayed equalities for all powers. (iii) Because the standard potential (Definition 9.335) is a real functional of X only, the HS potential (Definition 9.337)—a real functional of X^{HS}—reduces to it term by term, with identical couplings. The excitation subspace constraint $\mathcal{E}_{\mathrm{exc}}(x) \subseteq T^*_{|\Omega\rangle}\mathcal{M}_{\mathrm{vac}}$ (Definition 9.307) is respected in HS via the same band-limited fibres. □

The Kymon and the Emergence of the Higgs Boson

Definition 9.343 (Kymon and Higgs identification via typed, parasymmetric T–L–O)**.** Consider a background–fluctuation split of the Tantrakyma field,

$$\hat{\mathbf{\Theta}}(x) = \bar{\Theta}(x)\, \mathbb{I}_x + \delta\hat{\mathbf{\Theta}}(x), \qquad \big\langle \delta\hat{\mathbf{\Theta}}(x) \big\rangle_{\mathfrak{P}} = 0,$$

with $\bar{\Theta}$ a stationary solution of the EL system (eq. (9.148)) minimizing the effective potential V_Θ (cf. eqs. (9.134) and (9.176)). Work on a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definitions 9.307 and 9.310).

(i) Kymons (definition). Let $\Pi^{[\chi]}_{\Theta\Theta}$ denote the Tantrakyma typed projectors (Definition 9.295). The *kymons* are the one-particle excitations associated with the poles of the typed, retarded two-point kernels $\Delta^{[\chi]}_{\Theta\Theta}$ on $H^0(\hat{Q}_{\mathrm{BRST}})$, i.e. the solutions of the linear response equation

$$\boxed{\Big(\mathbb{K}^{[\chi]}_\Theta + \mathcal{K}^{[\chi]}_{\Theta\Theta}\Big)\, \delta\hat{\mathbf{\Theta}}^{[\chi]} = \hat{\mathcal{J}}^{[\chi]}, \qquad \delta\hat{\mathbf{\Theta}}^{[\chi]} := \Pi^{[\chi]}_{\Theta\Theta}\, \delta\hat{\mathbf{\Theta}},}\tag{9.184}$$

where $\mathbb{K}^{[\chi]}_\Theta$ is the typed kinetic block and $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ is the typed potential Hessian (cf. eqs. (9.143) and (9.175)). A simple pole of $\Delta^{[\chi]}_{\Theta\Theta}(k)$ with positive residue on $H^0(\hat{Q}_{\mathrm{BRST}})$ certifies a physical kymon.

(ii) Higgs (radial) mode (construction). Let $\mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ be the Tantrakyma invariant (cf. Remark 9.303) and define the *radial (amplitude) direction* at the realized background by the Fréchet derivative

$$\delta\mathsf{X}\Big|_{\bar{\Theta}} \;=\; 2\, g_C\Big(\delta\hat{\mathbf{\Theta}}, \bar{\Theta}\Big), \qquad \text{so that (via the } g_C\text{–Riesz isomorphism)} \;\; \hat{\mathsf{R}} \;\propto\; \bar{\Theta}.$$

Let Π_{H} be the g_C–orthogonal projector onto $\mathrm{span}\{\widehat{\mathsf{R}}\}$ (normalized within the typed basis and commuting with the triadic projectors). The *Higgs boson* is the scalar (singlet) kymon obtained by restricting the Hessian to this radial direction:

$$\boxed{\mathcal{K}_{\mathrm{H}} := \Pi_{\mathrm{H}}\, \frac{\delta^2 \mathcal{V}_\Theta}{\delta\hat{\mathbf{\Theta}}\,\delta\hat{\mathbf{\Theta}}}\bigg|_{\bar{\Theta}}\, \Pi_{\mathrm{H}}, \qquad M_{\mathrm{H}}^2 \;\in\; \mathrm{spec}\big(\mathcal{K}_{\mathrm{H}}\big),} \tag{9.185}$$

with the corresponding typed propagator exhibiting a single *gapped* pole at $k^2 = M_{\mathrm{H}}^2 > 0$ and no $k^2 = 0$ pole (contrast with NG/pNG directions).

Riesz map induced by g_C. On the Tantrakyma bundle $\mathcal{E}_\Theta$ with co-metric g_C (cf. Remark 9.303), define the Riesz/Legendre isomorphism

$$\mathcal{G}_C :\; \mathcal{E}_\Theta \longrightarrow \mathcal{E}_\Theta^*, \qquad \langle A,\; \mathcal{G}_C(B)\rangle \;=\; g_C(A,B) \quad (\forall\, A,B \in \mathcal{E}_\Theta),$$

with inverse $\mathcal{G}_C^{-1} : \mathcal{E}_\Theta^* \to \mathcal{E}_\Theta$. (Operator-valued details are compatible with the diagnostic realized reference configuration/connection choices; cf. Definition 9.310 and eq. (9.176).)

Radial direction is collinear with $\bar{\Theta}$. Let

$$\mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}}) \quad (\text{cf. } \textit{Remark } 9.303).$$

At the realized background $\bar{\Theta}$,

$$\delta\mathsf{X}\big|_{\bar{\Theta}}(\delta\hat{\mathbf{\Theta}}) = 2\, g_C\Big(\delta\hat{\mathbf{\Theta}}, \bar{\Theta}\Big) = 2\,\Big\langle \delta\hat{\mathbf{\Theta}},\, \mathcal{G}_C(\bar{\Theta})\Big\rangle.$$

Thus the gradient covector is $2\,\mathcal{G}_C(\bar{\Theta})$, and mapping back with the inverse Riesz map gives

$$\mathcal{G}_C^{-1}\Big(\delta\mathsf{X}\big|_{\bar{\Theta}}\Big) \;=\; 2\,\bar{\Theta}.$$

Hence the amplitude ("radial") direction at $\bar{\Theta}$ is collinear with $\bar{\Theta}$ itself, which the text summarizes as $\widehat{\mathsf{R}} \propto \bar{\Theta}$ (cf. Definition 9.343). A typed, normalized representative that commutes with the triadic projectors is

$$\widehat{\mathsf{R}} \;:=\; \frac{\Pi^{[\chi]}_{\Theta\Theta}\,\bar{\Theta}}{\sqrt{g_C\Big(\Pi^{[\chi]}_{\Theta\Theta}\bar{\Theta},\; \Pi^{[\chi]}_{\Theta\Theta}\bar{\Theta}\Big)}},$$

so $\widehat{\mathsf{R}} \in \mathrm{Ran}\,\Pi^{[\chi]}_{\Theta\Theta}$ and $[\widehat{\mathsf{R}}, \Pi_{\mathrm{corr/vac/spec}}] = 0$.

One–dimensional g_C–orthogonal projector. Define the rank–1 Riesz projector onto $\mathrm{span}\{\widehat{\mathsf{R}}\}$ by

$$\Pi_{\mathrm{H}}(V) \;=\; \frac{g_C\Big(V, \widehat{\mathsf{R}}\Big)}{g_C\Big(\widehat{\mathsf{R}}, \widehat{\mathsf{R}}\Big)}\,\widehat{\mathsf{R}}, \qquad \Pi_{\mathrm{H}}^2 = \Pi_{\mathrm{H}} = \Pi_{\mathrm{H}}^\dagger \text{ (with respect to } g_C).$$

Because $\widehat{\mathsf{R}} \propto \bar{\Theta}$, Π_{H} selects the amplitude/radial direction.

Higgs mass operator and typed linear response. Within the typed, BRST–clean linear response

$$\left(\mathbb{K}_{\Theta}^{[\chi]} + \mathcal{K}_{\Theta\Theta}^{[\chi]}\right) \delta\hat{\mathbf{\Theta}}^{[\chi]} = \hat{\mathcal{J}}^{[\chi]} \qquad \text{(cf. eq. (9.184))},$$

restrict the potential Hessian to the radial line:

$$\boxed{\mathcal{K}_{\mathrm{H}} \;:=\; \Pi_{\mathrm{H}}\, \frac{\delta^2 \mathcal{V}_{\Theta}}{\delta\hat{\mathbf{\Theta}}\,\delta\hat{\mathbf{\Theta}}}\bigg|_{\bar{\Theta}}\, \Pi_{\mathrm{H}}} \qquad \text{(cf. eq. (9.185))}.$$

By the typed spectral criterion, the *Higgs boson* is the scalar/singlet kymon whose propagator exhibits a single gapped pole at $k^2 = M_{\mathrm{H}}^2 > 0$, with $M_{\mathrm{H}}^2 \in \mathrm{spec}(\mathcal{K}_{\mathrm{H}})$; NG/pNG tangential directions satisfy $g_C(\delta\hat{\mathbf{\Theta}}, \bar{\Theta}) = 0$ and thus do not probe this radial eigenvalue.

Parasymmetric T–L–O certification (typed, triadic). For each type $[\chi] \in \{\mathrm{CK}, \mathrm{T}_{\pm}, \mathrm{L}\}$, assemble the SynTh meters (cf. eqs. (9.126) to (9.128)) using $\Delta_{\Theta\Theta}^{[\chi]}$ and the diagnostic realized reference configuration tags:

- $v_{[\chi]}^{(L)} = \left|\mathrm{Res}_{k^2=0}\, \Delta_{\Theta\Theta}^{[\chi]}(k)\right|$ diagnoses NG/pNG content (gapped $\Rightarrow v_{[\chi]}^{(L)} = 0$);
- $v_{[\chi]}^{(S)} = \left|\Delta_{\Theta\Theta}^{[\chi]}(t \to \infty; \mathbf{x} = 0)\right|_{H^0(\hat{Q}_{\mathrm{BRST}})}$ certifies long-time order;
- $v_{[\chi]}^{(LS)}$ measures helicity-resolved cross-channel gain.

Apply the typed quadrant predicate (cf. Definition 9.189 and Proposition 9.197) and stamp Type–Location–Onset entries (cf. Definitions 9.190 and 9.198) for the *Higgs channel* Π_{H} and for Goldstone channels. Consistency requires agreement, within plateau tolerances, between (a) NG/gapped predictions from $\mathrm{spec}\left(\mathcal{K}_{\Theta\Theta}^{[\chi]}\right)$ and (b) the quadrant ledger (Ch. 8).

SSB pattern and spectrum (diagnostic realized reference configuration semantics). For the quartic potential (9.176), if $m_{\Theta}^2 < 0$ and $\lambda_{\Theta} > 0$, the effective potential V_{Θ} (cf. eq. (9.134)) has nonzero minima $\bar{\Theta}$. Then:

1. *Goldstone directions* are tangent to the vacuum manifold and yield $v_{[\chi]}^{(L)} \neq 0$ with a pole at $k^2 = 0$, matching zero/pseudo-zero eigenvalues of $\mathcal{K}_{\Theta\Theta}^{[\chi]}$.
2. The *Higgs (radial) mode* is g_C–orthogonal to the vacuum manifold and exhibits $v_{[\chi]}^{(L)} = 0$ together with a single gapped pole at $k^2 = M_{\mathrm{H}}^2$, where M_{H}^2 is given by (9.185). Its typed quadrant outcome is gapped, and its Location band is determined by the pole position and residue (IR/meso per Definition 9.190).

Operational identification.

1. Solve the EL system for $\bar{\Theta}$ and compute $\mathcal{K}_{\Theta\Theta}^{[\chi]}$ (cf. eq. (9.175)).
2. Build Π_{H} from the g_C–radial direction $\hat{\mathsf{R}}$ and evaluate $\mathcal{K}_{\mathrm{H}}$ to obtain M_{H}^2 (cf. eq. (9.185)).

3. Compute $\Delta^{[\chi]}_{\Theta\Theta}$ on $H^0(\hat{Q}_{\mathrm{BRST}})$; extract meters $v^{(L)}, v^{(S)}, v^{(LS)}$ (cf. Section 9.17.11).

4. Decide quadrants (cf. Definition 9.189 and Proposition 9.197); stamp T–L–O for Higgs and NG channels (cf. Definitions 9.190 and 9.198).

This pipeline produces a *T–L–O–certified* emergence of the Higgs boson as the radial, scalar kymon in the Tantrakyma sector, consistent with symmetry breaking in V_Θ, BRST/Nielsen hygiene on the diagnostic realized reference configuration, and typed/triadic instrumentation (cf. Definition 9.307 and Remark 9.313).

Interpretative Clarification of the Formalism The unified construction (Definition 9.343) imposes a precise hierarchy of notions, certified on the diagnostic realized reference configuration $\mathfrak{P}$ by the typed, parasymmetric T–L–O pipeline (Section 9.17.11):

1. **Kymon (general notion).** The *kymon* is the fundamental quantum of the Tantrakyma field $\hat{\mathbf{\Theta}}$ (Definition 9.301). Operationally, it is any physical one-particle excitation corresponding to a simple pole of a typed, retarded two-point kernel $\Delta^{[\chi]}_{\Theta\Theta}$ on the BRST physical space $H^0(\hat{Q}_{\mathrm{BRST}})$, with positive residue (eq. (9.184) and Definition 9.295). This definition depends on: (i) the background $\bar{\Theta}$ solving the EL system (eq. (9.148)); (ii) the typed potential Hessian $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ (eq. (9.175)); and (iii) the chronogeometric kinetic pairing in $\mathcal{T}_\Theta$ (eq. (9.130)).

2. **Higgs boson (specific species).** The *Higgs* is the *radial, scalar* kymon: the gapped mode obtained by restricting the potential Hessian to the amplitude direction of the invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ at the realized vacuum $\bar{\Theta}$ (Remark 9.303 and eq. (9.185)). Its typed propagator shows a single pole at $k^2 = M_{\mathrm{H}}^2 > 0$ and no $k^2 = 0$ pole (contrast with NG/pNG directions), and its T–L–O stamp is *gapped* with an IR/mesoscopic location set by M_{H} (Section 9.17.11).

Unification within IQR (sector semantics). The matter and geometry sectors admit parallel, typed interpretations:

- **Gaiamiti/Apeiron → Graviton.** In the geometry sector, the Apeiron (quantum of the Gaiamiti field) organizes massless excitations in the appropriate typed channels; the graviton arises as the massless (Goldstone-like) mode within the chronogeometric arena $\bar{\Sigma}$ (Section 9.17).

- **Tantrakyma/Kymon → Higgs.** In the matter sector, the kymon organizes the typed spectrum of $\delta\hat{\mathbf{\Theta}}$; when V_Θ exhibits SSB (e.g. $m^2_\Theta < 0,\ \lambda_\Theta > 0$ in eqs. (9.133) and (9.134)), the radial typed mode is the Higgs, while tangential modes realize NG/pNG channels (eq. (9.175)).

Thus, mass generation for matter is not an add-on but a consequence of the *cotangent* geometry of the Tantrakyma potential and its coupling to the full chronogeometric background through $\bar{\Sigma}^{\mu\nu}$ (eq. (9.130)). Diagnostic realized reference configuration certification (BRST/Nielsen flatness) guarantees gauge-parameter independence of the spectral claims (Definition 9.307 and Remark 9.313).

On nomenclature. The neologism *kymon* designates the fundamental quantum of the Tantrakyma field, with the compound *tantrakyma* formed from Sanskrit *tantra* ("warp, loom; framework") and Greek κῦμα (*kyma*, "wave, undulation"). The intent is "*woven–wave*" (or "warp of waves"). The particle suffix "−on" follows standard usage. See [66, 74, 75] for *tantra* and [80] for κῦμα; cf. OED entries on scientific −on formations [302, 296].[7]

Derivation of the Mass Operator for the Kymon Field

Our goal is to extract the *mass operator* controlling linearized Tantrakyma fluctuations from the potential $\mathcal{V}_\Theta$ in Definition 9.335. The derivation mirrors the geometry-side analysis for the Apeiron (cf. Section 9.17.1), now carried out on the cotangent/operator side and in the typed, diagnostic realized reference configuration-certified setting of Definition 9.307.

Setup and notation. Write the invariant

$$\mathsf{X}(x) := g_C\Big(\hat{\mathbf{\Theta}}(x), \hat{\mathbf{\Theta}}(x)\Big) \;\in\; \mathrm{End}(\mathcal{H}_{\mathrm{em}}),$$

and recall

$$\boxed{\mathcal{V}_\Theta = \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X} + \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 + \cdots, \qquad \mathcal{V}_{\Theta,\mathrm{density}} = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathcal{V}_\Theta\}.} \tag{9.186}$$

We treat $\hat{\mathbf{\Theta}}$ and $\hat{\mathbf{\Theta}}^\dagger$ as independent variables and use the sesquilinearity of g_C (antilinear in the first slot, linear in the second; Remark 9.303).

Gâteaux derivatives of the invariant. In components relative to a cotangent basis $\{\mathbf{e}^a\}$ with $\hat{\mathbf{\Theta}} = \sum_a \hat{\Theta}_a\, \mathbf{e}^a$ and $\mathsf{X} = \sum_{ab} \hat{\Theta}_a^\dagger\, g_{C\,ab}\, \hat{\Theta}_b$, one has

$$\frac{\delta \mathsf{X}}{\delta \hat{\Theta}_c^\dagger} = \sum_b g_{C\,cb}\, \hat{\Theta}_b \;=\; \Big(g_C \cdot \hat{\mathbf{\Theta}}\Big)_c, \qquad \frac{\delta \mathsf{X}}{\delta \hat{\Theta}_c} = \sum_a \hat{\Theta}_a^\dagger\, g_{C\,ac} \;=\; \Big(\hat{\mathbf{\Theta}}^\dagger \cdot g_C\Big)_c. \tag{9.187}$$

In compact operator form:

$$\frac{\delta \mathsf{X}}{\delta \hat{\mathbf{\Theta}}^\dagger} = g_C \cdot \hat{\mathbf{\Theta}}, \qquad \frac{\delta \mathsf{X}}{\delta \hat{\mathbf{\Theta}}} = \hat{\mathbf{\Theta}}^\dagger \cdot g_C.$$

First functional derivative (gradient)

Using (9.186) and (9.187),

$$\boxed{\frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}^\dagger} = \Big(\tfrac{1}{2}\, m_\Theta^2 + \tfrac{\lambda_\Theta}{12}\, \mathsf{X}\Big)\Big(g_C \cdot \hat{\mathbf{\Theta}}\Big), \qquad \frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}} = \Big(\hat{\mathbf{\Theta}}^\dagger \cdot g_C\Big)\Big(\tfrac{1}{2}\, m_\Theta^2 + \tfrac{\lambda_\Theta}{12}\, \mathsf{X}\Big),} \tag{9.188}$$

which are the covariant analogues of the familiar $V'(\phi^\dagger\phi)\,\phi$ rule.

[7] These naming remarks are mnemonic and do not affect the formal content; all physical identifications are made diagnostic realized reference configuration-wise via $\Delta^{[x]}_{\Theta\Theta}$, the typed Hessians, and the T–L–O meters (Section 9.17.11).

Second functional derivative (Hessian operator)

Differentiating (9.188) with respect to $\hat{\boldsymbol{\Theta}}$ yields a linear map on variations $\delta\hat{\boldsymbol{\Theta}}$:

$$\boxed{\frac{\delta^2\mathcal{V}_\Theta}{\delta\hat{\boldsymbol{\Theta}}^\dagger\,\delta\hat{\boldsymbol{\Theta}}} = \left(\tfrac{1}{2}\,m_\Theta^2 + \tfrac{\lambda_\Theta}{12}\,\mathsf{X}\right)\left(g_C\cdot\delta\hat{\boldsymbol{\Theta}}\right) \;+\; \tfrac{\lambda_\Theta}{12}\left\langle\hat{\boldsymbol{\Theta}},\,\delta\hat{\boldsymbol{\Theta}}\right\rangle_{g_C}\left(g_C\cdot\hat{\boldsymbol{\Theta}}\right),} \tag{9.189}$$

where $\langle A, B\rangle_{g_C} := A^\dagger\cdot g_C\cdot B$ is the cotangent inner product. In index-free operator notation, (9.189) is the sum of an *isotropic* piece $\propto g_C$ and a *rank-1* projector along $g_C\cdot\hat{\boldsymbol{\Theta}}$.

Mass operator at a realized background and typed restriction. Evaluating (9.189) at $\hat{\boldsymbol{\Theta}} = \bar{\Theta}$ produces the background mass operator $\mathcal{M}_\Theta[\bar{\Theta}]$. Its typed, BRST-clean version is the Hessian restriction (mixed derivative) of eq. (9.175):

$$\boxed{\mathcal{K}^{[\chi]}_{\Theta\Theta} := \Pi^{[\chi]}_{\Theta\Theta}\;\frac{\delta^2\mathcal{V}_\Theta}{\delta\hat{\boldsymbol{\Theta}}^\dagger\,\delta\hat{\boldsymbol{\Theta}}}\bigg|_{\bar{\Theta}}\;\Pi^{[\chi]}_{\Theta\Theta}, \qquad [\chi]\in\{\mathrm{CK},\mathrm{T}_\pm,\mathrm{L}\},} \tag{9.190}$$

which feeds the linear response equation $\left(\mathbb{K}^{[\chi]}_\Theta + \mathcal{K}^{[\chi]}_{\Theta\Theta}\right)\delta\hat{\boldsymbol{\Theta}}^{[\chi]} = \hat{\mathcal{J}}^{[\chi]}$ (eq. (9.143)).

Two canonical vacua (diagnostic realized reference configuration semantics)

(a) Symmetric phase ($\bar{\Theta}=0$). Here $\mathsf{X}(\bar{\Theta})=0$ and the projector term in (9.189) vanishes. The (band-limited) mass operator is

$$\boxed{\mathcal{M}_\Theta\big|_{\bar{\Theta}=0} = \tfrac{1}{2}\,m_\Theta^2\,g_C, \qquad \mathcal{K}^{[\chi]}_{\Theta\Theta}\big|_{\bar{\Theta}=0} = \tfrac{1}{2}\,m_\Theta^2\,\Pi^{[\chi]}_{\Theta\Theta}\,g_C\,\Pi^{[\chi]}_{\Theta\Theta}.} \tag{9.191}$$

Normalization note. With the convention (9.186), the symmetric-phase mass scale carries a factor $\frac{1}{2}$. If one prefers the convention where the parameter in V equals the physical quadratic coefficient, replace $m_\Theta^2 \mapsto 2\,m_\Theta^2$ in (9.186); all formulas then read with m_Θ^2 in place of $\frac{1}{2}m_\Theta^2$.

(b) SSB phase ($m_\Theta^2<0,\ \lambda_\Theta>0$). Let $x := \langle \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\mathsf{X}\rangle$. Minimizing $V_\Theta = \langle\mathcal{V}_\Theta\rangle$ (eq. (9.134)) gives $\partial V_\Theta/\partial x = 0 \Rightarrow x_\star = -6\,m_\Theta^2/\lambda_\Theta > 0$. At a realized $\bar{\Theta}$ with this amplitude, the Hessian splits into:

$$\begin{aligned}\text{Goldstone subspace (tangent to the vacuum manifold):}\quad & \mathcal{K}^{[\chi]}_{\Theta\Theta}\approx 0\ \ (\mathrm{NG/pNG}),\\ \text{Radial direction:}\quad & \mathcal{K}_{\mathrm{H}}\approx -2\,m_\Theta^2\,(\Pi_{\mathrm{H}}\,g_C\,\Pi_{\mathrm{H}}),\end{aligned} \tag{9.192}$$

i.e. the *Higgs (radial) mass* is

$$\boxed{M_{\mathrm{H}}^2 = -\,2\,m_\Theta^2 > 0,} \tag{9.193}$$

in agreement with the explicit projector construction of eq. (9.185). The NG/pNG channels exhibit a $k^2=0$ pole in the typed propagators, while the Higgs channel shows a single gapped pole at $k^2 = M_{\mathrm{H}}^2$.

Parasymmetric T–L–O cross-check (typed, triadic). Using $\Delta^{[\chi]}_{\Theta\Theta}$ on H^0, assemble the meters $(v^{(L)}, v^{(S)}, v^{(LS)})$ (eqs. (9.126) to (9.128)), apply the typed quadrant predicate (Definition 9.189 and Proposition 9.197), and stamp TLO$^{[\chi]}$ (Definition 9.299). Agreement, within plateau tolerances, between NG/gapped predictions from spec($\mathcal{K}^{[\chi]}_{\Theta\Theta}$) and the quadrant ledger certifies the identification of NG modes and the Higgs (radial) kymon (Definition 9.343).

9.18.6 Spontaneous Symmetry Breaking of the Tantrakyma Field

Quadrant context (Parasymmetric T–L–O overview). Before specializing to the broken phase, recall that phase identification in the Tantrakyma sector is performed *typed* and *diagnostic realized reference configuration-wise* via the SynTh meters $(v^{(L)}, v^{(S)}, v^{(LS)})$ of eqs. (9.126) to (9.128), the typed witness $\mathbf{W}^{[\Theta\Theta]}_{[\chi]}$ (Definition 9.296), and the canonical quadrant predicate $\mathrm{Quad}^{[\Theta\Theta]}_{[\chi]}$ (Definition 9.297 and Proposition 9.298). At fixed tags $(\lambda_{\mathrm{UV}}, \ell)$ on a certified plateau $\mathfrak{P}$ (Definition 9.307), the informal map is:

Table 9.2: Classification from long-wavelength/long-time behavior of the typed order-parameter correlator Δ. Decision criteria connect phenomenology to the visibility metrics Λ_{law} and Λ_{state}.

Quadrant	$\boldsymbol{v^{(L)}}$	$\boldsymbol{v^{(S)}}$	**Decision & diagnostic realized reference configuration signature**
QI	pole at $k^2{=}0$	$\lim_{t\to\infty} \lvert\Delta(t;\mathbf{0})\rvert \geq \sigma_0$	(A) $\lvert\Lambda_{\mathrm{law}}\rvert \geq 1-\varepsilon_{\mathrm{law}}$, $\lvert\Lambda_{\mathrm{state}}\rvert \geq 1-\varepsilon_{\mathrm{state}}\rvert$; (B) NG channels show a $k^2{=}0$ pole and long-time order.
QII	pole at $k^2{=}0$	$\lim_{t\to\infty} \lvert\Delta(t;\mathbf{0})\rvert < \sigma_0$	(A) $\lvert\Lambda_{\mathrm{law}}\rvert \geq 1-\varepsilon_{\mathrm{law}}$, $\lvert\Lambda_{\mathrm{state}}\rvert < 1-\varepsilon_{\mathrm{state}}\rvert$; (B) Law-only: pole present, no sustained order.
QIII	no clean $k^2{=}0$ pole	$\lim_{t\to\infty} \lvert\Delta(t;\mathbf{0})\rvert \geq \sigma_0$	(A) $\lvert\Lambda_{\mathrm{state}}\rvert \geq 1-\varepsilon_{\mathrm{state}}\rvert$, $\lvert\Lambda_{\mathrm{law}}\rvert < 1-\varepsilon_{\mathrm{law}}\rvert$ with healing $d_{\mathrm{law}}(r) \leq C\, r^{-\beta}$; (B) State-only window: order present, law unresolved.
QIV	no $k^2{=}0$ pole	$\lim_{t\to\infty} \lvert\Delta(t;\mathbf{0})\rvert < \sigma_0$	(A) $\exists\, \delta_\star \in (\varepsilon_{\mathrm{law}}, 1) : d_{\mathrm{law}}(r) \geq \delta_\star$ uniformly, $\lvert\Lambda_{\mathrm{state}}\rvert < 1-\varepsilon_{\mathrm{state}}\rvert$; (B) Disordered: no pole, no long-time order.

Notes and references.

(N1) **Quadrant decision in visibility space.** The decision is made in $(\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}})$ with tolerances $(\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}})$ via the canonical rule; the healing clause $d_{\mathrm{law}}(r) := 1 - |\Lambda_{\mathrm{law}}(r)| \sim r^{-\beta}$ with $\beta > 0$ separates QIII from QIV (cf. Definition 9.297 and Proposition 9.298).

(N2) **Meters (Tantrakyma sector).**

$$v^{(L)} := \left|\mathrm{Res}_{k^2=0}\, \Delta^{[\chi]}_{\Theta\Theta}(k)\right|, \qquad v^{(S)} := \left|\Delta^{[\chi]}_{\Theta\Theta}(t \to \infty; \mathbf{x} = 0)\right|_{H^0}.$$

Diagnostic realized reference configuration thresholds (ρ_0, σ_0) are the instrument floors consistent with the typed witness normalization (cf. Definition 9.296).

(N3) **NG vs. Higgs labeling.** NG channels for Tantrakyma are stamped QI in the typed, parasymmetric readout, while the Higgs (radial) channel is gapped (cf. Definition 9.343 and eq. (9.185)).

(N4) **Synthesis baselines and stability.** SynTh meters elsewhere use a 1/2 baseline; here the quadrant call relies on visibilities $\Lambda_\bullet \in [0, 1]$ and their normalizers/aggregators (e.g. RSS), with monotonicity/continuity and plateau robustness ensuring stable decisions (cf. eqs. (9.126) to (9.128) and Definition 9.297).

Healing indicators $(\mathscr{H}_L, \mathscr{H}_S)$ refine QIII vs. QIV calls (cf. Definition 9.297). We now place the spontaneous symmetry breaking (SSB) analysis in this quadrant framework.

1. Symmetric potential and its invariance group

The Tantrakyma action $S_\Theta[\hat{\mathbf{\Theta}}]$ (Definition 9.310) employs the operator-valued potential $\mathcal{V}_\Theta$ of Definition 9.335 and eq. (9.133):

$$\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) = \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X} + \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 + \cdots, \qquad \mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}}),$$

which is invariant under internal, trace-preserving fiber $*$-automorphisms (cf. Remark 9.313) and, more generally, under a continuous internal group G_{matter} acting as $\hat{\mathbf{\Theta}} \mapsto U\, \hat{\mathbf{\Theta}}\, U^\dagger$, $U \in G_{\mathrm{matter}}$. Hence the *law* is symmetric. In the symmetric (disordered) phase, the typed meters typically place channels in QIV (no $k^2 = 0$ pole, no long-time order).

2. Asymmetric vacuum, vacuum manifold, and SSB

Let $V_\Theta = \langle \mathcal{V}_\Theta \rangle$ be the diagnostic realized reference configuration potential (eq. (9.134)). For $m_\Theta^2 < 0$, $\lambda_\Theta > 0$, the minima satisfy

$$\left\langle \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\, \mathsf{X} \right\rangle \;=\; v_\Theta^2 \;=\; -\,\frac{6\, m_\Theta^2}{\lambda_\Theta} \;>\; 0,$$

defining a continuous vacuum manifold with a realized background $\bar{\Theta}$ that solves the EL system (eq. (9.148)). The unbroken subgroup $\mathcal{H}_{\mathrm{matter}} \subset G_{\mathrm{matter}}$ leaves $\bar{\Theta}$ invariant; broken generators span the tangent (Goldstone) directions. In typed T–L–O, the corresponding channels exhibit QI stamps (law & state present): a $k^2 = 0$ pole and long-time order.

3. Physical spectrum and quadrant-certified identification of the Higgs

Decompose $\hat{\mathbf{\Theta}} = \bar{\Theta}\,\mathbb{I}_x + \delta\hat{\mathbf{\Theta}}$ (Definition 10.204) and restrict the potential Hessian to typed subspaces (eq. (9.175)):

$$\mathcal{K}^{[\chi]}_{\Theta\Theta} := \Pi^{[\chi]}_{\Theta\Theta}\ \frac{\delta^2\mathcal{V}_\Theta}{\delta\hat{\mathbf{\Theta}}^\dagger\,\delta\hat{\mathbf{\Theta}}}\bigg|_{\bar{\Theta}}\ \Pi^{[\chi]}_{\Theta\Theta}.$$

1. **Goldstone modes (NG/pNG).** Tangent-to-vacuum directions yield zero/pseudo-zero eigenvalues of $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ and a $k^2 = 0$ pole in $\Delta^{[\chi]}_{\Theta\Theta}$. Their T–L–O outcome is QI (nonzero $v^{(L)}$ and $v^{(S)}$); in gauged realizations, these may be eaten by gauge bosons as usual.

2. **Higgs (radial) kymon.** The amplitude (radial) direction—projected by Π_{H} built from $\hat{\mathsf{R}} \propto \delta\mathsf{X}/\delta\hat{\mathbf{\Theta}}\big|_{\bar{\Theta}}$—produces a scalar, gapped eigenvalue $M^2_{\mathrm{H}} = -2\,m^2_\Theta > 0$ (cf. eqs. (9.185) and (9.193)). Its typed quadrant is *gapped* (no $k^2 = 0$ pole; nonzero gap location in the meters), and its Location band (IR/mesoscopic) is set by M_{H} (Definition 9.299).

Quadrant map (phase semantics, by type).

- *Symmetric phase (no order):* QIV in all Tantrakyma types; $m^2_\Theta > 0$, $\bar{\Theta} = 0$.
- *Approach to criticality:* QII (law-only) channels appear as the $k^2 = 0$ pole emerges while $v^{(S)}$ remains suppressed.
- *Ordered window without resolved law:* QIII may occur (long-time order present, pole unresolved) depending on tags/tolerances.
- *SSB (broken phase):* QI for NG channels, plus a *gapped* radial (Higgs) typed entry.

All assignments are certified by $\mathbf{W}^{[\Theta\Theta]}_{[\chi]}$ with plateau tolerances (Definition 9.296 and Proposition 9.298).

Summary. The SSB analysis is *typed*, *diagnostic realized reference configuration-limited*, and *quadrant-certified*. It ties the sign structure of the quartic parameters (eqs. (9.133) and (9.134)) to the spectrum via the Hessian restriction (eq. (9.175)) and validates the NG/Higgs identification with Parasymmetric T–L–O meters and stamps (Section 9.17.11 and Definition 9.299), mirroring the Gaiamiti workflow and respecting the co-metric construction $g_C : T^* \times T^* \to \mathrm{End}(\mathcal{H}_{\mathrm{em}})$.

Remark 9.344 (General explanatory note: reading the spectrum from fluctuations)**.** To understand the particle content of the Tantrakyma sector, expand the field about a realized vacuum (cf. Definition 10.204):

$$\hat{\mathbf{\Theta}}(x) \;=\; \bar{\Theta}(x)\,\mathbb{I}_x \;+\; \delta\hat{\mathbf{\Theta}}(x), \qquad \big\langle \delta\hat{\mathbf{\Theta}}(x) \big\rangle_{\mathfrak{P}} = 0,$$

with diagnostic realized reference configuration expectation $\langle\cdot\rangle_{\mathfrak{P}}$ taken on $H^0(\hat{Q}_{\mathrm{BRST}})$. The quanta of $\delta\hat{\mathbf{\Theta}}$—the *kymons*—split kinematically according to their direction in field space relative to the minimum of the potential V_Θ (cf. Definition 9.335 and eq. (9.134)):

1. **Radial (amplitude) fluctuations ⇒ massive scalar (Higgs).** Variations that change the g_C-*amplitude* of the field, i.e. the invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$, probe the curvature of the potential at the minimum and thus acquire a nonzero mass. In the IQR framework this radial, scalar kymon is identified with the **Higgs boson** (cf. Section 9.18.5). Its mass is set by the second variation (Hessian) of the potential along the g_C-radial direction at $\bar{\Theta}$; equivalently, by the restricted operator $\mathcal{K}_{\mathrm{H}}$ of eq. (9.185).
2. **Tangential (phase) fluctuations ⇒ massless Goldstone modes.** Variations *tangent* to the vacuum manifold $G_{\mathrm{matter}}/\mathcal{H}_{\mathrm{matter}}$ cost no potential energy at leading order and therefore remain massless. These are the Goldstone modes implied by Goldstone's theorem [93, 94]. In a gauged realization they are "eaten" by the corresponding gauge bosons, which thereby become massive (the usual Higgs mechanism).

In short, the *kymon* is the general quantum of the Tantrakyma field, while the *Higgs boson* is the particular, radial, scalar kymon that appears when the Tantrakyma potential exhibits spontaneous symmetry breaking. Both identifications are certified on the diagnostic realized reference configuration by the typed Hessians $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ and by the poles/visibilities of the typed propagators $\Delta^{[\chi]}_{\Theta\Theta}$ used in the Parasymmetric T–L–O pipeline (cf. eqs. (9.175) and (9.184) and Section 9.17.11).

9.18.7 Gauge-Coupled Tantrakyma and the Brout–Englert–Higgs Mechanism

Definition 9.345 (Gauge sector and covariant coupling)**.** Work on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$, $K^{(\ell)}_{\mathrm{IR}}$ and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration discipline: Propositions 9.191, 9.207 and 9.223). Let a compact Lie group G act on the Tantrakyma fiber $\mathcal{E}_\Theta$ via a representation ρ with generators T_I. Introduce gauge fields A^I_μ with field strength $F^I_{\mu\nu}$ and kinetic metric G_{IJ}. Extend the covariant derivative used in Definition 9.323 (cf. the split connection, Section 6.12.2 and eq. (6.314)) to

$$D_\mu \hat{\mathbf{\Theta}} \;:=\; \nabla^{(\mathrm{rel})}_\mu \hat{\mathbf{\Theta}} \;+\; \partial_\mu \hat{\mathbf{\Theta}} \;+\; i\, g\, A^I_\mu\, \rho(T_I)\, \hat{\mathbf{\Theta}}.$$

On the diagnostic realized reference configuration, define the typed/triadic-inserted action

$$S_{\mathrm{gauge+}\Theta} = \int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}}\, \mathrm{Tr}\Big[-\tfrac{1}{4}\, G_{IJ}\, F^I_{\mu\nu} F^{J\,\mu\nu} + \tfrac{1}{2}\, (D_\mu \hat{\mathbf{\Theta}})^\dagger\, g_C\, (D^\mu \hat{\mathbf{\Theta}}) - \mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) \Big],$$

with $\mathcal{V}_\Theta$ as in Definition 9.310, and typed/triadic insertions as in Definition 9.187.

Definition 9.346 (SSB pattern and kymon split)**.** Let $\bar{\Theta}$ solve the EL system and minimize V_Θ (cf. Definition 9.343). The stabilizer $H \subset G$ satisfies $\rho(T_a)\bar{\Theta} = 0$ for $T_a \in \mathfrak{h}$. Broken generators T_b obey $\rho(T_b)\bar{\Theta} \neq 0$. Define the NG subspace

$$\mathcal{N} \;:=\; \mathrm{span}\{\, \rho(T_b)\bar{\Theta}\,\}_b \;\subset\; \mathcal{E}_\Theta,$$

and the g_C-Riesz projector onto $\mathcal{N}$ (typed version of Definition 9.249):

$$\Pi_{\mathrm{NG}}(V) \;:=\; \sum_{b,c} (B^{-1})^{bc}\, g_C\Big(V,\, \rho(T_b)\bar{\Theta}\Big)\; \rho(T_c)\bar{\Theta}, \qquad B_{bc} := g_C\Big(\rho(T_b)\bar{\Theta},\, \rho(T_c)\bar{\Theta}\Big).$$

The radial (Higgs) line is defined as in Definition 9.343 by $\hat{\mathsf{R}} \propto \bar{\Theta}$ with typed radial projector $\Pi^{[\chi]}_{\mathrm{rad}}$ as in Definition 9.250; the radial mass operator is $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (cf. eq. (9.185)). All projectors commute with the triadic channels (Proposition 9.207).

Proposition 9.347 (Vector mass matrix from BEH)**.** *Expanding $\hat{\mathbf{\Theta}} = \bar{\Theta} + \delta\hat{\mathbf{\Theta}}$ in Definition 9.345 and reading the quadratic terms in A_μ gives the internal vector mass term*

$$\mathcal{L}^{(A)}_{\mathrm{mass}} = \tfrac{1}{2}\, A^I_\mu\, (M^2)_{IJ}\, A^{J\,\mu}, \qquad (M^2)_{IJ} := g^2\, g_C\Big(\rho(T_I)\bar{\Theta},\ \rho(T_J)\bar{\Theta}\Big),$$

which is the Θ-sector specialization of the unified diagnostic realized reference configuration formula in Definition 9.252. Thus vectors associated with broken directions acquire masses $\{m_V^2\} \subset \mathrm{spec}(M^2)$, while H-vectors remain massless. The scalar spectrum splits into: (i) the Higgs (radial) kymon *from eq. (9.185), and (ii) the NG/pNG kymons spanning $\mathcal{N}$ (typed NG projector of Definition 9.346 / Definition 9.249). Typed transverse/longitudinal/helicity resolutions follow Definition 9.350.*

Proof of Proposition 9.347. Work on a certified plateau $\mathfrak{P}$ with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$, where typed/triadic meters commute and route–equivalence holds (Propositions 9.191, 9.207 and 9.223). Start from the gauge–coupled Tantrakyma action in Definition 9.345:

$$S_{\mathrm{gauge+}\Theta} = \int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}}\, \mathrm{Tr}\Big[-\tfrac{1}{4}\, G_{IJ} F^I_{\mu\nu} F^{J\,\mu\nu} + \tfrac{1}{2}\, (D_\mu \hat{\mathbf{\Theta}})^\dagger g_C (D^\mu \hat{\mathbf{\Theta}}) - \mathcal{V}_\Theta(\hat{\mathbf{\Theta}})\Big],$$

with covariant derivative $D_\mu \hat{\mathbf{\Theta}} = \nabla^{(\mathrm{rel})}_\mu \hat{\mathbf{\Theta}} + \partial_\mu \hat{\mathbf{\Theta}} + i\, g\, A^I_\mu\, \rho(T_I)\hat{\mathbf{\Theta}}$. Let $\hat{\mathbf{\Theta}} = \bar{\Theta} + \delta\hat{\mathbf{\Theta}}$ where $\bar{\Theta}$ minimizes V_Θ and realizes $G \to H$ (Definitions 9.343 and 9.346). Expanding the kinetic term to quadratic order in fields and using sesquilinearity of g_C,

$$\begin{aligned} \tfrac{1}{2}(D_\mu \hat{\mathbf{\Theta}})^\dagger g_C (D^\mu \hat{\mathbf{\Theta}}) &= \tfrac{1}{2}\Big(\cdots + i g\, A^I_\mu\, \rho(T_I)\bar{\Theta} + \cdots\Big)^\dagger\, g_C\, \Big(\cdots + i g\, A^{J\,\mu}\, \rho(T_J)\bar{\Theta} + \cdots\Big) \\ &\supset \tfrac{1}{2}\, g^2\, A^I_\mu\, A^{J\,\mu}\, g_C\Big(\rho(T_I)\bar{\Theta},\ \rho(T_J)\bar{\Theta}\Big), \end{aligned}$$

which yields the purely quadratic $A\cdot A$ mass term

$$\mathcal{L}^{(A)}_{\mathrm{mass}} = \tfrac{1}{2}\, A^I_\mu\, (M^2)_{IJ}\, A^{J\,\mu}, \qquad (M^2)_{IJ} := g^2\, g_C\Big(\rho(T_I)\bar{\Theta},\ \rho(T_J)\bar{\Theta}\Big).$$

The mixed A–NG terms are cancelled on the diagnostic realized reference configuration by the R_ξ gauge fixing of Definition 9.349; the associated ghost sector closes BRST and removes gauge–artefactual longitudinal contributions from H^0. Gauge–parameter independence of the physical pole positions/residues follows from the Nielsen/BRST identities (Theorem 9.351).

If $T_a \in \mathfrak{h} = \mathrm{Lie}(H)$ is unbroken, then $\rho(T_a)\bar{\Theta} = 0$ (Definition 9.346), so the corresponding rows/columns of M^2 vanish and those vectors remain massless. For broken generators T_b one has $\rho(T_b)\bar{\Theta} \neq 0$, producing strictly positive entries in M^2; transverse simple poles at $k^2 \in \mathrm{spec}(M^2)$ are then the physical vector masses. The scalar sector splits into the radial (Higgs) kymon from the typed restricted Hessian (eq. (9.185) and Definition 9.343) and the NG/pNG kymons spanning the typed NG subspace $\mathcal{N}$ (Riesz/Gram projector of Definitions 9.249 and 9.346). Vector polarizations are resolved with the typed transverse/longitudinal/helicity projectors of Definition 9.350. This proves the proposition. □

Definition 9.348 (Tantron: Tantrakyma spin–1 internal vector)**.** Let G act on the Tantrakyma fiber $\mathcal{E}_\Theta$ via ρ and let $\bar{\Theta}$ realize $G \to H$ (cf. Definitions 9.343 and 9.346). The *tantron* is a one–particle, spin–1 *internal* gauge quantum in the Tantrakyma sector, i.e. a mass–eigenstate of the bundle connection A^I_μ defined as follows.

(i) **Mass matrix and eigenmodes.** Form the BEH mass matrix

$$(M^2_\Theta)_{IJ} := g^2\, g_C\Big(\rho(T_I)\bar{\Theta},\ \rho(T_J)\bar{\Theta}\Big) \quad \text{(cf. } \textit{Definition } 9.345 \textit{and Proposition } 9.347\text{)}.$$

Choose $O \in \mathrm{O}(\dim G)$ with $O^\top M^2_\Theta O = \mathrm{diag}(m^2_{V,a})$. Define tantron fields (mass eigenvectors) by

$$W_{a\,\mu} \ := \ O^{\ I}{}_{a}\, A^I_\mu\,, \qquad m^2_{V,a} \in \mathrm{spec}(M^2_\Theta).$$

(ii) **Physical pole definition (diagnostic realized reference configuration).** On the diagnostic realized reference configuration $\mathfrak{P}$ with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$, the *physical tantron* labelled by a is the simple pole of the two–point function in the *transverse* channel at $k^2 = m^2_{V,a}$, isolated by the typed projectors Π_T (and helicity projectors when applicable) of Definition 9.350. Longitudinal parts are gauge–artefacts removed by BRST; pole positions/residues are ξ–independent (Nielsen/BRST, Theorem 9.351).

(iii) **Unbroken directions.** If $m^2_{V,a} = 0$, the corresponding $W_{a\,\mu}$ is a massless internal vector (unbroken H-direction). Otherwise $m^2_{V,a} > 0$ and the tantron is massive; the would–be NG partner is eaten (typed equivalence theorem Corollary 9.352).

(iv) **Separation from scalar content.** Tantrons are quanta of the bundle connection in the Θ sector; they are distinct from the scalar *Higgs/kymon*, whose mass is read from the typed radial Hessian $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (eq. (9.185) and Definition 9.343), and there is no spin–2 excitation in this sector.

Justification (Tantron). The spin–1 bundle–connection quantum in the Tantrakyma sector is called the *Tantron*. The name is an elegant truncation of the sector label, anchored in the Sanskrit root *tantra* (: "loom," "weave," "system"), which captures the particle's function: it furnishes the locally woven *framework* by which the wave–like *Kymon* field is compared covariantly across the internal fiber. Formally, the Tantron denotes the *internal* spin–1 gauge quantum corresponding to the dynamical components A^I_μ of the operator–bundle connection $\mathcal{A}_\mu$ once the Tantrakyma sector is gauged (cf. Definition 9.345). Under spontaneous breaking by $\bar{\Theta}$, the covariant kinetic term produces the Brout–Englert–Higgs mass matrix

$$(M^2_\Theta)_{IJ} = g^2\, g_C\Big(\rho(T_I)\bar{\Theta},\ \rho(T_J)\bar{\Theta}\Big) \quad \text{(see Proposition 9.347)},$$

so that transverse Tantrons appear as diagnostic realized reference configuration–physical poles at $k^2 \in \mathrm{spec}(M^2_\Theta)$ in the vector channel (isolated by the typed projectors of Definition 9.350 and gauge–parameter independent by Nielsen/BRST, Theorem 9.351). Conceptually, the Tantron provides the "threads" that weave Kymon wave–states through the internal bundle, serving as the structural vector complement to the spin–0 radial Kymon (the *Higgs* of Definition 9.343 and eq. (9.185)).

Tantrakyma (Θ) — what becomes massive, what is eaten, and how the vectors behave. Gauging an internal G acting on $\mathcal{E}_\Theta$ and realizing $\bar{\Theta}$ breaks $G \to H$ and produces the Tantrakyma BEH mass matrix

$$(M^2_\Theta)_{IJ} = g^2\, g_C\Big(\rho(T_I)\bar{\Theta},\ \rho(T_J)\bar{\Theta}\Big) \quad (\textit{Definition 9.345and Proposition 9.347}).$$

What becomes massive? The internal vectors along the *broken* generators—i.e. the *tantrons*—acquire masses $\{m_V^2\} = \mathrm{spec}(M^2_\Theta)$; vectors along unbroken H-directions remain *massless*. The would-be NG kymons are *eaten* and reappear as *longitudinal* polarizations. On the diagnostic realized reference configuration, physical one-particle tantron poles lie in the *transverse* channel (typed Π_T, Π_L; Definition 9.350); longitudinal pieces are BRST-removed from H^0. As in the Φ sector, both *masses and residues are ξ-independent* by Nielsen/BRST (Theorem 9.351), and the typed *Equivalence Theorem* matches longitudinal-vector and NG amplitudes at $\sqrt{s} \gg m_V$ up to $\mathcal{O}(m_V/\sqrt{s})$ (Corollary 9.352). The scalar spectrum simultaneously splits into the gapped *Higgs/kymon*—the radial eigenmode of the typed Hessian (Definition 9.343 and eq. (9.185))—and (if present) pNG modes only when explicit breaking is introduced and the corresponding directions are left ungauged (Definitions 9.249 and 9.346).

Physically, tantrons are *short-range carriers* with range $\sim m_V^{-1}$. They couple (i) to the *Higgs/kymon* via the covariant derivative and scalar potential, generating VVh and $VVhh$ vertices; (ii) to *other vectors* through Yang–Mills triple and quartic interactions; and (iii) to any *charged matter* introduced in the model. Non-diagonal M^2_Θ induces *mixing* of gauge directions; degeneracies yield *multiplets* under H. Unbroken-direction vectors remain *massless* and long-range unless further dynamics intervene. All statements are made with typed/triadic readouts on $\mathfrak{P}$ and inherit route-equivalence and BRST hygiene (Propositions 9.191, 9.207 and 9.223 and Definition 9.349).

Definition 9.349 (R_ξ gauge fixing and ghosts on the diagnostic realized reference configuration)**.** Choose the gauge-fixing functional (cf. Gaiamiti analogue Definition 9.261)

$$\mathcal{F}^I \ :=\ \nabla^{(\mathrm{rel})\,\mu} A^I_\mu \ -\ \xi\, g\, g_C\Big(\delta\hat{\mathbf{\Theta}},\ \rho(T^I)\bar{\Theta}\Big).$$

Add

$$\mathcal{L}_{\mathrm{GF}} \ =\ -\tfrac{1}{2\xi}\, G_{IJ}\, \mathcal{F}^I\, \mathcal{F}^J, \qquad \mathcal{L}_{\mathrm{ghost}} \ =\ \bar{c}_I \Big[\, -\nabla^{(\mathrm{rel})\,2}\delta^I{}_J \ -\ \xi\,(M^2)^I{}_J \ +\ \cdots \Big] c^J,$$

with BRST variations closing on $H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration discipline: Propositions 9.191 and 9.207). This cancels the A–NG mixing and yields longitudinal-vector masses $\xi^{1/2} m_V$, while keeping the physical spectra $\mathrm{spec}(M^2)$ and M^2_{H} gauge-parameter independent (Nielsen identities; see Theorem 9.351).

Definition 9.350 (Typed vector projectors and physical polarizations)**.** Let $\mathbb{K}_A$ be the vector kinetic operator (built from $\bar{\Sigma}^{\mu\nu}$ and G_{IJ}). Define the Σ- and g-compatible transverse/longitudinal projectors Π_T, Π_L and the helicity projectors $\Pi^{(\lambda)}_{\mathrm{hel}}$. Physical one-particle vector states on $H^0(\hat{Q}_{\mathrm{BRST}})$ are the simple poles in the Π_T channel; Π_L is gauge-artefactual (removed by BRST). This mirrors the typed scalar linear-response analysis $\Big(\mathbb{K}^{(\Theta)} - \omega^2\Big)\delta\hat{\mathbf{\Theta}} = 0$ in eq. (9.184).

Theorem 9.351 (Nielsen/BRST gauge-parameter independence)**.** *On the certified plateau $\mathfrak{P}$, the pole positions of the Higgs propagator and of the physical vector propagators are independent of the gauge parameter ξ:*

$$\frac{d\,M_{\mathrm{H}}^2}{d\xi} = 0, \qquad \frac{d\,m_V^2}{d\xi} = 0,$$

and likewise for residues in physical channels. Hence BEH mass generation is a diagnostic realized reference configuration-certified observable (route equivalence & BRST safety as in Propositions 9.191 and 9.223).

Proof of Theorem 9.351. **DRCC discipline and BRST/Nielsen setup.** Work on a certified plateau $\mathfrak{P}$ with BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ and commuting typed/triadic meters (Propositions 9.191, 9.207 and 9.223). Use R_ξ gauge fixing with ghosts as in Θ and Φ (Definitions 9.261 and 9.349). On the diagnostic realized reference configuration (DRCC), the (typed) Nielsen identity for the 1PI effective action Γ is written in *BRST-exact* form

$$\partial_\xi \Gamma \;=\; s\,\mathcal{N}_\xi,$$

where s is the BRST differential and $\mathcal{N}_\xi$ is a local functional built from the gauge-fixing/ghost sector and antifields at gauge parameter ξ (notation $\mathcal{N}_\xi$ replaces the inconsistent Ξ_ξ). Insertions of $s(\cdot)$ vanish between physical states (cohomology H^0) up to EOM terms, and this persists after typed/triadic insertions (Proposition 9.207).

Step 1 — Higgs (radial kymon) mass M_{H}^2. By Definitions 9.250 and 9.343 and eq. (9.185),

$$M_{\mathrm{H}}^2 \in \mathrm{spec}\Big(\mathcal{K}_{\mathrm{rad}}^{[\chi]}\Big), \qquad \mathcal{K}_{\mathrm{rad}}^{[\chi]} = \Pi_{\mathrm{rad}}^{[\chi]}\,\frac{\delta^2\Gamma}{\delta\Theta\,\delta\Theta}\Big|_{\bar\Theta}\,\Pi_{\mathrm{rad}}^{[\chi]},$$

with $\bar\Theta$ solving the EL system on $\mathfrak{P}$. Differentiating w.r.t. ξ gives

$$\partial_\xi\left(\frac{\delta^2\Gamma}{\delta\Theta\,\delta\Theta}\right) = \frac{\delta^2}{\delta\Theta\,\delta\Theta}\big(s\,\mathcal{N}_\xi\big).$$

Any explicit ξ-shift of the background drops out by the potential Nielsen identity at the minimum: $\partial_\xi\Gamma|_{\bar\Theta} = -(\partial_i\Gamma)\,\mathcal{C}_\xi^i|_{\bar\Theta} = 0$ since $\partial_i\Gamma(\bar\Theta) = 0$. Projecting onto the typed radial line shows the ξ-variation of the radial block is BRST-exact and cohomologically trivial on H^0. Equivalently, in the correlational route the Higgs pole is the simple zero of $G_H^{-1}(k^2;\xi)$; its typed Nielsen identity has on-shell form

$$\partial_\xi G_H^{-1}(k^2;\xi) = \mathcal{B}_\xi^{\mathrm{H}}(k^2)\,G_H^{-1}(k^2;\xi) + G_H^{-1}(k^2;\xi)\,\mathcal{B}_\xi^{\mathrm{H}\,\dagger}(k^2),$$

so at $k^2 = M_{\mathrm{H}}^2$ (where $G_H^{-1} = 0$) one has $\partial_\xi G_H^{-1}(M_{\mathrm{H}}^2;\xi) = 0$ and thus $\partial_\xi M_{\mathrm{H}}^2 = 0$. Route equivalence on $\mathfrak{P}$ (Proposition 9.223) finishes the step.

Step 2 — Physical vector masses m_V^2. For $U \in \{\Theta, \Phi\}$ use the typed transverse/longitudinal/helicity projectors of Definition 9.350; physical vectors live in the transverse channel on H^0. The typed inverse propagator near the pole reads

$$\big(G_V^{-1}\big)_{\mathrm{T}}(k^2;\xi) = k^2\,\Pi_{\mathrm{T}} - M_U^2\big|_{\mathrm{T}} - \Sigma_{\mathrm{T}}(k^2;\xi),$$

with the tree-level mass matrix M_U^2 given algebraically by the BEH formula (Definition 9.252; concretely Propositions 9.257 and 9.347). The typed Nielsen identity implies

$$\partial_\xi\big(G_V^{-1}\big)_{\mathrm{T}} = \Pi_{\mathrm{T}}\Big[\ \mathcal{B}_\xi^{\mathrm{V}}\, G_V^{-1} + G_V^{-1}\, \mathcal{B}_\xi^{\mathrm{V}\,\dagger}\ \Big]\Pi_{\mathrm{T}},$$

with $\mathcal{B}_\xi^{\mathrm{V}}$ built from BRST-exact, gauge-fixing structures. Evaluating at a transverse physical pole $k^2 = m_V^2$ where $\big(G_V^{-1}\big)_{\mathrm{T}} = 0$ yields $\partial_\xi\big(G_V^{-1}\big)_{\mathrm{T}}(m_V^2;\xi) = 0$ and hence $\partial_\xi m_V^2 = 0$. Background dependences through $\bar{U}$ cancel by the potential Nielsen identity as in Step 1.

Step 3 — Residues in physical channels. Let $Z_{\mathrm{H}}(\xi)$ and $Z_{\mathrm{T}}(\xi)$ be the residues at the Higgs and transverse–vector simple poles. Differentiating the LSZ residues and inserting the on-shell Nielsen forms shows $\partial_\xi Z_{\mathrm{H}} = 0$ and $\partial_\xi Z_{\mathrm{T}} = 0$ on H^0 (any ξ-dependence factors through G^{-1}, which vanishes at the pole). This is consistent with the typed equivalence theorem on $\mathfrak{P}$ (Corollary 9.352).

Conclusion. On the certified plateau, the BRST-exact Nielsen identity $\partial_\xi\Gamma = s\mathcal{N}_\xi$ implies $\frac{dM_{\mathrm{H}}^2}{d\xi} = 0$ and $\frac{dm_V^2}{d\xi} = 0$, and likewise ∂_ξ kills residues in physical channels. Therefore BEH mass generation is diagnostic realized reference configuration-certified (route equivalence & BRST safety), as claimed. □

Corollary 9.352 (Equivalence theorem (typed, on the diagnostic realized reference configuration))**.** *For $\sqrt{s} \gg m_V$, matrix elements with external longitudinal vectors equal those with the corresponding NG kymons in the Π_{NG} channel (typed projector in Definitions 9.249 and 9.346), up to $\mathcal{O}(m_V/\sqrt{s})$.*

Proof. **Diagnostic realized reference configuration discipline and typed setup.** Work on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$, with route–equivalence and gauge hygiene as in Propositions 9.191, 9.207 and 9.223. Use R_ξ gauge fixing and ghosts as in Definition 9.349 (Tantrakyma) / Definition 9.261 (Gaiamiti). Let the internal vectors be typed by the transverse/helicity projectors of Definition 9.350, and let the NG projector be the typed version of Definitions 9.249 and 9.346. Tree–level masses arise from spec(M^2) with M^2 given by Propositions 9.257 and 9.347 and Definition 9.252.

Step 1 — Longitudinal polarization at high energy. For an external massive vector with momentum k and mass m_V, choose the *helicity–0* (longitudinal) polarization vector $\varepsilon_L^\mu(k)$ from the physical (transverse) typed space ($\varepsilon_L \cdot k = 0$; cf. Definition 9.350). Kinematically,

$$\varepsilon_L^\mu(k) \;=\; \frac{k^\mu}{m_V} \;+\; \mathcal{O}\!\left(\frac{m_V}{\sqrt{s}}\right), \qquad s \equiv k_{\mathrm{cm}}^2 \gg m_V^2,$$

so any amplitude with an external longitudinal vector satisfies $\mathcal{M}[\ldots, A_L^I(k), \ldots] = \varepsilon_L^\mu(k)\,\mathcal{T}_\mu^I(k,\ldots) = \frac{k^\mu}{m_V}\,\mathcal{T}_\mu^I + \mathcal{O}(m_V/\sqrt{s})$, where $\mathcal{T}_\mu^I$ is the amputated Green's function for the vector leg in the typed channel.

Step 2 — Typed Slavnov–Taylor/Nielsen identity with one vector leg. From the R_ξ gauge functionals in Definitions 9.261 and 9.349 and BRST closure on the diagnostic realized

reference configuration, the (typed, triadic–inserted) Slavnov–Taylor/Nielsen identity for the amputated 1PI functional with one vector leg implies

$$k^\mu \mathcal{T}^I_\mu \;=\; m_V \mathcal{T}^I_{\mathrm{NG}} \;+\; \mathcal{R}^I,$$

where $\mathcal{T}^I_{\mathrm{NG}}$ is the amputated functional with the NG insertion projected by Π_{NG} (typed version of Definitions 9.249 and 9.346) and $\mathcal{R}^I$ is a sum of BRST–exact terms and gauge–fixing artefacts proportional to the inverse kernels. On the diagnostic realized reference configuration and on shell, $\mathcal{R}^I$ vanishes between physical states in $H^0(\hat{Q}_{\mathrm{BRST}})$ (by Proposition 9.207 and the EOM at the realized background), leaving

$$k^\mu \mathcal{T}^I_\mu \;=\; m_V \mathcal{T}^I_{\mathrm{NG}} \quad \text{on } H^0.$$

Step 3 — LSZ reduction and comparison of matrix elements. Insert the identity above into the LSZ expression for the matrix element with one external longitudinal vector:

$$\mathcal{M}[\ldots, A^I_L(k), \ldots] = \frac{k^\mu}{m_V}\mathcal{T}^I_\mu \;+\; \mathcal{O}\!\left(\frac{m_V}{\sqrt{s}}\right) = \mathcal{T}^I_{\mathrm{NG}} \;+\; \mathcal{O}\!\left(\frac{m_V}{\sqrt{s}}\right),$$

where the $\mathcal{O}(m_V/\sqrt{s})$ terms originate from the subleading part of ε^μ_L in Step 1 and any suppressed BRST–exact remainders. By route–equivalence on $\mathfrak{P}$ (Proposition 9.223) and gauge–parameter independence (Theorem 9.351), both sides are diagnostic realized reference configuration–certified observables in the typed channels.

Conclusion. For $\sqrt{s} \gg m_V$,

$$\mathcal{M}[\ldots, A^I_L(k), \ldots] = \mathcal{M}[\ldots, \phi^I_{\mathrm{NG}}(k), \ldots]_{\Pi_{\mathrm{NG}}} \;+\; \mathcal{O}\!\left(\frac{m_V}{\sqrt{s}}\right),$$

i.e. the matrix element with an external longitudinal vector equals the one with the corresponding NG kymon projected by Π_{NG} (typed projector in Definitions 9.249 and 9.346), up to $\mathcal{O}(m_V/\sqrt{s})$. □

Relation to existing Chapter 10 structures.

(i) **Higgs = radial kymon (typed, on the diagnostic realized reference configuration).** The Higgs boson is precisely the *radial kymon* defined in Definition 9.343, with mass extracted from the typed radial Hessian $\mathcal{K}^{[\chi]}_{\mathrm{rad}}$ (eq. (9.185) and Definition 9.250). All statements are made on the certified plateau and respect route–equivalence and BRST/Nielsen safety (Propositions 9.191 and 9.223).

(ii) **NG/pNG sector = $\mathrm{Ran}\,\Pi_{\mathrm{NG}}$ (typed).** The Nambu–Goldstone sector is the range of the NG projector defined for Tantrakyma in Definition 9.346 and, in typed generality, in Definition 9.249. With small explicit breaking, the NG cluster becomes pseudo–NG with GMOR scaling on the diagnostic realized reference configuration; quadrant assignment flips to QIV as in Proposition 9.251 (diagnostic realized reference configuration sources/healing and NG diagnostics in Definition 9.188 and Proposition 9.197).

(iii) **Typed & triadic compatibility (T–L–O ready).** The typed projectors $\Pi_{UU}^{[\chi]}$ commute with the triadic channels $\Pi_{\mathrm{corr}}, \Pi_{\mathrm{vac}}, \Pi_{\mathrm{spec}}$ (Definition 9.186 and Proposition 9.207), and, by construction, with the NG and radial projectors (Π_{NG}, Π_{H} for Tantrakyma in Definition 9.346, and $\Pi_{\mathrm{A}}^{(\Phi)}$ for Gaiamiti in Definition 9.259). Consequently, all SynTh readouts—typed witnesses and potential–based operators $\mathcal{O}^{(\bullet)}$—remain compatible with the *Type–Location–Onset* pipeline (Definitions 9.187, 9.190 and 9.221). Typed decisions and their recording use the ledger interfaces (Definition 9.198 and Corollaries 9.194 and 9.218).

(iv) **Consistency with gauging and mass generation.** Under internal gauging, vector masses are generated by the diagnostic realized reference configuration–algebraic BEH matrices (Θ: Proposition 9.347 and Definition 9.252; Φ: Proposition 9.257 and Definition 9.252), while the radial scalars are governed by $\mathcal{K}_{\mathrm{rad}}^{[\chi]}$ (eq. (9.185) and Definition 9.259). Gauge–parameter independence of Higgs and transverse–vector poles and residues follows from the diagnostic realized reference configuration Nielsen theorem (Theorem 9.351); at high energy, longitudinal vectors match NG kymons in the typed NG channel (Corollary 9.352).

(v) **Quadrant semantics preserved.** Typed quadrant decisions (QI–QIV) follow the canonical rule on the diagnostic realized reference configuration (Definition 7.685 and Propositions 9.251 and 9.254), with TT graviton masslessness protected (for Φ) by the relational Ward structure (Section 9.17.2 and Remark 9.260).

9.18.8 A Minimal $U(1)$ Worked Example of the BEH Mechanism

All constructions below are evaluated on a certified plateau $\mathfrak{P}$ with band tags $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$; typed projectors commute with the triadic channels $\Pi_{\mathrm{corr}}, \Pi_{\mathrm{vac}}, \Pi_{\mathrm{spec}}$ (Propositions 9.191, 9.207 and 9.223 and Definition 9.186).

Setup and action. Let $G = U(1)$ act on the Tantrakyma fiber $\mathcal{E}_\Theta$ by a representation ρ with charge q, normalized anti–self–adjointly with respect to g_C,

$$\rho(T)^\dagger\, g_C + g_C\, \rho(T) = 0,$$

so that the NG (phase) direction is g_C-orthogonal to the radial one (diagnostic realized reference configuration hygiene per Proposition 9.207). Introduce a gauge field A_μ with field strength $F_{\mu\nu}$, coupling g, and extend the covariant derivative of Definition 9.323 (cf. Section 6.12.2 and eq. (6.314)) to

$$D_\mu \hat{\boldsymbol{\Theta}} := \nabla_\mu^{(\mathrm{rel})} \hat{\boldsymbol{\Theta}} \;+\; \partial_\mu \hat{\boldsymbol{\Theta}} \;+\; i\, g\, A_\mu\, \rho(T)\, \hat{\boldsymbol{\Theta}}.$$

On the certified plateau $\mathfrak{P}$, the (operator-valued) action with typed/triadic insertion is

$$S_{U(1)+\Theta} = \int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}}\, \mathrm{Tr}\Big[-\tfrac{1}{4}\, F_{\mu\nu} F^{\mu\nu} + \tfrac{1}{2}\, (D_\mu \hat{\boldsymbol{\Theta}})^\dagger\, g_C\, (D^\mu \hat{\boldsymbol{\Theta}}) - \mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}}) \Big],$$

with $\mathcal{V}_\Theta$ as in Definition 9.343.

SSB, radial/NG directions, and projectors. Let $\hat{\mathbf{\Theta}} = \bar{\Theta} + \delta\hat{\mathbf{\Theta}}$ with $\bar{\Theta}$ minimizing V_Θ (cf. Definition 9.343). Define the invariant $\mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ and its background derivative

$$\delta\mathsf{X}\big|_{\bar{\Theta}}(\delta\hat{\mathbf{\Theta}}) = 2\, g_C(\delta\hat{\mathbf{\Theta}}, \bar{\Theta}) \quad \text{(cf. Remark 9.303)}.$$

The radial (Higgs) direction is $\hat{\mathsf{R}} \propto \bar{\Theta}$ with one-dimensional projector Π_{H} as in Definitions 9.250 and 9.343 and eq. (9.185). The Nambu–Goldstone direction is the g_C-orthogonal phase vector $v := \rho(T)\bar{\Theta}$ with $g_C(\bar{\Theta}, v) = 0$ by the normalization above. The g_C–Riesz NG projector (the $U(1)$ specialization of Definitions 9.249 and 9.346) is

$$\Pi_{\mathrm{NG}}(V) := \frac{g_C\Big(V, \rho(T)\bar{\Theta}\Big)}{g_C\Big(\rho(T)\bar{\Theta}, \rho(T)\bar{\Theta}\Big)}\, \rho(T)\bar{\Theta}, \qquad \operatorname{Ran}\Pi_{\mathrm{NG}} = \operatorname{span}\{\rho(T)\bar{\Theta}\}.$$

All projectors commute with triadic channels (Proposition 9.207).

Vector mass from BEH. Expanding the kinetic term $\frac{1}{2}(D_\mu\hat{\mathbf{\Theta}})^\dagger g_C(D^\mu\hat{\mathbf{\Theta}})$ about $\bar{\Theta}$ yields

$$\mathcal{L}^{(A)}_{\mathrm{mass}} = \tfrac{1}{2}\, m_V^2\, A_\mu A^\mu, \qquad m_V^2 \;:=\; g^2\, g_C\Big(\rho(T)\bar{\Theta},\ \rho(T)\bar{\Theta}\Big) \;=\; g^2\, q^2\, g_C(\bar{\Theta}, \bar{\Theta}),$$

which is the $U(1)$ case of the unified diagnostic realized reference configuration formula in Definition 9.252 and the sector proposition Proposition 9.347. The scalar sector splits into: (i) the *Higgs (radial) kymon*, defined by

$$\mathcal{K}_{\mathrm{H}} := \Pi_{\mathrm{H}}\, \frac{\delta^2\mathcal{V}_\Theta}{\delta\hat{\mathbf{\Theta}}\,\delta\hat{\mathbf{\Theta}}}\bigg|_{\bar{\Theta}}\, \Pi_{\mathrm{H}}, \qquad M_{\mathrm{H}}^2 \in \operatorname{spec}(\mathcal{K}_{\mathrm{H}}) \quad \text{(cf. eq. (9.185) and Definition 9.250)},$$

and (ii) the NG direction $\operatorname{Ran}\Pi_{\mathrm{NG}}$.

R_ξ gauge fixing and BRST cancellation of A–NG mixing. Define

$$\mathcal{F} := \nabla^{(\mathrm{rel})\,\mu} A_\mu \;-\; \xi\, g\, g_C\Big(\delta\hat{\mathbf{\Theta}}, \rho(T)\bar{\Theta}\Big), \qquad \mathcal{L}_{\mathrm{GF}} = -\tfrac{1}{2\xi}\,\mathcal{F}^2,$$

together with the standard ghost term so BRST closes on $H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definitions 9.261 and 9.349 and Proposition 9.207). This cancels the A–NG mixing, gives the would–be NG a gauge-dependent mass $\sqrt{\xi}\, m_V$, and leaves the physical transverse-vector pole at $k^2 = m_V^2$. Typed readouts use Π_T, Π_L for vectors and $\Pi_{\mathrm{H}}, \Pi_{\mathrm{NG}}$ for scalars (cf. the linear response eq. (9.184) and Definition 9.350).

Propagators and gauge-parameter independence (diagnostic realized reference configuration certification). In the typed channels Π_T, Π_L and $\Pi_{\mathrm{H}}, \Pi_{\mathrm{NG}}$ (cf. Definitions 9.249, 9.343 and 9.350),

$$\frac{d\, m_V^2}{d\xi} = 0, \qquad \frac{d\, M_{\mathrm{H}}^2}{d\xi} = 0,$$

and residues are ξ–independent by the diagnostic realized reference configuration Nielsen theorem Theorem 9.351. Hence both the vector mass m_V and the Higgs mass M_{H} are diagnostic realized reference configuration-certified observables (route equivalence and BRST safety: Propositions 9.191 and 9.223).

Quadrant viewpoint. With $\mathcal{V}_\Theta$ exhibiting SSB and no explicit $U(1)$ breaking, the typed predicate gives QII (NG present, eaten $\Rightarrow$ massive vector m_V, gapped radial kymon M_{H}) as in Proposition 9.251. With a small explicit breaking spurion, the system moves to QIV with a pseudo–NG of mass $\mathcal{O}(\epsilon)$ (GMOR scaling; Definition 9.188 and Proposition 9.197), while the vector/Higgs poles remain diagnostic realized reference configuration–certified (Theorem 9.351).

Typed Vector Projectors and Quadratic Lagrangian (U(1) BEH)

Typed vector projectors. Work locally in momentum space on $\mathfrak{P}$, with relational metric $\bar{\Sigma}_{\mu\nu}$. Define

$$\Pi_T^{\mu\nu}(k) := \bar{\Sigma}^{\mu\nu} - \frac{k^\mu k^\nu}{k^2}, \qquad \Pi_L^{\mu\nu}(k) := \frac{k^\mu k^\nu}{k^2},$$

so that $\Pi_T^2 = \Pi_T,\ \Pi_L^2 = \Pi_L,\ \Pi_T\Pi_L = 0,\ \Pi_T + \Pi_L = \mathbb{1}$. We decompose $A_\mu = A_T^\mu + A_L^\mu$ with $A_T^\mu := \Pi_{T\nu}^\mu A^\nu$, $A_L^\mu := \Pi_{L\nu}^\mu A^\nu$ (Definition 9.350).

SSB pattern and masses. Let $G = U(1)$ with generator T in representation ρ, charge q, and coupling g. For the realized background $\bar{\Theta}$ (cf. Definition 9.343),

$$m_V^2 := g^2\, g_C\Big(\rho(T)\bar{\Theta}, \rho(T)\bar{\Theta}\Big) = g^2 q^2\, g_C(\bar{\Theta}, \bar{\Theta}),$$

and the Higgs (radial) mass operator is

$$\mathcal{K}_{\mathrm{H}} \;:=\; \Pi_{\mathrm{H}}\, \frac{\delta^2 \mathcal{V}_\Theta}{\delta\hat{\boldsymbol{\Theta}}\,\delta\hat{\boldsymbol{\Theta}}}\Big|_{\bar{\Theta}}\, \Pi_{\mathrm{H}}, \quad M_{\mathrm{H}}^2 \in \mathrm{spec}(\mathcal{K}_{\mathrm{H}}) \quad \text{(cf. eq. (9.185) and Definition 9.250).}$$

The NG direction is $\mathrm{span}\{\rho(T)\bar{\Theta}\}$ with projector Π_{NG} as in Definitions 9.249 and 9.346.

R_ξ gauge fixing and ghosts. Choose the momentum–space gauge-fixing functional

$$\mathcal{F} \;:=\; k_\mu A^\mu \;-\; \xi\, g\, g_C\Big(\delta\hat{\boldsymbol{\Theta}},\, \rho(T)\bar{\Theta}\Big), \quad \mathcal{L}_{\mathrm{GF}} = -\frac{1}{2\xi}\,\mathcal{F}^2,$$

and the Abelian ghost Lagrangian

$$\mathcal{L}_{\mathrm{ghost}} = \bar{c}\,(k^2 + \xi\, m_V^2)\, c,$$

with diagnostic realized reference configuration BRST closing in $H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definition 9.349 and Proposition 9.207).

Riesz construction of the scalar projectors (one line each). Using the typed resolvent definition (cf. Definition 9.249),

$$\boxed{\Pi_{\mathrm{H}} = \frac{1}{2\pi i}\oint_{\Gamma_{\mathrm{H}}} \Big(z - \mathcal{K}_{\Theta\Theta}^{[\chi]}\Big)^{-1} dz, \qquad \Pi_{\mathrm{NG}} = \frac{1}{2\pi i}\oint_{\Gamma_0} \Big(z - \mathcal{K}_{\Theta\Theta}^{[\chi]}\Big)^{-1} dz\ .}$$

Equivalently, in rank-1 g_C–Riesz form (cf. Definitions 9.343 and 9.346),

$$\Pi_{\mathrm{H}}(V) = \frac{g_C\big(V, \widehat{\mathsf{R}}\big)}{g_C\big(\widehat{\mathsf{R}}, \widehat{\mathsf{R}}\big)}\, \widehat{\mathsf{R}}, \qquad \Pi_{\mathrm{NG}}(V) = \frac{g_C\big(V, \rho(T)\bar{\Theta}\big)}{g_C\big(\rho(T)\bar{\Theta}, \rho(T)\bar{\Theta}\big)}\, \rho(T)\bar{\Theta},$$

where $\widehat{\mathsf{R}} \propto \bar{\Theta}$.

Cluster (multiplet) Riesz projector for NG directions (non-Abelian, quasi-degenerate). Let the broken generators be $\{T_b\}_{b\in\mathcal{B}}$ and set $v_b := \rho(T_b)\bar{\Theta}$. When the NG sector forms a quasi-degenerate cluster, isolate the cluster of the typed scalar Hessian $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ near $z = 0$ by a contour Γ_{NG}. The *cluster Riesz projector* is

$$\boxed{\Pi^{\mathrm{cl}}_{\mathrm{NG}} \;=\; \frac{1}{2\pi i}\oint_{\Gamma_{\mathrm{NG}}} \Big(z - \mathcal{K}^{[\chi]}_{\Theta\Theta}\Big)^{-1}\, dz}$$

and admits the finite-rank g_C–Riesz form

$$\boxed{\Pi^{\mathrm{cl}}_{\mathrm{NG}}(V) \;=\; \sum_{b,c\in\mathcal{B}} (B^{-1})^{bc}\, g_C\Big(V,\, v_b\Big)\, v_c, \qquad B_{bc} := g_C(v_b, v_c)}$$

(which coincides with the contour form on the cluster subspace), consistent with the typed NG construction in Definition 9.249.

pNG case (small explicit breaking). With a controlled explicit breaking ($\epsilon \ll 1$), replace Γ_{NG} by a contour Γ_{pNG} that encloses the small eigenvalues $z = \mathcal{O}(\epsilon)$; the same formulas define $\Pi^{\mathrm{cl}}_{\mathrm{pNG}}$. On the diagnostic realized reference configuration, $\Pi^{\mathrm{cl}}_{\mathrm{NG}}$ and $\Pi^{\mathrm{cl}}_{\mathrm{pNG}}$ commute with the triadic projectors and with the scalar readouts used in Definition 9.343 and eq. (9.185).

Quadratic Lagrangian matrix (field order A_T, A_L, NG, H). Expand to quadratic order around $\bar{\Theta}$ and move to momentum space. After adding $\mathcal{L}_{\mathrm{GF}}$, the A_L–NG mixing cancels. In the basis $\Psi := (A_T,\ A_L,\ \pi_{\mathrm{NG}},\ h_{\mathrm{H}})$ (transverse vector, longitudinal vector, NG scalar, Higgs scalar), the quadratic form is diagonal:

$$\mathcal{L}^{(2)} = \tfrac{1}{2}\, \Psi^\dagger\, \mathbb{Q}(k)\, \Psi,$$

$$\mathbb{Q}(k) = \begin{pmatrix} k^2 - m_V^2 & 0 & 0 & 0 \\ 0 & \dfrac{k^2 - m_V^2}{\xi} & 0 & 0 \\ 0 & 0 & k^2 - \xi\, m_V^2 & 0 \\ 0 & 0 & 0 & k^2 - M_{\mathrm{H}}^2 \end{pmatrix},$$

where $k^2 := \bar{\Sigma}^{\mu\nu} k_\mu k_\nu$.

Poles: A_T : $k^2 = m_V^2$ (physical), A_L : $k^2 = m_V^2$ (gauge-artefactual numerator), π_{NG} : $k^2 = \xi m_V^2$, h_{H} : $k^2 = M_{\mathrm{H}}^2$. On $H^0(\hat{Q}_{\mathrm{BRST}})$ the physical poles are $k^2 = m_V^2$ and $k^2 = M_{\mathrm{H}}^2$; ξ-dependence cancels in S–matrix elements and matches NG amplitudes at high energy by Corollary 9.352.

Propagators and physical content. The vector propagator is

$$D_{\mu\nu}(k) = \frac{-i}{k^2 - m_V^2}\,\Pi_{T\,\mu\nu} \;+\; \frac{-i\,\xi}{k^2 - \xi\,m_V^2}\,\Pi_{L\,\mu\nu},$$

the NG propagator is $D_{\mathrm{NG}}(k) = \frac{i}{k^2 - \xi\,m_V^2}$, and the Higgs propagator is $D_{\mathrm{H}}(k) = \frac{i}{k^2 - M_{\mathrm{H}}^2}$. Gauge–parameter independence of the physical residues follows from Theorem 9.351.

Typed/triadic compatibility. Typed scalar readouts use $\Pi_{\mathrm{H}}, \Pi_{\mathrm{NG}}$ (cf. Definitions 9.249 and 9.343), and vector readouts use Π_T, Π_L (Definition 9.350); all commute with the triadic projectors $\Pi_{\mathrm{corr}}, \Pi_{\mathrm{vac}}, \Pi_{\mathrm{spec}}$ (Proposition 9.207). This keeps the BEH completion fully consistent with the T–L–O program and the linear response equation *eq.* (9.184).

The worked $U(1)$ example demonstrates that *diagnostic realized reference configuration discipline*—evaluation on a certified plateau $\mathfrak{P}$ with typed/triadic insertions and reading in the physical BRST cohomology $H^0(\hat{Q}_{\mathrm{BRST}})$—renders the potential and correlational routes equivalent and the results insensitive to gauge–fixing choices. In this setting, pole locations and residues extracted from typed channels are bona fide observables rather than gauge artefacts (route equivalence and Nielsen/BRST safety as in Propositions 9.191 and 9.223).

The *scalar sector* separates cleanly into two directions. The *radial (Higgs) kymon* is defined by the typed radial Hessian $\mathcal{K}_{\mathrm{H}} \equiv \mathcal{K}_{\mathrm{rad}}^{[\chi]}$ (Definitions 9.250 and 9.343 and eq. (9.185)), which determines the Higgs mass M_{H}^2. The *NG sector* is captured by a typed Riesz/Gram projector Π_{NG}, rank–1 in the $U(1)$ case and realized as a cluster projector for non–Abelian or pseudo–NG multiplets (Definitions 9.249 and 9.346).

An *anti–self–adjoint normalization* of the representation with respect to g_C ensures $g_C\big(\bar{\Theta}, \rho(T)\bar{\Theta}\big) = 0$. This fixes the orthogonality of the NG (phase) direction to the radial one at the level of definitions and prevents hidden radial–phase mixing in subsequent calculations (Proposition 9.207).

Vector masses arise algebraically from the BEH mechanism and depend only on the vacuum orientation in the internal space:

$$m_V^2 \;=\; g^2\, g_C\Big(\rho(T)\bar{\Theta}, \rho(T)\bar{\Theta}\Big) \quad (\text{for } U(1)\text{: } g^2 q^2\, g_C(\bar{\Theta}, \bar{\Theta})),$$

the $U(1)$ specialization of the unified typed mass matrix (Definition 9.252; see also Proposition 9.347). No explicit mass term is needed.

Typed *projectors* make the physical content manifest. Vectors are decomposed with Π_T, Π_L; scalars with $\Pi_{\mathrm{H}}, \Pi_{\mathrm{NG}}$ (Definitions 9.249, 9.343 and 9.350). On $H^0(\hat{Q}_{\mathrm{BRST}})$ only the *transverse vector pole* at $k^2 = m_V^2$ and the *Higgs pole* at $k^2 = M_{\mathrm{H}}^2$ remain; longitudinal and would–be NG components are gauge artefacts removed by BRST.

R_ξ *gauge fixing* is used purely as a computational device. The functional chosen cancels A–NG mixing and gives the would–be NG a gauge–dependent mass $\sqrt{\xi}\,m_V$, while leaving transverse and Higgs poles untouched (Definition 9.349). The *Nielsen/BRST theorem* then guarantees

$$\frac{\mathrm{d}m_V^2}{\mathrm{d}\xi} = 0 \qquad \text{and} \qquad \frac{\mathrm{d}M_{\mathrm{H}}^2}{\mathrm{d}\xi} = 0,$$

and likewise for physical residues (Theorem 9.351).

At high energy, the *typed Equivalence Theorem* applies: for $\sqrt{s} \gg m_V$, amplitudes with an external longitudinal vector coincide with those with the corresponding NG mode in the Π_{NG} channel up to $\mathcal{O}(m_V/\sqrt{s})$ (Corollary 9.352). This provides a practical replacement rule for computations while preserving diagnostic realized reference configuration certification.

The *quadrant semantics* remain intact. With SSB and no explicit breaking, the typed predicate yields *QII*: NG present and eaten ($\Rightarrow$ massive internal vector and gapped radial scalar). Introducing a small explicit spurion yields *QIV* with a pNG cluster obeying GMOR scaling, while the transverse vector and Higgs poles remain diagnostic realized reference configuration–certified (Propositions 9.197 and 9.251 and Definition 9.188).

The worked example is explicitly carried out in the Tantrakyma sector. For non–Abelian internal symmetry, the replacement of the rank–1 NG projector by a *cluster* Riesz projector is immediate and preserves all typed/diagnostic realized reference configuration properties (Definitions 9.249 and 9.346). For the Gaiamiti sector, the corresponding BEH completion is *not* rederived here; instead, the consequences are established elsewhere in this chapter: the gauge–coupled action and SSB pattern (Definitions 9.255 and 9.256), the internal vector mass matrix $(M^2)_{IJ} = g^2\, g_T\Big(\rho_\Phi(T_I)\bar{\Phi}, \rho_\Phi(T_J)\bar{\Phi}\Big)$ (Proposition 9.257), the Apeiron (trace–typed) radial operator $\mathcal{K}_{\mathrm{A}}^{(\Phi)}$ and its mass M_{A}^2 (Definition 9.259), and the masslessness of the TT graviton protected by relational/diffeomorphism Ward identities (Remark 9.260 and Section 9.17.2). In summary, internal gauging in the Gaiamiti sector gives masses only to *internal* vectors (Section 9.17.3), leaves the TT graviton massless, and realizes a radial "stiffness" mode governed by $\mathcal{K}_{\mathrm{A}}^{(\Phi)}$, consistent with the typed quadrant semantics and diagnostic realized reference configuration certification.

Finally, a *pragmatic workflow* emerges for any model: fix typed projectors; determine the realized background $\bar{U}$ and construct Π_{H} and Π_{NG}; read M_{H}^2 from the typed radial Hessian and m_V^2 from the BEH matrix; use R_ξ for convenience; report gauge–independent poles/residues under Nielsen/BRST control; and record Type/Location/Onset and the quadrant decision in the ledger (Definitions 9.190 and 9.198). The result is a coherent, end–to–end pipeline with clean mode separation, algebraic mass generation, and invariant physical content.

Derivation of the Higgs Boson Mass from the Tantrakyma Potential

We extract the *radial (Higgs) mass* as the curvature of the Tantrakyma potential along the vacuum (amplitude) direction. Equivalently, in operator form this is the radial restriction of the potential Hessian (cf. eqs. (9.175) and (9.185)).

1. Potential and its minimum. Start from the operator-valued potential (cf. Definition 9.335 and eq. (9.133))

$$\mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) = \tfrac{1}{2}\, m_\Theta^2\, \mathsf{X} \;+\; \tfrac{\lambda_\Theta}{4!}\, \mathsf{X}^2 \;+\; \cdots, \qquad \mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}}),$$

with $m_\Theta^2 < 0$, $\lambda_\Theta > 0$ for SSB. To obtain a scalar amplitude on the diagnostic realized reference configuration, define

$$x(x') \;:=\; \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\mathsf{X}(x')\Big\}, \qquad \text{and set} \;\; v_\Theta^2 \;:=\; \Big\langle x \Big\rangle_{\mathfrak{P}}.$$

Then $V_\Theta(v_\Theta) = \frac{1}{2}m_\Theta^2 v_\Theta^2 + \frac{\lambda_\Theta}{4!}v_\Theta^4 + \cdots$ (cf. eq. (9.134)). Minimizing in v_Θ gives

$$\frac{\partial V_\Theta}{\partial v_\Theta} = m_\Theta^2\, v_\Theta + \frac{\lambda_\Theta}{6}\, v_\Theta^3 = 0 \quad \Longrightarrow \quad v_\Theta^2 = -\,\frac{6\, m_\Theta^2}{\lambda_\Theta} \;>\; 0.$$

2. Curvature at the minimum (radial mass). The radial (Higgs) mass is the curvature along v_Θ:

$$\frac{\partial^2 V_\Theta}{\partial v_\Theta^2} = m_\Theta^2 + \frac{\lambda_\Theta}{2}\, v_\Theta^2, \qquad M_{\mathrm{H}}^2 := \left.\frac{\partial^2 V_\Theta}{\partial v_\Theta^2}\right|_{v_\Theta^2 = -6m_\Theta^2/\lambda_\Theta}.$$

Substituting the vacuum value yields

$$M_{\mathrm{H}}^2 = m_\Theta^2 + \frac{\lambda_\Theta}{2}\left(-\frac{6m_\Theta^2}{\lambda_\Theta}\right) = -\,2\, m_\Theta^2.$$

3. Final expression and equivalence with the Hessian projector.

$$\boxed{M_{\mathrm{H}}^2 \;=\; -\,2\, m_\Theta^2 \;>\; 0 \qquad (\text{SSB phase: } m_\Theta^2 < 0).} \tag{9.194}$$

This matches the operator–projector construction: if Π_{H} projects onto the g_C-radial direction $\hat{\mathsf{R}} \propto \delta\mathsf{X}/\delta\hat{\boldsymbol{\Theta}}\big|_{\bar{\Theta}}$ (cf. eq. (9.185)), then the radial eigenvalue of the Hessian $\Pi_{\mathrm{H}}\left(\delta^2\mathcal{V}_\Theta/\delta\hat{\boldsymbol{\Theta}}^\dagger\delta\hat{\boldsymbol{\Theta}}\right)\big|_{\bar{\Theta}}\Pi_{\mathrm{H}}$ equals M_{H}^2 in (9.194), while tangent directions yield NG/pNG zeros certified by the typed meters (eqs. (9.126) to (9.128)) and the T–L–O quadrant call (Definition 9.297).

Interpretation

- **Positivity.** In the SSB phase $m_\Theta^2 < 0$, (9.194) gives $M_{\mathrm{H}}^2 > 0$, i.e. a physical, gapped scalar kymon (cf. Section 9.18.5).
- **Emergent scale.** M_{H} is fixed by $(m_\Theta^2, \lambda_\Theta)$ via $v_\Theta^2 = -6m_\Theta^2/\lambda_\Theta$; it is not an independent parameter (cf. Definition 9.335 and eq. (9.133)).
- **Typed/TLO certification.** On the diagnostic realized reference configuration $\mathfrak{P}$, NG channels show a $k^2 = 0$ pole (QI), while the Higgs (radial) channel has a single gapped pole at $k^2 = M_{\mathrm{H}}^2$ and no massless pole, with a consistent Type–Location–Onset stamp (cf. Definition 9.299).

In sum, the Higgs boson emerges as the *radial, scalar kymon* mandated by spontaneous symmetry breaking (cf. Section 9.18.6), with its mass fixed by the Tantrakyma potential and its physical status certified by the typed, parasymmetric T–L–O workflow—paralleling the Standard Model mechanism [82, 91] while remaining faithful to the IQR formalism.

The Composite Nature of the Higgs Boson

Just as the graviton in the geometry sector resolves into triadic species under the Gaiamiti instrumentation, the Higgs boson—as the radial, scalar kymon of the Tantrakyma sector—inherits the *triadic* structure of its parent field and must be identified *typed* and *channel-wise* on a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ (cf. Definitions 5.54 and 9.301 and Section 9.17.11).

1. Triadic matter channels and typed slicing. The Tantrakyma fluctuation field $\delta\hat{\mathbf{\Theta}}$ carries both a *type* index $[\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}$ and a *channel* index $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$. With channel projectors Π_α commuting with the typed projectors $\Pi^{[\chi]}_{\Theta\Theta}$ (triadic compatibility; cf. Definition 9.295), we write

$$\delta\hat{\mathbf{\Theta}} = \sum_\alpha \Pi_\alpha\, \delta\hat{\mathbf{\Theta}} = \sum_{\alpha,[\chi]} \Pi^{[\chi]}_{\Theta\Theta}\, \Pi_\alpha\, \delta\hat{\mathbf{\Theta}} \;=:\; \sum_{\alpha,[\chi]} \delta\hat{\mathbf{\Theta}}^{(\alpha,[\chi])}, \qquad [\Pi_\alpha, \Pi^{[\chi]}_{\Theta\Theta}] = 0. \tag{9.195}$$

All kernels and meters below are evaluated on $H^0(\hat{Q}_{\mathrm{BRST}})$ and respect band limitations $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (cf. Definition 9.306).

2. The Higgs as a composite kymon (typed, triadic). Let Π_{H} denote the projector onto the radial (amplitude) direction at the realized vacuum, $\hat{\mathsf{R}} \propto \delta\mathsf{X}/\delta\hat{\mathbf{\Theta}}\big|_{\bar{\Theta}}$ with $\mathsf{X} := g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ (cf. eq. (9.185)). The Higgs operator field $\hat{\phi}_{\mathrm{H}}$ is the *scalar, radial* component of $\delta\hat{\mathbf{\Theta}}$:

$$\hat{\phi}_{\mathrm{H}}(x) := \Pi_{\mathrm{H}}\, \delta\hat{\mathbf{\Theta}}(x) = \sum_\alpha \Pi_\alpha\, \Pi_{\mathrm{H}}\, \delta\hat{\mathbf{\Theta}}(x) \;=:\; \sum_\alpha \hat{\phi}^{(\alpha)}_{\mathrm{H}}(x), \qquad \alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}. \tag{9.196}$$

Thus the *single observed* Higgs boson corresponds to a *coherent superposition* across triadic channels, with relative weights fixed operationally by the typed, retarded propagators and the parasymmetric meters (cf. Section 9.17.11 and Definition 9.296).[8]

3. Parasymmetric T–L–O diagnostics of the composite Higgs. For each type $[\chi]$ and channel α, form the band-limited retarded kernel $\Delta^{(\alpha,[\chi])}_{\Theta\Theta}$ and meters $(v^{(L)}, v^{(S)}, v^{(LS)})_{(\alpha,[\chi])}$ (cf. eqs. (9.126) to (9.128)). The *Higgs-certified* outcome requires:

1. **Gapped radial pole.** In the Π_{H}-projected sector, a simple pole at $k^2 = M_{\mathrm{H}}^2 > 0$ with positive residue and no $k^2 = 0$ pole (contrast NG/pNG channels), agreeing with $\mathrm{spec}(\mathcal{K}_{\mathrm{H}})$ (cf. eqs. (9.185) and (9.194)).

2. **Typed quadrant call.** The Higgs channel stamps *gapped* (no massless pole) with a Location band (IR/meso) set by M_{H} and Onset given by the first certified threshold (cf. Definitions 9.297 and 9.299).

3. **Cross-channel coherence.** The helicity-resolved gain $v^{(LS)}_{(\alpha,[\chi])}$ quantifies mixing among channels, enabling a *parasymmetric* reconstruction of the coherent superposition $\hat{\phi}_{\mathrm{H}} = \sum_\alpha \hat{\phi}^{(\alpha)}_{\mathrm{H}}$.

4. Channel semantics for the Higgs species. With $\hat{\phi}^{(\alpha)}_{\mathrm{H}} = \Pi_\alpha \hat{\phi}_{\mathrm{H}}$, the triadic "species" acquire precise meanings:

- **Correlational Higgs** $\hat{\phi}^{(\mathrm{corr})}_{\mathrm{H}}$: Dominant response to relational (entanglement) structure; enhanced long-time meter $v^{(S)}$ with modest law-pole $v^{(L)}$ indicates complexity-driven mass attribution.

[8] "Composite" here means *triadic-channel composition* within the same field, not a preonic bound state.

- **Vacuum Higgs** $\hat{\phi}_{\mathrm{H}}^{(\mathrm{vac})}$: Sensitive to vacuum-manifold geometry and SSB topology; its Location bands track vacuum-sector windows (useful for defect/texture diagnostics).
- **Spectral Higgs** $\hat{\phi}_{\mathrm{H}}^{(\mathrm{spec})}$: Closest to the textbook Higgs of conventional QFT, with mass and residues governed by the spectral curvature of $\mathcal{V}_\Theta$ and standard couplings (e.g. Yukawa-like terms [82]).

In practice, experiments predominantly access the spec channel; the corr and vac channels are predictions of the triadic formalism and provide *additional* structure beyond the standard picture.

5. Composite mass and effective pole. Let $\Delta_{\mathrm{H}}(k)$ denote the Π_{H}-projected, triad-resolved propagator matrix $\left(\Delta_{\mathrm{H}}^{(\alpha\beta)}(k)\right)_{\alpha,\beta}$ with entries $\Delta_{\mathrm{H}}^{(\alpha\beta)} := \Pi_\alpha\,\Pi_{\mathrm{H}}\,\Delta_{\Theta\Theta}\,\Pi_{\mathrm{H}}\,\Pi_\beta$. The observable Higgs pole $k^2 = M_{\mathrm{H}}^2$ solves

$$\det\Big[k^2\mathbf{1} - \mathcal{M}_{\mathrm{H}}^{\mathrm{eff}}(k^2)\Big]_{(\alpha,\beta)} = 0, \qquad \mathcal{M}_{\mathrm{H}}^{\mathrm{eff}}(k^2) := \mathbb{K}_{\mathrm{H}}(k^2) + \Sigma_{\mathrm{H}}(k^2), \tag{9.197}$$

where $\mathbb{K}_{\mathrm{H}}$ is the radial kinetic block (typed and banded) and Σ_{H} the triadic self-energy, both restricted by Π_{H}. When cross-channel mixing (off-diagonal $\alpha \neq \beta$) is weak (small $v^{(LS)}$), one may approximate

$$M_{\mathrm{H}}^2 \;\simeq\; \sum_\alpha w_\alpha \left(M_{\mathrm{H}}^{(\alpha)}\right)^2, \qquad w_\alpha := \frac{\mathrm{Res}_{k^2=M_{\mathrm{H}}^2}\;\Delta_{\mathrm{H}}^{(\alpha\alpha)}(k)}{\sum_\gamma \mathrm{Res}_{k^2=M_{\mathrm{H}}^2}\;\Delta_{\mathrm{H}}^{(\gamma\gamma)}(k)}\,, \tag{9.198}$$

which makes precise the "composite mass" intuition in terms of channel residues (law-side) certified by meters (cf. eqs. (9.126) and (9.128)). The exact value is fixed by (9.197).

6. Symmetry and sectoral unification. The triadic composite picture mirrors the geometry sector:

- **Apeiron → gravitons (triadic).** In Gaiamiti, with channel-resolved species and T–L–O stamps (cf. Section 9.17).
- **Kymon → Higgs (triadic).** In Tantrakyma, identified via the radial projector and Hessian spectrum (cf. eqs. (9.175), (9.185) and (9.194)) and triadic meters.

In both sectors, the *spectral* species aligns with conventional particle notions, while the *correlational* and *vacuum* species are novel, IQR-specific predictions tied to quantum information structure and vacuum topology.

Narrative synthesis. The Higgs boson, as accessed in standard experiments, is the *spectral face* of a deeper composite object whose full identity is triadic. Parasymmetric T–L–O provides the operational calculus: typed kernels $\Delta_{\Theta\Theta}^{(\alpha,[\chi])}$, meters $(v^{(L)}, v^{(S)}, v^{(LS)})$, quadrant calls, and T–L–O stamps collectively certify the presence of a gapped, radial kymon and quantify its channel composition. This preserves the familiar phenomenology (e.g. Yukawa couplings [82]) while revealing additional correlational and vacuum contributions that enrich the mass-generating narrative within the IQR framework.

Regime & Scale	Gaiamiti Sector (Geometry)	Tantrakyma Sector (Matter)	Ontological Level	Parasymmetric T–L–O Signature (typed/triadic)
Ultra-sub-Planckian $\ll \ell_P$	Fibrewise Gaiamiti operator algebra in $\mathfrak{F}_x$; pre-metric correlations	Fibrewise Tantrakyma operator algebra in $\mathfrak{F}_x$; pre-matter correlations	Coherence-only domain; pre-geometric and pre-particle	*Tags:* $(\lambda_{\mathrm{UV}}, \ell)$ extreme. *Meters:* $v^{(L)}, v^{(S)} \approx 0$. *Quadrant:* QIV (no pole, no order) across channels $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$; BRST projection to H^0 assumed (Definitions 9.306 and 9.307).
Planckian $\sim \ell_P$	Onset of stable modal structure; incipient Apeiron fluctuations	Onset of stable modal structure; incipient Kymon fluctuations	Proto-geometry and proto-particles	*Meters:* $v^{(L)}$ begins to rise in select types $[\chi]$; $v^{(S)}$ still low. *Quadrant:* QII (law-only incipience) in some typed channels (Section 9.17.11 and Definition 9.297).
Relational / Mesoscopic $\gtrsim \ell_{\mathrm{PQS}}^{-1}$	Expectation tensor $\bar{\Sigma}_{\mu\nu}$ emerges; semi-classical geometry	SSB in V_Θ; Higgs mechanism; typed mass operators $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ from potential Hessian (eq. (9.175))	Emergent geometry and particle properties	*NG channels:* $v^{(L)} \neq 0$ with $k^2 = 0$ pole $\Rightarrow$ QI. *Higgs (radial):* gapped pole at $k^2 = M_H^2$ (no $k^2 = 0$), *Location* IR/meso, stamped via Definition 9.299. Cross-channel mixing quantified by $v^{(LS)}$ (eqs. (9.126) to (9.128) and (9.194)).
Macroscopic (IR) $\gg \ell_P$	Causal manifold $\mathcal{M}_{\mathrm{geom}}$; GR regime	Stable kymon quanta (incl. Higgs) and interactions; SM-like windows	Classical fields and stable particles	*Geometry:* long-time order robust; NG channels remain QI (massless). *Matter:* Higgs radial channel remains gapped; depending on tags, state-dominant windows can appear as QIII in some types; T–L–O stamps fix Onset thresholds (Definition 9.299).
Cosmological $\sim \mathcal{L}_U$	Global solutions of chronogeometric dynamics	Thermodynamics of kymon fields; cosmic backgrounds	Thermodynamic/statistical limit	Channel-wise vacuum energetics regulated via triadic balance with geometry (Section 9.18.8); meters certify plateau stability ($v^{(S)}$) and gauge-independence (H^0). Effective large-scale behavior often *state-dominant* (tending toward QIII) depending on windowing.

Table 9.3: Unified hierarchy of emergent geometric and matter regimes with typed/triadic Parasymmetric T–L–O certification. Meters and quadrants per eqs. (9.126) to (9.128), Definition 9.297, and Proposition 9.298; typed mass operators and Higgs identification per Definition 9.295 and eqs. (9.175), (9.185) and (9.194).

The Higgs Boson: Parallel Challenges and Triadic Resolutions

Just as the graviton's masslessness is clarified when viewed through the typed, triadic Gaiamiti instrumentation, the Higgs boson reveals its own constellation of conceptual challenges that invite a *parasymmetric T–L–O* reading. In the IQR framework, the Higgs is the *radial, scalar kymon* of the Tantrakyma sector (Section 9.18.5 and eq. (9.194)), and its identification is *diagnostic realized reference configuration-certified* by typed kernels, SynTh meters, quadrant calls, and T–L–O stamps (Section 9.17.11, Definitions 9.296, 9.297 and 9.299, and Proposition 9.298). This section reframes three classic paradoxes with explicit reference to the typed/triadic structure and the quadrant semantics.

Quadrant prelude (typed phase semantics). At fixed tags $(\lambda_{\mathrm{UV}}, \ell)$ on a certified plateau $\mathfrak{P}$ (Definitions 9.306 and 9.307), the SynTh meters $(v^{(L)}, v^{(S)}, v^{(LS)})$ (eqs. (9.126) to (9.128)) feed the typed predicate $\mathrm{Quad}^{[\Theta\Theta]}_{[\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$ (Definition 9.297). In brief:

$$\begin{aligned} \mathrm{QI}: &\ \text{NG/pNG present and ordered;} \\ \mathrm{QII}: &\ \text{incipient law (critical) without long-time order;} \\ \mathrm{QIII}: &\ \text{state-only order;} \\ \mathrm{QIV}: &\ \text{symmetric (no pole, no order).} \end{aligned}$$

The *Higgs (radial) channel* is gapped and stamps with a nonzero Location band (IR/meso) and finite Onset (eqs. (9.185) and (9.194) and Definition 9.299); NG channels stamp QI with a $k^2 = 0$ pole.

1. The Hierarchy Problem: a question of emergent scales

Problem. The Higgs mass appears unnaturally small relative to an ultraviolet scale (often taken as the Planck scale), inviting fine-tuning [91, 112].

Triadic T–L–O resolution (IQR). In IQR, the UV threshold is an emergent diagnostic realized reference configuration tag rather than a fundamental constant (cf. *sub/ultra-Planck* discussion), and the observed Higgs is a *composite* radial kymon across the triadic channels (Section 9.18.8). Operationally, the Π_{H}-projected, channel-resolved propagator $\Delta_{\mathrm{H}}^{(\alpha\beta)}(k)$ determines the physical pole $k^2 = M_{\mathrm{H}}^2$ via the triadic pole condition (eq. (9.197)). When off-diagonal mixing is small, the effective mass admits the residue-weighted approximation (eq. (9.198)):

$$M_{\mathrm{H}}^2 \simeq \sum_{\alpha \in \{\mathrm{corr,vac,spec}\}} w_\alpha \left(M_{\mathrm{H}}^{(\alpha)}\right)^2, \quad w_\alpha \propto \mathrm{Res}\ \Delta_{\mathrm{H}}^{(\alpha\alpha)}.$$

Thus the "hierarchy" becomes a *channel composition* question governed by meters: (i) $v^{(L)}$ nails the law-side pole content per channel; (ii) $v^{(S)}$ constrains long-time order (stability of the low mass); (iii) $v^{(LS)}$ quantifies cross-channel seesaw/cancellations. Quadrant diagnostics localize the phenomenon: near-critical behavior registers QII in specific channels, explaining light composite masses without fine-tuning of a single bare parameter.

2. The Nature of the Higgs Potential: a question of triadic origin

Problem. The Standard Model posits a quartic "wine-bottle" potential $\mathcal{V}(\phi)$ by fiat [82].

Triadic T–L–O resolution (IQR). IQR derives the Tantrakyma potential from cotangent invariants ($\mathsf{X} = g_C^{-1}(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$); Definition 9.335, Remark 9.303, and eq. (9.133)) and admits a *triadic decomposition*

$$\mathcal{V}_\Theta \;=\; \mathcal{V}_\Theta^{(\mathrm{corr})} \;+\; \mathcal{V}_\Theta^{(\mathrm{vac})} \;+\; \mathcal{V}_\Theta^{(\mathrm{spec})},$$

consistent with the commuting channel projectors (Definition 9.295 and eq. (9.195)). The sign of the quadratic coefficient (driving SSB) is an *emergent balance* among channel contributions. Meters and quadrant calls track how a negative correlational contribution (information-driven) can outweigh positive spectral/vacuum pieces, pushing the system from QIV (symmetric) through QII (incipient) to QI (NG present), while the radial channel registers a gapped stamp with mass fixed by $\partial^2 V_\Theta$ at the minimum (eq. (9.194)). Thus the potential's profile is *explained* by channel competition rather than postulated.

3. The Cosmological Constant Problem: a question of a triadic vacuum

Problem. Naïve vacuum energy estimates from the Higgs sector vastly exceed the observed cosmological constant [211, 212].

Triadic T–L–O resolution (IQR). The total diagnostic realized reference configuration stress–energy is $\bar{T}^{\mu\nu}_{\mathrm{total}} = \bar{T}^{\mu\nu}_{(\Sigma)} + \bar{T}^{\mu\nu}_{(\Theta)}$ (Definition 9.358 and Sections 9.17.9 and 9.17.11). In the triadic split, *each channel* contributes and must *self-regulate*:

$$\langle \mathcal{V}_\Theta^{(\mathrm{corr})} \rangle + \langle \mathcal{V}_\Sigma^{(\mathrm{corr})} \rangle \approx 0, \quad \langle \mathcal{V}_\Theta^{(\mathrm{vac})} \rangle + \langle \mathcal{V}_\Sigma^{(\mathrm{vac})} \rangle \approx 0, \quad \langle \mathcal{V}_\Theta^{(\mathrm{spec})} \rangle + \langle \mathcal{V}_\Sigma^{(\mathrm{spec})} \rangle \approx 0,$$

up to a small residual that reads as the observed cosmological constant. Parasymmetric meters provide the consistency checks: state-side plateaus $v^{(S)}$ certify long-time vacuum stability per channel; law-side content $v^{(L)}$ ensures the cancellations are not gauge-artifacts (BRST/Nielsen clean). This structured, channel-wise mechanism replaces a brute-force two-number cancellation.

Synthesis: from paradox to a composite principle

The triadic, typed, parasymmetric T–L–O formalism turns the Higgs challenges into *operational questions* about channel composition, quadrant placement, and diagnostic realized reference configuration-certified meters. The Higgs boson emerges as a *composite radial kymon* whose mass, potential, and vacuum contributions are distributed across correlational, vacuum, and spectral channels (Section 9.18.8). The same logic applies mutatis mutandis in the geometry sector for the graviton, yielding a sector-by-sector symmetry (Sections 9.17 and 9.17.10). Rather than invoking new ultra-heavy particles, IQR attributes the observed phenomena to the *diagnostic realized reference configuration-instrumented* structure of reality—triadic channels, typed projections, SynTh meters, and quadrant semantics—which together determine Type, Location, and Onset of the excitations we call particles. In this sense, what appear as paradoxes at the Lagrangian level become *composite principles* when read through Parasymmetric T–L–O.

9.18.9 Euler–Lagrange Equation for the Tantrakyma Field

The dynamics of the Tantrakyma field are determined by applying the *Principle of Stationary Action* to its action functional $S_\Theta[\hat{\mathbf{\Theta}}]$ (cf. Definition 9.310). By extremizing this action with respect to the field $\hat{\mathbf{\Theta}}(x)$, we obtain the operator-valued Euler–Lagrange (EL) equation that governs matter-like excitations on the emergent quantum manifold.

Definition 9.353 (Euler–Lagrange equation for $\hat{\mathbf{\Theta}}(x)$)**.** Let $\hat{\mathbf{\Theta}}(x)$ be the Tantrakyma field operator on the relational manifold $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$, with dynamics governed by $S_\Theta[\hat{\mathbf{\Theta}}]$. Then the corresponding operator-valued Euler–Lagrange equation can be written in divergence form as

$$\boxed{\frac{1}{\sqrt{-\det \bar{\Sigma}}}\,\nabla_\mu\Big(\sqrt{-\det \bar{\Sigma}}\;\bar{\Sigma}^{\mu\nu}\, g_C^\sharp\Big(\nabla_\nu \hat{\mathbf{\Theta}},\,\cdot\,\Big)\Big) \;=\; \frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}^\dagger}(x),} \tag{9.199}$$

where:

(i) Total covariant derivative
$\nabla_\mu \hat{\mathbf{\Theta}}(x)$ is the total covariant derivative (relational Levi–Civita + operator-bundle/gauge connection; cf. Definition 9.323).

(ii) Inverse chronogeometric tensor
$\bar{\Sigma}^{\mu\nu}(x)$ is the inverse chronogeometric tensor (cf. Definition 6.24).

(iii) Co-metric Riesz map
$g_C^\sharp$ is the Riesz map associated with the operator-valued co-metric g_C, sending the second slot to an $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$-valued element (cf. Remark 9.303).

(iv) Potential gradient
$\delta \mathcal{V}_\Theta / \delta \hat{\mathbf{\Theta}}^\dagger$ is the functional derivative of the Tantrakyma potential built from the invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ (cf. Definition 9.335).

Using $\nabla_\mu^{(\mathrm{rel})} \bar{\Sigma}_{\alpha\beta} = 0$ and $D_\mu g_C = 0$ (cf. Definition 6.7 and Proposition 9.324), (9.199) is equivalently

$$\bar{\Sigma}^{\mu\nu}\,\nabla_\mu\Big(g_C^\sharp\Big(\nabla_\nu \hat{\mathbf{\Theta}},\,\cdot\,\Big)\Big) \;=\; \frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}^\dagger}(x), \tag{9.200}$$

and, since $g_C^\sharp$ is covariantly constant, this further reduces to $\bar{\Sigma}^{\mu\nu}\, g_C^\sharp\Big(\nabla_\mu \nabla_\nu \hat{\mathbf{\Theta}},\,\cdot\,\Big) = \delta \mathcal{V}_\Theta / \delta \hat{\mathbf{\Theta}}^\dagger$. The companion adjoint equation follows from varying $\hat{\mathbf{\Theta}}$ instead of $\hat{\mathbf{\Theta}}^\dagger$.

Diagnostic realized reference configuration-ready (band-limited, BRST-clean) EL. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ and physical projector $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definitions 9.306 and 9.307), the working EL equation is

$$\mathsf{P}_{\mathrm{phys}}\left[\frac{1}{\sqrt{-\det \bar{\Sigma}}}\,\nabla_\mu\Big(\sqrt{-\det \bar{\Sigma}}\;\bar{\Sigma}^{\mu\nu}\, g_C^\sharp\Big(\nabla_\nu^{(\lambda_{\mathrm{UV}},\ell)} \hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)},\,\cdot\,\Big)\Big) - \frac{\delta \mathcal{V}_\Theta}{\delta \hat{\mathbf{\Theta}}^\dagger}\right] = 0, \tag{9.201}$$

which is BRST-closed and gauge-parameter independent (Nielsen-flat).

Typed, parasymmetric EL (projection to types and channels). Let $\Pi^{[\chi]}_{\Theta\Theta}$ be the typed projectors ($[\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}$; cf. Definition 9.295) commuting with the triadic channel projectors Π_α, $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$. The typed EL equations are

$$\Pi^{[\chi]}_{\Theta\Theta}\left[\frac{1}{\sqrt{-\det\bar{\Sigma}}}\,\nabla_\mu\Big(\sqrt{-\det\bar{\Sigma}}\;\bar{\Sigma}^{\mu\nu}\,g^\sharp_C\big(\nabla_\nu\hat{\boldsymbol{\Theta}},\,\cdot\,\big)\Big) - \frac{\delta\mathcal{V}_\Theta}{\delta\hat{\boldsymbol{\Theta}}^\dagger}\right] = 0, \qquad [\Pi^{[\chi]}_{\Theta\Theta}, \Pi_\alpha] = 0. \quad (9.202)$$

This prepares the EL system for *typed* Parasymmetric T–L–O analysis.

Linearized, typed EL and the Hessian link. With the background–fluctuation split $\hat{\boldsymbol{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\boldsymbol{\Theta}}$ (cf. Definition 10.204), the linearized, typed EL takes the standard form

$$\boxed{\big(\mathbb{K}^{[\chi]}_\Theta + \mathcal{K}^{[\chi]}_{\Theta\Theta}\big)\,\delta\hat{\boldsymbol{\Theta}}^{[\chi]} = \hat{\mathcal{J}}^{[\chi]}, \qquad \delta\hat{\boldsymbol{\Theta}}^{[\chi]} := \Pi^{[\chi]}_{\Theta\Theta}\,\delta\hat{\boldsymbol{\Theta}},} \quad (9.203)$$

where $\mathbb{K}^{[\chi]}_\Theta$ is the typed kinetic block (from $\mathcal{T}_\Theta$; cf. eq. (9.130)), and $\mathcal{K}^{[\chi]}_{\Theta\Theta}$ is the typed potential Hessian (mass/curvature operator) defined by restriction (cf. eq. (9.175)). The typed retarded kernels $\Delta^{[\chi]}_{\Theta\Theta}$ are inverses of the EL operators in (9.203).

Parasymmetric T–L–O interpretation (meters → quadrants → stamps). From $\Delta^{[\chi]}_{\Theta\Theta}$ build the SynTh meters (cf. eqs. (9.126) to (9.128)):

$$\begin{aligned} v^{(L)}_{[\chi]} &= \big|\mathrm{Res}_{k^2=0}\,\Delta^{[\chi]}_{\Theta\Theta}\big|, \\ v^{(S)}_{[\chi]} &= \big|\Delta^{[\chi]}_{\Theta\Theta}(t\to\infty;\mathbf{x}=0)\big|_{H^0}, \\ v^{(LS)}_{[\chi]} &= \text{helicity-resolved cross-channel gain}, \end{aligned}$$

assemble the typed witness $\mathbf{W}^{[\Theta\Theta]}_{[\chi]}$ (cf. Definition 9.296), and apply the typed quadrant predicate $\mathrm{Quad}^{[\Theta\Theta]}_{[\chi]} \in \{\mathrm{QI}, \mathrm{QII}, \mathrm{QIII}, \mathrm{QIV}\}$ (cf. Definition 9.297 and Proposition 9.298). Consistency requires that NG/pNG versus gapped expectations from $\mathrm{spec}(\mathcal{K}^{[\chi]}_{\Theta\Theta})$ match the quadrant call within tolerances (Ch. 8). The certified outcome is recorded as a *typed T–L–O stamp* (cf. Definition 9.299) with *Location* (IR/meso/UV windows) and *Onset* thresholds.

Noether current and BRST/Nielsen safety. On-shell EL implies covariant conservation of the matter-sector Noether current $\hat{J}^\mu_\Theta$ built from $\mathcal{L}_\Theta$ (cf. Section 9.17.11), providing additional Location diagnostics consistent with the typed meters. All statements are made on H^0 and are therefore gauge-parameter independent (Nielsen-flat), as guaranteed by the diagnostic realized reference configuration discipline (cf. Definitions 9.306 and 9.307).

Interpretation Equation (9.199) is the foundational law for how *relational material content*, encoded by the Tantrakyma field $\hat{\boldsymbol{\Theta}}(x)$, evolves within the emergent spacetime. It generalizes a relativistic wave equation to the full *chronogeometric* arena: the propagation operator is built from the unified tensor $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Definitions 5.26 and 6.24), rather than the

metric alone. Consequently, kymon dynamics are simultaneously sensitive to the curvature of distinguishability ($\bar{g}_{\mu\nu}$) and to the curvature of quantum phase flow ($\bar{t}_{\mu\nu}$). In the expanded form of the EL operator one encounters a term $\big(\nabla_\mu \bar{\Sigma}^{\mu\nu}\big)\nabla_\nu \hat{\mathbf{\Theta}}$; however, with the $\bar{\Sigma}$-compatible (relational Levi–Civita) connection used here this term *vanishes identically*, so propagation is governed by $\bar{\Sigma}^{\mu\nu}\, g_C^\sharp\big(\nabla_\mu\nabla_\nu \hat{\mathbf{\Theta}}, \cdot\,\big)$. All derivatives are taken with the composite covariant derivative ∇_μ that combines the relational Levi–Civita and operator-bundle connections (Definition 9.323).

The right-hand side $\delta\mathcal{V}_\Theta/\delta\hat{\mathbf{\Theta}}^\dagger$ supplies the *identity* of the excitations via the Tantrakyma potential (Definition 9.335), which—because $\hat{\mathbf{\Theta}}$ is *covector*-valued—must be built from the co-metric invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$, not from g_C^{-1}. Around a realized vacuum $\bar{\Theta}$ (eq. (9.134)), the background–fluctuation split $\hat{\mathbf{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\mathbf{\Theta}}$ leads to the *typed* linear response (eq. (9.203)): the kinetic block $\mathbb{K}_\Theta^{[\chi]}$ pairs with the typed Hessian $\mathcal{K}_{\Theta\Theta}^{[\chi]}$ extracted from the potential by projector restriction (eq. (9.175)). The spectrum (NG/pNG vs. gapped) is therefore read directly from $\operatorname{spec}\mathcal{K}_{\Theta\Theta}^{[\chi]}$, providing, in particular, the mass of the radial (Higgs) kymon in the SSB phase (eq. (9.194) and Section 9.18.5).

Parasymmetric T–L–O reading. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$, we project the EL system to types $[\chi]$ and channels $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ using BRST-closed, triad-compatible projectors (Definition 9.295). The corresponding typed retarded kernels $\Delta_{\Theta\Theta}^{[\chi]}$ drive the SynTh meters $(v^{(L)}, v^{(S)}, v^{(LS)})$ (eqs. (9.126) to (9.128)), assembled into the typed witness $\mathbf{W}_{[\chi]}^{[\Theta\Theta]}$ (Definition 9.296). The *quadrant predicate* $\mathrm{Quad}_{[\chi]}^{[\Theta\Theta]}$ (Definition 9.297 and Proposition 9.298) then certifies phase semantics: NG channels stamp QI with a $k^2 = 0$ pole; the Higgs (radial) channel stamps as *gapped* (no massless pole) with a *Location* band (IR/meso) and an *Onset* threshold recorded by the T–L–O entry (Definition 9.299). Thus, the EL equation is not only the formal equation of motion; it is the *generator* of operational diagnostics—linking chronogeometric propagation (left-hand side) and identity-defining self-interactions (right-hand side) to measurable meters, quadrant calls, and stamps on $H^0(\hat{Q}_{\mathrm{BRST}})$.

9.18.10 Noether Current for the Dynamical Tantrakyma Field

The action $S_\Theta[\hat{\mathbf{\Theta}}]$ (cf. Definition 9.310) admits internal fiber symmetries acting on the excitation sector via local unitary automorphisms of $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$ (cf. Definition 9.323 and the symmetry remarks in Definition 9.301). When S_Θ is invariant under a continuous family of such transformations, Noether's theorem furnishes a (conserved) current that diagnoses the local flow of excitation charge across $\mathcal{X}_q$. Throughout, recall that the Tantrakyma *potential* is built with the co-metric g_C (not g_C^{-1}).

We consider infinitesimal, local unitary variations

$$\delta\hat{\mathbf{\Theta}}(x) = i\,\epsilon^a(x)\,[T_a,\, \hat{\mathbf{\Theta}}(x)], \qquad [T_a, T_b] = i f_{ab}{}^c T_c, \tag{9.204}$$

with Hermitian generators T_a and small real functions $\epsilon^a(x)$. The total covariant derivative is $\nabla_\mu = \nabla_\mu^{(\mathrm{rel})} + D_\mu$ (cf. Definition 9.323).

Definition 9.354 (Noether current for the Tantrakyma field)**.** If the band-limited, BRST-clean Lagrangian density $\mathcal{L}_\Theta$ is invariant under (9.204) up to a total divergence, the associated

operator-level current kernel is

$$\boxed{\widehat{\mathcal{J}}^{\mu}_{\Theta;a}(x) := -\,i\,\hat{\Pi}^{\mu}_{\Theta}(x)\Big([T_a,\,\hat{\mathbf{\Theta}}(x)]\Big)\;\in\;\mathrm{End}(\mathcal{H}_{\mathrm{em}}),} \tag{9.205}$$

where $\hat{\Pi}^{\mu}_{\Theta}$ is the canonical momentum (operator) map defined by

$$\boxed{\hat{\Pi}^{\mu}_{\Theta}(x)\Big[\,\delta\hat{\mathbf{\Theta}}\,\Big]\;:=\;\bar{\Sigma}^{\mu\nu}(x)\;g_C\Big(\delta\hat{\mathbf{\Theta}}(x),\,\nabla_\nu\hat{\mathbf{\Theta}}(x)\Big).} \tag{9.206}$$

Equivalently, in a symmetrized (manifestly Hermitian) form one may write

$$\widehat{\mathcal{J}}^{\mu}_{\Theta;a} = \frac{i}{2}\,\bar{\Sigma}^{\mu\nu}\Big[g_C\Big([T_a,\hat{\mathbf{\Theta}}],\,\nabla_\nu\hat{\mathbf{\Theta}}\Big) - g_C\Big(\nabla_\nu\hat{\mathbf{\Theta}},\,[T_a,\hat{\mathbf{\Theta}}]\Big)\Big]\,.$$

The corresponding *scalar* Noether current density is obtained by tracing over the fiber algebra:

$$J^{\mu}_{\Theta;a}(x)\;:=\;\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{J}}^{\mu}_{\Theta;a}(x)\Big\}\,.$$

On-shell conservation (total covariant form). For compactly supported ϵ^a, variation of the action—after integration by parts and using the EL equations (9.199)—yields the covariant conservation law

$$\boxed{\nabla_\mu\,\widehat{\mathcal{J}}^{\mu}_{\Theta;a}(x)\;=\;0\quad\text{on-shell},} \tag{9.207}$$

where $\nabla_\mu = \nabla^{(\mathrm{rel})}_\mu + i[\mathcal{A}_\mu,\,\cdot\,]$ acts on the spacetime index and on the fiber operator (cf. Definition 9.323). Taking the fiber trace gives $\nabla_\mu J^{\mu}_{\Theta;a} = 0$. For a pure internal symmetry with anomaly-free gauging this is equivalent to the gauge-covariant statement $D_\mu J^{\mu}_{\Theta;a} = 0$.

Diagnostic realized reference configuration (band-limited, BRST-clean) form and expectation current. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}},\ell)$ and physical projector $\mathsf{P}_{\mathrm{phys}} : \mathcal{H}\to H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definitions 9.306 and 9.307), we use $\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}$ and $\nabla^{(\lambda_{\mathrm{UV}},\ell)}_\mu$. Define the band-limited canonical momentum (operator) map by

$$\hat{\Pi}^{\mu\,(\lambda_{\mathrm{UV}},\ell)}_{\Theta}\Big[\,\delta\hat{\mathbf{\Theta}}\,\Big] := \bar{\Sigma}^{\mu\nu}(x)\;g_C\Big(\delta\hat{\mathbf{\Theta}}(x),\,\nabla^{(\lambda_{\mathrm{UV}},\ell)}_\nu\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}(x)\Big),$$

and the operator-level current kernel by

$$\widehat{\mathcal{J}}^{\mu\;(\lambda_{\mathrm{UV}},\ell)}_{\Theta;a}(x) := -\,i\,\hat{\Pi}^{\mu\,(\lambda_{\mathrm{UV}},\ell)}_{\Theta}\Big([T_a,\,\hat{\mathbf{\Theta}}^{(\lambda_{\mathrm{UV}},\ell)}(x)\Big). \tag{9.208}$$

The scalar current is the fiber trace

$$J^{\mu\;(\lambda_{\mathrm{UV}},\ell)}_{\Theta;a}(x) := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{J}}^{\mu\;(\lambda_{\mathrm{UV}},\ell)}_{\Theta;a}(x)\Big\}\,,$$

and the realized (c-number) current on H^0 is

$$\bar{J}^{\mu}_{\Theta;a}(x) := \Big\langle\,\mathring{\mathbf{\Psi}}\;\Big|\;\mathsf{P}_{\mathrm{phys}}\,\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\widehat{\mathcal{J}}^{\mu\;(\lambda_{\mathrm{UV}},\ell)}_{\Theta;a}(x)\}\;\Big|\;\mathring{\mathbf{\Psi}}\,\Big\rangle,\qquad \nabla_\mu\bar{J}^{\mu}_{\Theta;a} = 0\;\;\text{on-shell}.$$

Typed & triadic resolution (parasymmetric). Let $\Pi_{\Theta\Theta}^{[\chi]}$ be the typed projectors ($[\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}$; cf. Definition 9.295) and Π_α the channel projectors $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, with $[\Pi_\alpha, \Pi_{\Theta\Theta}^{[\chi]}] = 0$. The typed/channel-resolved current kernels are

$$\widehat{\mathcal{J}}^{\mu\ (\alpha,[\chi])}_{\Theta;a} := \Pi_\alpha\, \Pi_{\Theta\Theta}^{[\chi]}\, \widehat{\mathcal{J}}^{\mu}_{\Theta;a}\, \Pi_{\Theta\Theta}^{[\chi]}\, \Pi_\alpha, \qquad J^{\mu\ (\alpha,[\chi])}_{\Theta;a} := \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{J}}^{\mu\ (\alpha,[\chi])}_{\Theta;a}\Big\}. \tag{9.209}$$

Their retarded two-point functions provide *Location* diagnostics: peaks in the spectral density of $\langle \widehat{\mathcal{J}}\, \widehat{\mathcal{J}} \rangle$ co-locate with the $\Delta_{\Theta\Theta}$ poles that certify NG channels (QI) or the gapped Higgs (radial) channel, reinforcing T–L–O stamps (cf. Definition 9.299 and eqs. (9.126) to (9.128)).

Consistency with EL and symmetry of $\mathcal{V}_\Theta$. Using the EL equation (9.199) and the fact that the potential depends only on the co-metric invariant $\mathsf{X} = g_C(\hat{\mathbf{\Theta}}, \hat{\mathbf{\Theta}})$ (hence is invariant under fiber inner $*$-automorphisms; cf. Definition 9.335 and Remark 9.313), one obtains $\nabla_\mu \widehat{\mathcal{J}}^{\mu}_{\Theta;a} = 0$ on-shell. Spontaneous symmetry breaking (SSB) is signaled by a nonzero $\bar{\Theta}$ and manifests as *massless* NG channels (QI stamp) together with a *gapped* radial (Higgs) channel, as certified by the typed meters and quadrant predicate (cf. Section 9.18.5, eq. (9.194), and Definition 9.297).

Boundary pass. On $\mathfrak{P}_\partial$, conservation reads as vanishing flux through the boundary (up to specified sources), providing an *edge* Location diagnostic that must agree with bulk T–L–O stamping within tolerance budgets (cf. Proposition 9.300).

Expectation-Level Current As in the geometric (Gaiamiti) sector, the *observable* conserved quantity is the expectation value of the current in the Quantum Holo-State (cf. Definition 1.27). On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ and projection to the physical cohomology $H^0(\hat{Q}_{\mathrm{BRST}})$, the BRST-clean, band-limited current is

$$\boxed{\bar{J}^{\mu}_{\Theta;a}(x) := \Big\langle \mathring{\mathbf{\Psi}} \Big|\, \mathsf{P}_{\mathrm{phys}}\, \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\widehat{\mathcal{J}}^{\mu\ (\lambda_{\mathrm{UV}},\ell)}_{\Theta;a}(x)\Big\}\, \Big|\, \mathring{\mathbf{\Psi}}\Big\rangle, \qquad \nabla_\mu \bar{J}^{\mu}_{\Theta;a} = 0 \ \text{ on-shell},} \tag{9.210}$$

where $\widehat{\mathcal{J}}^{\mu}_{\Theta;a}$ is the operator-level current kernel of Definition 9.354 (cf. (9.208)), $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is the band functor (cf. Definition 9.306), and $\mathsf{P}_{\mathrm{phys}}$ projects onto $H^0(\hat{Q}_{\mathrm{BRST}})$. This guarantees gauge-parameter independence (Nielsen flatness) of $\bar{J}^{\mu}_{\Theta;a}$.

Typed & triadic expectation (parasymmetric). With typed projectors $\Pi_{\Theta\Theta}^{[\chi]}$ and channel projectors Π_α that commute (cf. Definition 9.295), the resolved expectation currents are

$$\bar{J}^{\mu\ (\alpha,[\chi])}_{\Theta;a}(x) := \Big\langle \mathring{\mathbf{\Psi}} \Big|\, \mathsf{P}_{\mathrm{phys}}\, \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\Pi_\alpha\, \Pi_{\Theta\Theta}^{[\chi]}\, \widehat{\mathcal{J}}^{\mu\ (\lambda_{\mathrm{UV}},\ell)}_{\Theta;a}(x)\, \Pi_{\Theta\Theta}^{[\chi]}\, \Pi_\alpha\Big\}\, \Big|\, \mathring{\mathbf{\Psi}}\Big\rangle, \qquad [\Pi_\alpha, \Pi_{\Theta\Theta}^{[\chi]}] = 0, \tag{9.211}$$

which provide *Location* diagnostics consistent with the typed SynTh meters $(v^{(L)}, v^{(S)}, v^{(LS)})$ and the T–L–O stamps (cf. eqs. (9.126) to (9.128) and Definition 9.299). In NG channels (QI) one finds characteristic low-frequency spectral weight aligned with the $k^2 = 0$ pole of $\Delta_{\Theta\Theta}$; in the Higgs (radial) channel the spectral peak co-locates with the gapped pole $k^2 = M_{\mathrm{H}}^2$ (cf. eq. (9.194)), corroborating the quadrant call (cf. Definition 9.297 and Proposition 9.298).

Proposition 9.355 (Conservation of the Tantrakyma Noether Current)**.** *If the Tantrakyma field $\hat{\mathbf{\Theta}}(x)$ satisfies its Euler–Lagrange equation (9.199) and the action is invariant under the internal fiber automorphism generated by a Hermitian T_a (global parameter), then the expectation-level Noether current component $\bar{J}^{\mu}_{\Theta;a}(x)$ (cf. eq. (9.210)) is covariantly conserved with respect to the relational connection:*

$$\boxed{\nabla^{(\mathrm{rel})}_{\mu}\, \bar{J}^{\mu}_{\Theta;a}(x) = 0 \quad \textit{(on-shell).}} \tag{9.212}$$

If the symmetry is gauged, the statement upgrades to gauge-covariant *conservation, $D_{\mu}\, \bar{J}^{\mu}_{\Theta;a} = 0$ (cf. Definition 9.323).*

Proof of Proposition Proposition 9.355. We use a localized-parameter Noether variation and then impose the Euler–Lagrange (EL) equation (9.199).

(i) Localized internal variation. Let

$$\delta\hat{\mathbf{\Theta}}(x) = i\,\epsilon(x)\,[T_a,\, \hat{\mathbf{\Theta}}(x)], \tag{9.213}$$

with smooth $\epsilon(x)$. With the total covariant derivative $\nabla_{\mu} = \nabla^{(\mathrm{rel})}_{\mu} + D_{\mu}$ (cf. Definition 9.323),

$$\delta\Big(\nabla_{\mu}\hat{\mathbf{\Theta}}\Big) = \nabla_{\mu}\Big(\delta\hat{\mathbf{\Theta}}\Big) = i\,(\partial_{\mu}\epsilon)\,[T_a, \hat{\mathbf{\Theta}}] + i\,\epsilon\,[T_a,\, \nabla_{\mu}\hat{\mathbf{\Theta}}]. \tag{9.214}$$

(ii) Variation of the Lagrangian density. For the (scalar) Lagrangian density $\mathcal{L}_{\Theta}$ (cf. Definition 9.301),

$$\delta\mathcal{L}_{\Theta} = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\left\{ \frac{\delta\mathcal{L}_{\Theta}}{\delta\hat{\mathbf{\Theta}}}\,\delta\hat{\mathbf{\Theta}} + \frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}\,\delta(\nabla_{\mu}\hat{\mathbf{\Theta}}) \right\}. \tag{9.215}$$

Insert (9.213)–(9.214) and separate the ϵ- and $\partial_{\mu}\epsilon$-terms:

$$\delta\mathcal{L}_{\Theta} = i\,\epsilon\,\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\left\{ \frac{\delta\mathcal{L}_{\Theta}}{\delta\hat{\mathbf{\Theta}}}[T_a, \hat{\mathbf{\Theta}}] + \frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}[T_a, \nabla_{\mu}\hat{\mathbf{\Theta}}] \right\} + i\,(\partial_{\mu}\epsilon)\,\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\left\{ \frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}[T_a, \hat{\mathbf{\Theta}}] \right\}. \tag{9.216}$$

(iii) On-shell reduction and total divergence. Using the EL identity (on-shell) $\frac{\delta\mathcal{L}_{\Theta}}{\delta\hat{\mathbf{\Theta}}} = \nabla_{\mu}\Big(\frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}\Big)$ and cyclicity of the trace, we obtain

$$i\,\epsilon\,\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\left\{ \frac{\delta\mathcal{L}_{\Theta}}{\delta\hat{\mathbf{\Theta}}}[T_a, \hat{\mathbf{\Theta}}] + \frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}[T_a, \nabla_{\mu}\hat{\mathbf{\Theta}}] \right\} = i\,\epsilon\,\nabla^{(\mathrm{rel})}_{\mu}\,\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\left\{ \frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}[T_a, \hat{\mathbf{\Theta}}] \right\}. \tag{9.217}$$

Define the *scalar* Noether current (trace of the operator-level kernel, cf. Definition 9.354)

$$J^{\mu}_{\Theta;a} := -\,i\,\mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\left\{ \frac{\delta\mathcal{L}_{\Theta}}{\delta(\nabla_{\mu}\hat{\mathbf{\Theta}})}\,[T_a, \hat{\mathbf{\Theta}}] \right\}. \tag{9.218}$$

Then, by the Leibniz rule for $\nabla^{(\mathrm{rel})}$,

$$\delta\mathcal{L}_{\Theta} = -\,\nabla^{(\mathrm{rel})}_{\mu}\Big(\epsilon\, J^{\mu}_{\Theta;a}\Big). \tag{9.219}$$

(iv) Localized-parameter argument & conservation. Integrating over $\mathcal{X}_q$ with $d\mu = d^d x \sqrt{-\det \bar{\Sigma}}$ and integrating by parts (discarding boundary terms under the diagnostic realized reference configuration IR window) yields

$$\delta S_\Theta = -\int_{\mathcal{X}_q} d\mu(x)\, \epsilon(x)\, \nabla^{(\mathrm{rel})}_\mu J^\mu_{\Theta;a}(x). \tag{9.220}$$

If the transformation is a symmetry for constant ϵ, the localized-parameter argument implies the on-shell conservation law $\nabla^{(\mathrm{rel})}_\mu J^\mu_{\Theta;a} = 0$. For a gauged symmetry, $\nabla^{(\mathrm{rel})}_\mu$ is promoted to D_μ, giving $D_\mu J^\mu_{\Theta;a} = 0$.

(v) Expectation-level statement. Taking the expectation value in the Quantum Holo-State and using linearity of $\nabla^{(\mathrm{rel})}$, together with the BRST-clean projection $\mathsf{P}_{\mathrm{phys}}$, gives $\nabla^{(\mathrm{rel})}_\mu \bar{J}^\mu_{\Theta;a} = 0$, and, in the gauged case, $D_\mu \bar{J}^\mu_{\Theta;a} = 0$. □

Physical Interpretation The Tantrakyma Noether current components $\widehat{\mathcal{J}}^\mu_{\Theta;a}(x)$ (operator level) and their scalar trace $J^\mu_{\Theta;a}(x)$ (cf. Definition 9.354) account for the flow of *excitation content*—the matter-like internal quantum numbers carried by kymons—across the emergent spacetime. For each continuous internal symmetry generated by a Hermitian T_a, on-shell invariance of the action implies the covariant conservation law for the expectation-level, BRST-clean current $\bar{J}^\mu_{\Theta;a}(x)$ (eq. (9.210)): $\nabla^{(\mathrm{rel})}_\mu \bar{J}^\mu_{\Theta;a} = 0$ (Proposition 9.355). Unlike the conserved diagnostics in the Gaiamiti (geometric) sector—which characterize the chronogeometric background itself—$\bar{J}^\mu_{\Theta;a}$ tracks the transport of *matter-sector* charges, flavors, and symmetry fluxes borne by kymons.

The conservation law is *relational*: it is defined with the Levi–Civita connection of the unified chronogeometric tensor $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Definitions 5.26 and 6.24), i.e. in the same chronogeometric arena that governs propagation in the Euler–Lagrange equation (eq. (9.199)). Operationally, the expectation current provides a state-side diagnostic that complements the law-side EL operator: its spectral weight co-locates with the poles of the typed retarded kernels $\Delta^{[\chi]}_{\Theta\Theta}$, revealing NG channels (massless; quadrant QI) and the *gapped* radial (Higgs) channel, whose *Location* band (IR/meso) is set by the gap and certified within the Parasymmetric T–L–O workflow (eqs. (9.126) to (9.128) and Definitions 9.297 and 9.299).

At higher resolution, typed and triadic projections $\bar{J}^{\mu\ (\alpha,[\chi])}_{\Theta;a}$ (eq. (9.211)) separate the current into channels $\alpha \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ and type slices $[\chi] \in \{\mathrm{CK}, \mathrm{T}_\pm, \mathrm{L}\}$ (Definition 9.295). Their measured plateaus and healing behavior align with the SynTh meters and the quadrant predicate, supplying *Location* (IR/meso/UV window) and *Onset* thresholds recorded in the typed T–L–O stamps. In short, $\bar{J}^\mu_{\Theta;a}$ is not only a formal consequence of symmetry; it is a diagnostic realized reference configuration-certified probe of how conserved excitation content is conveyed—coherently and locally—through the chronogeometric medium across the emergent manifold $\mathcal{X}_q$.

9.18.11 The Noether Stress–Energy Tensor of the Tantrakyma Field

Continuous spacetime symmetries of the Tantrakyma action $S_\Theta[\hat{\boldsymbol{\Theta}}]$ (cf. Definition 9.310) imply, via Noether's theorem, a conserved stress–energy object that encodes energy–momentum

flow carried by kymon excitations. In the IQR formalism we distinguish the *operator-valued* (pre-trace) density from its scalar (trace) used in the action, and keep the construction *diagnostic realized reference configuration-ready* (band-limited, BRST-clean). Throughout, the potential is built from the *co-metric* g_C (never g_C^{-1}).

Definition 9.356 (Hilbert/Noether stress–energy (operator-valued, pre-trace))**.** Let the operator-valued Lagrangian density be

$$\mathscr{L}^{\mathrm{op}}_{\Theta}(x) := \bar{\Sigma}^{\alpha\beta}(x)\, g_C\Big(\nabla_\alpha \hat{\boldsymbol{\Theta}}(x),\, \nabla_\beta \hat{\boldsymbol{\Theta}}(x)\Big) \;+\; \mathcal{V}_\Theta\Big(\hat{\boldsymbol{\Theta}}(x)\Big) \;\in\; \mathrm{End}(\mathcal{H}_{\mathrm{em}}), \tag{9.221}$$

so that the scalar density in the action is $\mathcal{L}_\Theta(x) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\{\mathscr{L}^{\mathrm{op}}_\Theta(x)\}$ (cf. Definition 9.301). Define $\nabla^\mu := \bar{\Sigma}^{\mu\lambda}\nabla_\lambda$. The *operator-valued* (symmetric) stress–energy tensor of the Tantrakyma sector is

$$\boxed{\hat{T}^{\mu\nu}_{(\Theta)}(x) := \tfrac{1}{2}\Big[g_C\Big(\nabla^\mu \hat{\boldsymbol{\Theta}},\, \nabla^\nu \hat{\boldsymbol{\Theta}}\Big) + g_C\Big(\nabla^\nu \hat{\boldsymbol{\Theta}},\, \nabla^\mu \hat{\boldsymbol{\Theta}}\Big)\Big] \;-\; \bar{\Sigma}^{\mu\nu}(x)\, \mathscr{L}^{\mathrm{op}}_\Theta(x).} \tag{9.222}$$

This form is Hermitian provided g_C is Hermitian and ∇_μ is $*$-compatible (cf. Definition 9.323).

Variational characterization (unified-tensor response). Varying the action with respect to $\bar{\Sigma}_{\mu\nu}$ gives

$$\boxed{\delta S_\Theta = \frac{1}{2}\int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}(x)}\; \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\hat{T}^{\mu\nu}_{(\Theta)}(x)\Big\}\; \delta\bar{\Sigma}_{\mu\nu}(x),} \tag{9.223}$$

hence the familiar scalar (trace) object is

$$T^{\mu\nu}_{(\Theta)}(x) := \frac{2}{\sqrt{-\det \bar{\Sigma}(x)}}\,\frac{\delta S_\Theta}{\delta \bar{\Sigma}_{\mu\nu}(x)} = \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\hat{T}^{\mu\nu}_{(\Theta)}(x)\Big\}. \tag{9.224}$$

Diagnostic realized reference configuration (band-limited, BRST-clean) and expectation tensor. On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\mathrm{UV}}, \ell)$ and physical projector $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definitions 9.306 and 9.307), use band-limited fields/derivatives in (9.222). The observable (expectation-level) tensor is

$$\boxed{\bar{T}^{\mu\nu}_{(\Theta)}(x) := \Big\langle \overset{\circ}{\boldsymbol{\Psi}} \Big|\, \mathsf{P}_{\mathrm{phys}}\, \mathrm{Tr}_{\mathcal{H}_{\mathrm{em}}}\Big\{\hat{T}^{\mu\nu}_{(\Theta)}(x)\Big\} \Big|\, \overset{\circ}{\boldsymbol{\Psi}}\Big\rangle.} \tag{9.225}$$

Conservation (on-shell). If $\hat{\boldsymbol{\Theta}}$ satisfies the Euler–Lagrange equation (9.199) and the connections are compatible (cf. Definition 9.323), then the relationally covariant conservation law holds:

$$\boxed{\nabla^{(\mathrm{rel})}_\mu\, \bar{T}^{\mu\nu}_{(\Theta)}(x) = 0.} \tag{9.226}$$

In a gauged realization, energy–momentum exchanges between matter and gauge sectors imply conservation of the *total* (matter+gauge) stress–energy; the matter piece alone is conserved whenever the gauge Lorentz-force exchange term vanishes on-shell (e.g. $\mathcal{F}_{\mu\nu} = 0$).

Typed & triadic resolution (parasymmetric diagnostics). With typed projectors $\Pi^{[\chi]}_{\Theta\Theta}$ and channel projectors Π_α that commute (cf. Definition 9.295), define

$$\hat{T}^{\mu\nu\,(\alpha,[\chi])}_{(\Theta)} := \Pi_\alpha\,\Pi^{[\chi]}_{\Theta\Theta}\,\hat{T}^{\mu\nu}_{(\Theta)}\,, \qquad \bar{T}^{\mu\nu\,(\alpha,[\chi])}_{(\Theta)} := \Big\langle \mathring{\boldsymbol{\Psi}} \,\Big|\, \mathsf{P}_{\text{phys}}\,\mathrm{Tr}_{\mathcal{H}_{\text{em}}}\{\hat{T}^{\mu\nu\,(\alpha,[\chi])}_{(\Theta)}\} \,\Big|\, \mathring{\boldsymbol{\Psi}} \Big\rangle. \tag{9.227}$$

Their spectral content provides *Location* diagnostics coherent with the SynTh meters and quadrant semantics (cf. eqs. (9.126) to (9.128) and Definitions 9.297 and 9.299): NG channels (QI) exhibit low-frequency spectral weight aligned with the $k^2 = 0$ pole; the Higgs (radial) channel shows a gapped peak at $k^2 = M_{\text{H}}^2$ (cf. eq. (9.194)), with *Onset* thresholds stamped per diagnostic realized reference configuration tags. Equations (9.222)–(9.226) complete the Noether/diffeomorphism response for the Tantrakyma sector, furnishing both the variational definition used in the field equations and the operational typed/triadic observables used by the Parasymmetric T–L–O workflow—all expressed purely with the co-metric pairing $g_C(\cdot,\cdot)$.

Interpretation and Physical Role The Tantrakyma stress–energy tensor encodes the energetic and dynamical content of the matter sector at the operator level (cf. Definition 9.356). In its pre-trace form $\hat{T}^{\mu\nu}_{(\Theta)}$ (cf. eq. (9.222)) it tracks how kymon excitations carry energy and momentum through the emergent configuration space $\mathcal{X}_q$. After taking the fiber trace and the diagnostic realized reference configuration expectation, one obtains the observable tensor $\bar{T}^{\mu\nu}_{(\Theta)}$ (cf. eq. (9.225)), which couples to geometry (see the Gaiamiti sector, Section 9.17.9).

- **Propagation (kinetic flow).** The symmetrized pairings

  $$\tfrac{1}{2}\Big[g_C(\nabla^\mu\hat{\boldsymbol{\Theta}},\nabla^\nu\hat{\boldsymbol{\Theta}}) + g_C(\nabla^\nu\hat{\boldsymbol{\Theta}},\nabla^\mu\hat{\boldsymbol{\Theta}})\Big]$$

  capture directional transport and kinetic energy of kymons along the chronogeometric directions set by $\bar{\Sigma}^{\mu\nu}$ (cf. Definitions 5.26 and 9.323).

- **Internal excitation content.** The subtraction in $\hat{T}^{\mu\nu}_{(\Theta)}$ is $-\,\bar{\Sigma}^{\mu\nu}\,\mathscr{L}^{\text{op}}_{\Theta}$, i.e.

  $$-\,\bar{\Sigma}^{\mu\nu}\Big[\bar{\Sigma}^{\alpha\beta}\,g_C(\nabla_\alpha\hat{\boldsymbol{\Theta}},\nabla_\beta\hat{\boldsymbol{\Theta}}) + \mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}})\Big]\,,$$

  which removes the kinetic trace and adds the potential contribution exactly as in eq. (9.222) (cf. Definitions 9.301 and 9.335).

Observable role and conservation. Taking the BRST-clean expectation on the diagnostic realized reference configuration yields the classical source field $\bar{T}^{\mu\nu}_{(\Theta)}$ (cf. eq. (9.225)). When the field is on-shell, this tensor is covariantly conserved with the relational connection, $\nabla^{(\text{rel})}_\mu \bar{T}^{\mu\nu}_{(\Theta)} = 0$ (cf. eq. (9.226)), expressing energy–momentum conservation of the matter sector within the chronogeometric arena determined by $\bar{\Sigma}_{\mu\nu}$.

Parasymmetric T–L–O diagnostics. Typed/triadic resolutions $\bar{T}^{\mu\nu\,(\alpha,[\chi])}_{(\Theta)}$ (cf. eq. (9.227)) act as *Location* probes consistent with the SynTh meters $(v^{(L)}, v^{(S)}, v^{(LS)})$ and quadrant semantics (cf. eqs. (9.126) to (9.128) and Definitions 9.297 and 9.299). NG channels (QI) exhibit low-frequency spectral weight aligned with the $k^2 = 0$ pole of the typed kernels, whereas the radial (Higgs) channel shows a gapped peak at $k^2 = M_{\text{H}}^2$ (cf. eq. (9.194)), with *Onset* thresholds stamped per diagnostic realized reference configuration tags.

9.18.12 The Source of Emergent Curvature: A Unified View

A central question in any theory of gravity is the origin of spacetime curvature. In the IQR framework, where geometry is emergent, curvature arises from the relational dynamics of the foundational quantum fields. Both the geometric Gaiamiti field and the matter-like Tantrakyma field contribute to the total stress–energy content, and this *unified* content sources curvature of the emergent chronogeometric manifold.

Definition 9.357 (Total Relational Action)**.** The complete dynamics are governed by

$$S_{\text{total}}\big[\hat{\mathbf{\Phi}},\,\hat{\mathbf{\Theta}}\big] \;:=\; S_{\Phi}\big[\hat{\mathbf{\Phi}}\big] \;+\; S_{\Theta}\big[\hat{\mathbf{\Theta}}\big] \;+\; S_{\text{int}}\big[\hat{\mathbf{\Phi}},\,\hat{\mathbf{\Theta}}\big]\,, \tag{9.228}$$

where:

- $S_{\Phi}[\hat{\mathbf{\Phi}}]$ is the Gaiamiti (geometry) action (cf. Section 6.5);
- $S_{\Theta}[\hat{\mathbf{\Theta}}]$ is the Tantrakyma (matter) action (cf. Definition 9.310);
- $S_{\text{int}}[\hat{\mathbf{\Phi}},\hat{\mathbf{\Theta}}]$ encodes geometry–matter coupling (cf. Section 10.19.4).

All integrals use the relational volume element $d\mu(x) := d^d x\,\sqrt{-\det \bar{\Sigma}(x)}$ (cf. Definition 6.33 and the measure note following Definition 9.310).

Definition 9.358 (Total stress–energy and expectation source)**.** Let $\hat{T}^{\mu\nu}_{(\Phi)}$ and $\hat{T}^{\mu\nu}_{(\Theta)}$ be the *operator-valued* (pre-trace) stress–energy tensors for the Gaiamiti and Tantrakyma sectors (cf. Section 9.17.9 and Definition 9.356), and let $\hat{T}^{\mu\nu}_{(\text{int})}$ be the interaction contribution obtained by varying S_{int} with respect to $\bar{\Sigma}_{\mu\nu}$. Their scalar (trace) forms are $T^{\mu\nu}_{(\bullet)} = \mathrm{Tr}\{\hat{T}^{\mu\nu}_{(\bullet)}\}$ (cf. eq. (9.224)). Define the *total* operator and scalar tensors by

$$\hat{T}^{\mu\nu}_{\text{total}} := \hat{T}^{\mu\nu}_{(\Phi)} + \hat{T}^{\mu\nu}_{(\Theta)} + \hat{T}^{\mu\nu}_{(\text{int})}, \qquad T^{\mu\nu}_{\text{total}} := \mathrm{Tr}\Big\{\hat{T}^{\mu\nu}_{\text{total}}\Big\}\,. \tag{9.229}$$

On a certified plateau $\mathfrak{P}$ with tags $(\lambda_{\text{UV}}, \ell)$ and projection $\mathsf{P}_{\text{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\text{BRST}})$, the expectation-level source of emergent curvature is

$$\boxed{\bar{T}^{\mu\nu}_{\text{total}}(x) \;:=\; \Big\langle \overset{\circ}{\mathbf{\Psi}} \Big|\, \mathsf{P}_{\text{phys}}\, \mathrm{Tr}\Big\{\hat{T}^{\mu\nu}_{\text{total}}(x)\Big\} \Big|\, \overset{\circ}{\mathbf{\Psi}} \Big\rangle.} \tag{9.230}$$

Unified variational identity and conservation. The unified (Hilbert) variation with respect to $\bar{\Sigma}_{\mu\nu}$ yields

$$\delta S_{\text{total}} = \frac{1}{2}\int d\mu(x)\;\; T^{\mu\nu}_{\text{total}}(x)\,\delta\bar{\Sigma}_{\mu\nu}(x), \tag{9.231}$$

so $T^{\mu\nu}_{\text{total}}$ is the *unique* source for the chronogeometric response. On-shell (EL equations satisfied in both sectors; cf. eq. (9.199) and the Gaiamiti EL), the relationally covariant conservation law holds:

$$\boxed{\nabla^{(\text{rel})}_{\mu}\,\bar{T}^{\mu\nu}_{\text{total}}(x) = 0.} \tag{9.232}$$

When there is no geometry–matter exchange ($\hat{T}^{\mu\nu}_{(\text{int})} = 0$), the separate pieces are conserved; otherwise only the *sum* is conserved. Typed/triadic resolutions of $\bar{T}^{\mu\nu}_{\text{total}}$ provide *Location*

diagnostics consistent with the SynTh meters and quadrant semantics (cf. eqs. (9.126) to (9.128) and Definitions 9.297 and 9.299).

Notes. (i) In the Tantrakyma sector all potential invariants are built from the co-metric $g_C : T^*\times T^* \to \mathrm{End}(\mathcal{H}_{\mathrm{em}})$ (not g_C^{-1}), ensuring that both $\hat{T}^{\mu\nu}_{(\Theta)}$ and $T^{\mu\nu}_{(\Theta)}$ are computed with the correct cotangent pairing. (ii) Diagnostic realized reference configuration-limited, BRST-clean expectation values guarantee gauge-parameter independence (Nielsen flatness) of $\bar{T}^{\mu\nu}_{\mathrm{total}}$.

Evaluation of the Total Expectation-Valued Stress–Energy Tensor

We evaluate the total source in three steps, keeping the operator/scalar distinction explicit and enforcing diagnostic realized reference configuration (band-limited, BRST-clean) discipline.

1. Additivity and expectation linearity (including interaction). By linearity of the expectation and the variational definition of stress–energy (cf. eq. (9.224)), the *total* scalar tensor is the sum of sectoral and interaction pieces:

$$\boxed{\bar{T}^{\mu\nu}_{\mathrm{total}}(x) = \bar{T}^{\mu\nu}_{(\Phi)}(x) + \bar{T}^{\mu\nu}_{(\Theta)}(x) + \bar{T}^{\mu\nu}_{(\mathrm{int})}(x),} \tag{9.233}$$

with

$$\bar{T}^{\mu\nu}_{(\bullet)}(x) := \Big\langle \mathring{\boldsymbol{\Psi}} \,\Big|\, \mathsf{P}_{\mathrm{phys}}\, T^{\mu\nu}_{(\bullet)}(x) \,\Big|\, \mathring{\boldsymbol{\Psi}} \Big\rangle, \qquad (\bullet) \in \{\Phi, \Theta, \mathrm{int}\}, \tag{9.234}$$

where $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\mathrm{BRST}})$ is the physical projector (diagnostic realized reference configuration semantics; cf. Definitions 9.306 and 9.307). Here $T^{\mu\nu}_{(\bullet)} = \mathrm{Tr}\{\hat{T}^{\mu\nu}_{(\bullet)}\}$ is the scalar (fiber-traced) tensor associated with the operator-valued $\hat{T}^{\mu\nu}_{(\bullet)}$ (cf. Section 9.17.9 and Definition 9.356).

2. Operator forms and diagnostic realized reference configuration expectations. Raise indices with $\nabla^\mu := \bar{\Sigma}^{\mu\lambda}\nabla_\lambda$. Let the operator-valued Lagrangians be

$$\mathscr{L}^{\mathrm{op}}_{\Phi} = \bar{\Sigma}^{\alpha\beta} g_T\Big(\nabla_\alpha\hat{\boldsymbol{\Phi}},\, \nabla_\beta\hat{\boldsymbol{\Phi}}\Big) + \mathcal{V}_\Phi(\hat{\boldsymbol{\Phi}}), \quad \mathscr{L}^{\mathrm{op}}_{\Theta} = \bar{\Sigma}^{\alpha\beta} g_C\Big(\nabla_\alpha\hat{\boldsymbol{\Theta}},\, \nabla_\beta\hat{\boldsymbol{\Theta}}\Big) + \mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}}),$$

whose fiber traces enter the actions (cf. Definition 9.301).

- **Gaiamiti (geometry) sector** (cf. Section 9.17.9): with the tangent metric g_T and operator field $\hat{\boldsymbol{\Phi}}$,

$$\begin{aligned}\hat{T}^{\mu\nu}_{(\Phi)}(x) := {}& \tfrac{1}{2}\Big[g_T\Big(\nabla^\mu\hat{\boldsymbol{\Phi}},\, \nabla^\nu\hat{\boldsymbol{\Phi}}\Big) + g_T\Big(\nabla^\nu\hat{\boldsymbol{\Phi}},\, \nabla^\mu\hat{\boldsymbol{\Phi}}\Big)\Big] \\ & - \tfrac{1}{2}\,\bar{\Sigma}^{\mu\nu}\bar{\Sigma}^{\alpha\beta}\, g_T\Big(\nabla_\alpha\hat{\boldsymbol{\Phi}},\, \nabla_\beta\hat{\boldsymbol{\Phi}}\Big) - \bar{\Sigma}^{\mu\nu}\,\mathcal{V}_\Phi(\hat{\boldsymbol{\Phi}}).\end{aligned} \tag{9.235}$$

- **Tantrakyma (matter) sector** (cf. Definition 9.356): with the cotangent co-metric g_C and operator field $\hat{\boldsymbol{\Theta}}$,

$$\begin{aligned}\hat{T}^{\mu\nu}_{(\Theta)}(x) := {}& \tfrac{1}{2}\Big[g_C\Big(\nabla^\mu\hat{\boldsymbol{\Theta}},\, \nabla^\nu\hat{\boldsymbol{\Theta}}\Big) + g_C\Big(\nabla^\nu\hat{\boldsymbol{\Theta}},\, \nabla^\mu\hat{\boldsymbol{\Theta}}\Big)\Big] \\ & - \tfrac{1}{2}\,\bar{\Sigma}^{\mu\nu}\bar{\Sigma}^{\alpha\beta}\, g_C\Big(\nabla_\alpha\hat{\boldsymbol{\Theta}},\, \nabla_\beta\hat{\boldsymbol{\Theta}}\Big) - \bar{\Sigma}^{\mu\nu}\,\mathcal{V}_\Theta(\hat{\boldsymbol{\Theta}}).\end{aligned} \tag{9.236}$$

- **Interaction sector**:

$$\hat{T}^{\mu\nu}_{(\mathrm{int})}(x) \text{ is defined variationally by } \quad \delta S_{\mathrm{int}} = \frac{1}{2}\int d\mu\, \mathrm{Tr}\Big\{\hat{T}^{\mu\nu}_{(\mathrm{int})}(x)\Big\}\, \delta\bar{\Sigma}_{\mu\nu}(x), \tag{9.237}$$

so $T^{\mu\nu}_{(\mathrm{int})} = \mathrm{Tr}\{\hat{T}^{\mu\nu}_{(\mathrm{int})}\}$.

Taking the fiber trace and the diagnostic realized reference configuration expectation (cf. eqs. (9.224) and (9.225)) yields

$$\boxed{\bar{T}^{\mu\nu}_{\mathrm{total}} = \Big\langle \mathsf{P}_{\mathrm{phys}}\, \mathrm{Tr}\Big\{\hat{T}^{\mu\nu}_{(\Phi)} + \hat{T}^{\mu\nu}_{(\Theta)} + \hat{T}^{\mu\nu}_{(\mathrm{int})}\Big\}\Big\rangle_{\mathfrak{P}},} \tag{9.238}$$

with $\langle\cdot\rangle_{\mathfrak{P}} := \langle\mathring{\mathbf{\Psi}}|\,(\cdot)\,|\mathring{\mathbf{\Psi}}\rangle$ at fixed tags $(\lambda_{\mathrm{UV}}, \ell)$. Equation (9.238) is the diagnostic realized reference configuration form of eq. (9.230).

3. Parasymmetric T–L–O resolution (typed, triadic; optional but recommended). For diagnostics and cross-sector consistency, resolve $\bar{T}^{\mu\nu}_{\mathrm{total}}$ by type and channel using projectors $\Pi^{[\chi]}$ and Π_α that commute (cf. Definitions 5.54 and 9.295):

$$\bar{T}^{\mu\nu}_{\mathrm{total}}{}^{(\alpha,[\chi])} := \Big\langle \mathsf{P}_{\mathrm{phys}}\, \mathrm{Tr}\{\Pi_\alpha\, \Pi^{[\chi]}\, (\hat{T}^{\mu\nu}_{(\Phi)} + \hat{T}^{\mu\nu}_{(\Theta)} + \hat{T}^{\mu\nu}_{(\mathrm{int})})\}\Big\rangle_{\mathfrak{P}}. \tag{9.239}$$

Their spectral content co-locates with the typed kernel poles used by the SynTh meters $v^{(L)}, v^{(S)}, v^{(LS)}$ (cf. eqs. (9.126) to (9.128)), enabling a *typed quadrant* decision via $\mathrm{Quad}^{[\cdot]}_{[\chi]}$ and T–L–O stamping (cf. Definitions 9.297 and 9.299). NG channels (QI) exhibit low-frequency weight aligned with $k^2 = 0$, while a Higgs (radial) entry shows a single gapped peak at $k^2 = M_{\mathrm{H}}^2$ (cf. eq. (9.194)), with Location/Onset set by diagnostic realized reference configuration tags.

Conservation (unified, on-shell). When both EL systems hold and connections are compatible (cf. Definitions 9.305 and 9.323 and the geometry-side EL), the total source is covariantly conserved:

$$\nabla^{(\mathrm{rel})}_{\mu}\, \bar{T}^{\mu\nu}_{\mathrm{total}} = 0, \tag{9.240}$$

with separate sectoral conservation when the interaction exchange vanishes and, in general, conservation in the sum.

Interpretation.

- *Kinetic/transport content.* The first (symmetrized) terms in $\hat{T}^{\mu\nu}_{(\Phi)}$ and $\hat{T}^{\mu\nu}_{(\Theta)}$ are the operator-valued metric/co-metric pairings

$$\tfrac{1}{2}\Big[g_T(\nabla^\mu\hat{\mathbf{\Phi}}, \nabla^\nu\hat{\mathbf{\Phi}}) + g_T(\nabla^\nu\hat{\mathbf{\Phi}}, \nabla^\mu\hat{\mathbf{\Phi}})\Big], \qquad \tfrac{1}{2}\Big[g_C(\nabla^\mu\hat{\mathbf{\Theta}}, \nabla^\nu\hat{\mathbf{\Theta}}) + g_C(\nabla^\nu\hat{\mathbf{\Theta}}, \nabla^\mu\hat{\mathbf{\Theta}})\Big],$$

capturing directional transport and kinetic flow of the Apeiron (geometry) and kymon (matter) fields along the chronogeometric directions selected by $\bar{\Sigma}^{\mu\nu}$ (cf. Section 9.17.9 and Definitions 9.323 and 9.356).

- *Potential/interaction content.* The subtraction structure in $\hat{T}^{\mu\nu}_{(\bullet)}$ (with $(\bullet) \in \{\Phi, \Theta\}$) consists of the kinetic trace term $-\frac{1}{2}\,\bar{\Sigma}^{\mu\nu}\bar{\Sigma}^{\alpha\beta}\,(\cdots)_{\alpha\beta}$ and the potential piece $-\,\bar{\Sigma}^{\mu\nu}\,\mathcal{V}_{\bullet}$, exactly as in eq. (9.222) and its geometry-side analogue. After taking the fiber trace and the diagnostic realized reference configuration expectation, this yields a conserved energy–momentum flux consistent with the Hilbert variational identity $\delta S = \frac{1}{2}\int d\mu\ \mathrm{Tr}\{\hat{T}^{\mu\nu}\}\delta\bar{\Sigma}_{\mu\nu}$ (cf. eqs. (9.223), (9.224) and (9.238)). Interaction contributions are included via $\hat{T}^{\mu\nu}_{(\mathrm{int})}$ by variation of S_{int}.

- *Back-reaction mediator.* The background tensor $\bar{\Sigma}^{\mu\nu}(x)$ raises/lowers indices, defines the relational covariant derivative, and mediates the back–reaction of both sectors on curvature. On-shell one has $\nabla^{(\mathrm{rel})}_{\mu}\bar{T}^{\mu\nu}_{\mathrm{total}} = 0$ (cf. eq. (9.240)), ensuring consistent sourcing of emergent chronogeometry.

This furnishes a self-consistent matter–geometry interplay in the IQR framework, echoing Wheeler's dictum [146, 239] in diagnostic realized reference configuration-ready form.

> *Spacetime tells matter how to move* (paraphrasing [146]): the emergent $\bar{\Sigma}_{\mu\nu}$, constructed from the Gaiamiti field $\hat{\mathbf{\Phi}}$, governs the covariant propagation of $\hat{\mathbf{\Theta}}$ via eq. (9.199).
>
> *Matter tells spacetime how to curve* (paraphrasing [146]): the total source $\bar{T}^{\mu\nu}_{\mathrm{total}}$ (including Tantrakyma excitations and interaction exchange) drives the evolution of $\hat{\mathbf{\Phi}}$, thereby reshaping $\bar{\Sigma}_{\mu\nu}$.

Parasymmetric T–L–O perspective. Typed/triadic resolutions of $\bar{T}^{\mu\nu}_{\mathrm{total}}$ provide Location diagnostics that co-locate with poles of the typed kernels and agree with SynTh meters and quadrant calls (NG vs. gapped channels), yielding consistent T–L–O stamps across geometry and matter (cf. eqs. (9.126) to (9.128) and (9.239) and Definitions 9.297 and 9.299).

Chapter 10

The Weave of Geometry and Matter

10.1 The Inter-Modal Correlators of Fields

This chapter revisits the *Unified Inter-Modal Correlator* as the kinematic backbone from which both geometry (Gaiamiti) and matter/temporality (Tantrakyma) draw their operational meaning, and equips that backbone with the covariant dynamics previously introduced, so that we may linearize the geometric sector, isolate graviton channels, and state the chronogeometric Einstein equations $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ in their natural $\bar{\Sigma}$-geometry (Section 11.7.3). Concretely, the unified object is the matrix of two-point functions

$$\hat{\mathbf{G}}_{\Lambda}(x,x') := \begin{pmatrix} \hat{G}_{\mathbf{\Phi\Phi}} & \hat{G}_{\mathbf{\Phi\Theta}} \\ \hat{G}_{\mathbf{\Theta\Phi}} & \hat{G}_{\mathbf{\Theta\Theta}} \end{pmatrix}(x,x').$$

Its entries are obtained by specializing the Fourfold correlator $\hat{G}_{\Lambda}^{\alpha\beta}$ (Definition 6.4).

From Fourfold Kinematics to the Unified Two-Block. As formalized in Definition 4.9 and Section 4.1.4, the Fourfold correlator is the gauge-covariant, operator-valued kernel that transports and couples the four dialectic modes $\{0,1,p,s\}$, with a path-ordered parallel transporter $\mathcal{U}(x \leftarrow x';\gamma)$ effecting frame alignment across loci in $\mathcal{X}_q$. In tensor form,

$$\hat{G}_{\Lambda}^{\alpha\beta}(x,x') \;=\; \hat{\mathcal{F}}_{\alpha}^{\dagger}(x)\,\mathcal{U}(x \leftarrow x';\gamma)\,\hat{\mathcal{F}}_{\beta}(x'),$$

and the unified matrix above is precisely its organization into the $(\mathbf{\Phi},\mathbf{\Theta})$ sectors (Section 4.1.5). The fibre inner products are *generated*—not postulated—by Holo-State expectation in the coincident limit, yielding well-posed Hilbert fibres and a Hilbert bundle of dialectic modes (Sections 4.1.3 and 4.6.1); the modal basis $\{|0\rangle_x, |1\rangle_x, |p\rangle_x, |s\rangle_x\}$ realizes parasymmetric/holosymmetric directions as independent rays (not superpositions of $|0\rangle, |1\rangle$) (Section 4.1.5).

Relational Covariance and Operator Dynamics. Given the expectation-level chronogeometric tensor $\bar{\Sigma}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$, there exists a unique torsion-free, metric-compatible connection $\nabla^{(\mathrm{rel})}$ with Christoffel symbols $\Gamma^{\lambda}_{\mu\nu}[\bar{\Sigma}]$ (Definition 6.7). Operator fields are sections of bundles twisted both by $\nabla^{(\mathrm{rel})}$ and by an internal operator connection $\mathcal{A}_\mu$. For the Gaiamiti field,

$$\nabla_\mu \hat{\mathbf{\Phi}} \;=\; \nabla^{(\mathrm{rel})}_{\mu} \hat{\mathbf{\Phi}} \;+\; D_\mu \hat{\mathbf{\Phi}}, \qquad (\nabla_\mu \hat{\mathbf{\Phi}})^{\lambda} = \partial_\mu \hat{\mathbf{\Phi}}^{\lambda} + \Gamma^{\lambda}_{\mu\nu}[\bar{\Sigma}]\hat{\mathbf{\Phi}}^{\nu} + i[\mathcal{A}_\mu, \hat{\mathbf{\Phi}}^{\lambda}], \tag{10.1}$$

(Definition 6.184); this enters the action $S_\Phi = \int \sqrt{-\det \bar{\Sigma}}\, \mathcal{L}_\Phi$ and Euler–Lagrange equations, with Noether stress–energy $\hat{T}^{\mu\nu}_{(\Phi)}$ (Definition 6.174 and Section 9.17.9). Analogously, for Tantrakyma,

$$\nabla_\mu \hat{\boldsymbol{\Theta}} \;=\; \nabla^{(\mathrm{rel})}_\mu \hat{\boldsymbol{\Theta}} \;+\; D_\mu \hat{\boldsymbol{\Theta}}, \tag{10.2}$$

(Definition 9.323).

Σ–Realization, Acceptance, and Quadrants. Building on this, we evaluate all kinematics and dynamics on a certified plateau $\mathfrak{P}$ and then project to the physical cohomology via the Σ–*realization map* (Definition 9.80)

$$\boxed{\bar{\Sigma}_{\mu\nu}(x) = \Big\langle \mathsf{P}_{\mathrm{phys}} \lim_{(\lambda,\ell)\in\mathfrak{P}} \mathfrak{B}_{\lambda,\ell}![\hat{\Sigma}_{\mu\nu}(x)]\; \mathsf{P}_{\mathrm{phys}} \Big\rangle},$$

after which all Chapter 7 constructions are *read as functions of* $\bar{\Sigma}$ with the BRST sector and proofs unchanged (Remark 9.81). Thus $\bar{\Sigma}^{\mu\nu}$ (the inverse of $\bar{\Sigma}_{\mu\nu}$, cf. eq. (6.62)) raises indices and fixes the chronogeometric cones that support linear response; in particular, the retarded kernels built from $\hat{\mathbf{G}}_\Lambda$ are Σ-*causal* (support contained in the $\bar{\Sigma}$-cones) by Remark 9.83, and mode normalization with respect to $\bar{\Sigma}$ is equivalent—up to bounded reweighting—to the triad metrics (Remark 9.84). The *holosymmetric visibilities* $\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$ from Chapter 7 (Definition 7.35) are the witnesses we continue to use here, but only on *accepted* scale bands certified by Chapter 8. Concretely, acceptance is enforced on the (u, v)-plane by the mask $\mathfrak{M}_{\mathrm{mask}}$ with guards C1–C5 (eq. (7.626)), yielding an IR window $\mathcal{I}_{\mathrm{IR}}$ on which the smoothed slope $\psi(v) = \mathsf{LP}_\tau(\Lambda'_{\mathrm{law}})(v)$ enjoys Lipschitz, total-variation, and positivity stability (Lemma 7.386 and Proposition 7.383). Within $\mathcal{I}_{\mathrm{IR}}$, the *quadrant decision* is then made canonically using $\{\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}\}$ (Definition 7.685), providing the QI–QIV classification that will guide graviton-channel isolation and the formulation of $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ in Section 11.7.3.

Pre-Physics → Physics and Parasymmetric Overlay. Before realization, in the *pre-physical band* ($\ell_{\mathrm{PQS}} \le \ell < \ell_P$) Chapter 10 prescribes *operator-level* Σ-diagnostics only: one forms quadratic probes $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ and expectation surrogates $\bar{Q}_x[v]$ (Definitions 9.20 and 9.22), aggregates contrasts via the RSS rule (Definition 9.47), and assigns a pre-physical quadrant (Definition 9.49). *Physical* poles/residues and visibilities are read *only after* a certified plateau and BRST projection to $H^0(\hat{Q}_{\mathrm{BRST}})$ ($\mathfrak{P}$ and $\mathsf{P}_{\mathrm{phys}}$ in Definition 9.80), which is the precise pre-physics → physics transition used throughout this chapter. The *parasymmetric overlay* of Chapter 9 remains intact and confined to H^0: parasymmetric/holosymmetric meters operate on the realized data, the quadrant assignment is functorial and cone-preserving under the certified maps (Theorem 8.45), and the law–state exhaustion link holds on $\mathfrak{P}$. Consequently, the QIII/QIV refinement and "no fifth quadrant" property from Chapters 8–9 carry over verbatim into the present $\bar{\Sigma}$-based formulation used to organize channels and residues for $\hat{\mathbf{G}}_\Lambda$.

TT Isolation for Graviton Channels. Finally, to *linearize the geometric sector and isolate graviton channels*, we work on the realized weave configuration with the typed triad $1 =$

$\Pi^{(\mathrm{spec})} + \Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})}$ (Definition 10.2) and the $\bar{\Sigma}$-TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 10.3). The York–Helmholtz/polarization bookkeeping and the graviton-projector identity (Eq. (10.28)) enforce TT purity, while the *TT leak* ε (Definition 10.32) is bounded purely by non-spectral channel content (Lemma 10.103), ensuring that the TT sector extracted from $\hat{\mathbf{G}}_\Lambda$ is well-posed for the chronogeometric Einstein equations $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ in Section 11.7.3.

10.2 Realized Weave Configuration and Typed Algebra

We fix the operational "rig" in this section so that all subsequent objects (τ–kairos, graviton, Higgs, Chrono–Kymon) are defined *on this realized weave configuration*, and so they inherit BRST/Nielsen safety, cone preservation, triad compatibility, and band-covariance from the outset (cf. Definitions 6.280 and 9.10, eq. (9.2), and Section 9.5 upstream).

Definitions.

Definition 10.1 (Realized weave configuration)**.** For any sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and arena $\mathfrak{P} \in \{\mathrm{bulk}, \mathrm{boundary}\}$, the *realized weave configuration* is the tuple

$$\mathcal{I}^{[\mathscr{S}]} := \Big(\mathcal{A},\ r\ ;\ P_x(\lambda_{\mathrm{UV}}),\ K_{\mathrm{IR}}^{(\ell)}\ ;\ \mathsf{P}_{\mathrm{phys}}\ ;\ \bar{\Sigma}_{\mu\nu} \Big),$$

whose entries are as follows (with explicit upstream definitions):

1. $\mathcal{A}$ = *admissible holosymmetric settings*: the background/arena choice and kinematic domain on which band operators act. The arena action and admissibility conditions used by band maps are stated in eq. (9.2).
2. $r \in \mathbb{R}_{\geq 0}$ = *IR knob*: the parameter that indexes the infrared windows $K_{\mathrm{IR}}^{(\ell)}$ and their tightening along admissible retunes; cf. the window family in Definition 6.280.
3. $P_x(\lambda_{\mathrm{UV}})$ = *band tags*: orthogonal projectors implementing the certified ultraviolet cut and band selection; see the tag definition and properties in Definition 9.10, with their arena action given by eq. (9.2).
4. $K_{\mathrm{IR}}^{(\ell)}$ = *IR windows*: smoothing/compression operators forming an admissible family that controls long-distance content and defines IR retunes; see Definition 6.280.
5. $\mathsf{P}_{\mathrm{phys}}$ = *BRST projector onto* H^0: the idempotent that projects to the physical cohomology (degree-zero BRST cohomology). The physical carrier for all readouts is
$$\mathcal{H}_{\mathrm{phys}} := \mathrm{Ran}\, \mathsf{P}_{\mathrm{phys}}.$$
6. $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ = *expectation-level chronogeometric tensor*: the background-covariant, expectation-valued chronogeometry used to define covariant TT maps and traces; construction and properties are recalled in Section 9.5.

All band objects act on $\mathcal{H}_{\mathrm{phys}}$ and satisfy the certified commutation/compatibility relations:

$$[P_x(\lambda_{\mathrm{UV}}), \mathsf{P}_{\mathrm{phys}}] = 0,$$
$$[K_{\mathrm{IR}}^{(\ell)}, \mathsf{P}_{\mathrm{phys}}] = 0,$$

and the arena action of $P_x(\lambda_{\mathrm{UV}})$ is as in eq. (9.2). Norms and stability estimates are evaluated with the admissible family $\|\cdot\|_{\mathcal{I}}$ of Definition 10.143.

Meaning. *realized weave configuration* (Definition 10.1) fixes the baseline measurement frame—our *realized weave configuration* $\mathcal{I}^{[\mathscr{S}]}$—on which all subsequent geometric/matter diagnostics are performed. Concretely, the configuration is assembled *after* Σ–realization (Definition 9.80), so every operator and kernel is evaluated on the realized chronogeometry $\bar{\Sigma}$. It packages (i) the physical sector $\mathcal{H}_{\mathrm{phys}}$, (ii) the typed triad of channels $1 = \Pi^{(\mathrm{spec})} + \Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})}$ for bookkeeping and mode extraction (Definition 10.2), and (iii) the $\bar{\Sigma}$-transverse–traceless projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ used to isolate graviton channels (Definition 10.3). With this configuration in place, the unified two-point matrix $\hat{\mathbf{G}}_\Lambda$ is read Σ-causally and all covariant dynamics use the relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$ compatible with $\bar{\Sigma}$ (Definition 6.7), exactly as required later when stating $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ (Section 11.7.3).

Realized weave configuration vs. Plateaux. A *plateau* $\mathfrak{P}$ is a *scale-certification* in the (u, v) plane: it is the accepted window picked out by the mask $\mathfrak{M}_{\mathrm{mask}}$ and guards C1–C5 (eq. (7.626)), within which the witnesses $\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$ are stable (Lipschitz/TV/positivity bounds; Lemma 7.386 and Proposition 7.383). Plateaux certify *where* the data are reliable. By contrast, the *realized weave configuration* $\mathcal{I}^{[\mathscr{S}]}$ is the *instrument set*—projectors, connections, domains—on which we then operate. In practice: $\mathfrak{P} \Rightarrow$ apply the Σ–realization map to obtain $\bar{\Sigma}$ (Definition 9.80) $\Rightarrow$ *install* the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$. Thus, plateaux are *scale-local certifications of input*, while the realized weave configuration is a *structural, sector-conditioned apparatus* that persists for analysis (e.g., TT isolation and stress–energy evaluation) once $\bar{\Sigma}$ is fixed.

Intent and Use. The intent of Definition 10.1 is to guarantee that downstream statements—quadrant assignment (Definition 7.685), TT purity and TT-leak control (ε bounded by non-spectral content; Definition 10.32, Lemma 10.103), and ultimately the formulation of the chronogeometric Einstein equations—are executed on a *calibrated* and *BRST/Nielsen-clean* stage determined by $\bar{\Sigma}$. In short, plateaux supply certified data; the realized weave configuration supplies certified tools. Together they make the extraction of graviton channels with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 10.3) and the use of $\nabla^{(\mathrm{rel})}$ (Definition 6.7) mathematically well-posed for the construction of $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ in Section 11.7.3.

Definition 10.2 (Triad channels)**.** Work on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1). We use mutually commuting projectors $\Pi^{(a)}$ for $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (triad decomposition; see also band invariance Proposition 10.10 and masks/selectors Definitions 7.665 and 10.7), with

$$\Pi^{(\mathrm{spec})} + \Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})} = \mathbf{1}, \qquad \Pi^{(a)}\Pi^{(b)} = \delta_{ab}\Pi^{(a)}. \tag{10.3}$$

These triads are the provenance maps used throughout ledgers/meters (Definitions 10.80 and 10.82) and typed correlator insertions (Definition 10.113).

Definition 10.3 (Background-covariant TT projector)**.** On symmetric 2-tensors $h \in \Gamma(S^2T^*\mathcal{X}_q)$, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is the $\bar{\Sigma}$–compatible transverse–traceless projector (a background-covariant pseudodifferential lift defined with the relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$; cf. Ch. 7 Definition 6.7 and eq. (6.22); see also [84, 248]). Let $d := \dim \mathcal{X}_q$ and define

$$\mathrm{tr}_{\bar{\Sigma}}\, h := \bar{\Sigma}^{\mu\nu}h_{\mu\nu}, \qquad (\mathrm{div}_{\bar{\Sigma}}h)_\nu := \nabla^{(\mathrm{rel})\mu}h_{\mu\nu}, \qquad (\mathcal{L}_{\bar{\Sigma}}v)_{\mu\nu} := \nabla^{(\mathrm{rel})}_{(\mu}v_{\nu)} - \frac{1}{d}\,\bar{\Sigma}_{\mu\nu}\,\nabla^{(\mathrm{rel})}\cdot v,$$

together with the $\bar{\Sigma}$–adjoint

$$(\mathcal{L}_{\bar{\Sigma}}^{\dagger} h)_{\mu} := -2\Big(\nabla^{(\mathrm{rel})\nu} h_{\mu\nu} - \frac{1}{d}\,\nabla_{\mu}^{(\mathrm{rel})}\,\mathrm{tr}_{\bar{\Sigma}}\,h\Big)\,,$$

where adjoints are taken with respect to the $\bar{\Sigma}$–inner product (cf. Definition 9.33). Writing the *York vector–Laplacian* as $\Delta_V^{(\mathrm{rel})} := \mathcal{L}_{\bar{\Sigma}}^{\dagger}\mathcal{L}_{\bar{\Sigma}}$—elliptic on the realized weave configuration, modulo Killing vectors [43, 44, 7]—the projector is

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \;:=\; \mathbf{1} \;-\; \mathcal{L}_{\bar{\Sigma}}\,(\Delta_V^{(\mathrm{rel})})^{-1}\,\mathcal{L}_{\bar{\Sigma}}^{\dagger} \;-\; \frac{1}{d}\,\bar{\Sigma}\otimes\mathrm{tr}_{\bar{\Sigma}}} \tag{10.4}$$

acting on $\Gamma(S^2T^*\mathcal{X}_q)$. The construction (10.4) is the standard York–Lichnerowicz TT projector written in background–covariant form [43, 44].

This operator is idempotent and $\bar{\Sigma}$–self-adjoint,

$$(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]})^2 = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}, \qquad \langle \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} h, k\rangle_{\bar{\Sigma}} = \langle h, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} k\rangle_{\bar{\Sigma}},$$

and it enforces the TT conditions

$$\mathrm{tr}_{\bar{\Sigma}}\Big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} h\Big) = 0, \qquad \mathrm{div}_{\bar{\Sigma}}\Big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} h\Big) = 0,$$

hence annihilates pure traces and longitudinal pieces,

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}(\varphi\,\bar{\Sigma}) = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big(\mathcal{L}_{\bar{\Sigma}} v\Big) = 0, \qquad \forall\,\varphi \in C^{\infty},\ v \in \Gamma(T^*\mathcal{X}_q).$$

It is stable and commuting with the certified band/typed structure (Propositions 10.9 and 10.10), in particular

$$\Big[\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]},\, \Pi^{(\mathrm{spec})}\Big] = \Big[\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]},\, \Pi^{(\mathrm{vac})}\Big] = \Big[\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]},\, \Pi^{(\mathrm{corr})}\Big] = 0,$$

and it satisfies TT purity as recorded in Lemma 10.28.

Meaning and role of $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ Definition Definition 10.3 provides a *background–covariant* way to extract the physically relevant, gauge–invariant content of a symmetric 2–tensor $h_{\mu\nu}$ relative to the realized chronogeometry $\bar{\Sigma}$ (with $\nabla^{(\mathrm{rel})}$ from Definition 6.7). The projector removes (i) pure traces and (ii) longitudinal, diffeomorphism–generated pieces, leaving the *transverse–traceless* remainder that carries spin–2 gravitational radiation. Because it is built from $\bar{\Sigma}$ and $\nabla^{(\mathrm{rel})}$, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is compatible with the realized weave configuration (Definition 10.1) and commutes with the typed/triad structure (Proposition 10.9), ensuring that TT extraction is consistent with the rest of the weave calculus (e.g., TT purity and leak control in Lemma 10.28).

Why the York vector–Laplacian and Killing fields? The decomposition encoded by (10.4) is the York–Lichnerowicz split: for suitable h one has the *orthogonal* decomposition

$$h_{\mu\nu} = \underbrace{\big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} h\big)_{\mu\nu}}_{\mathrm{TT}} + \underbrace{(\mathcal{L}_{\bar{\Sigma}} v)_{\mu\nu}}_{\text{longitudinal}} + \underbrace{\frac{1}{d}\,\bar{\Sigma}_{\mu\nu}\,\mathrm{tr}_{\bar{\Sigma}}\,h}_{\text{trace}}, \qquad v \;=\; (\Delta_V^{(\mathrm{rel})})^{-1}\,\mathcal{L}_{\bar{\Sigma}}^{\dagger} h \;\;\mathrm{mod}\;\; \ker\Delta_V^{(\mathrm{rel})}.$$

Here $\Delta_V^{(\mathrm{rel})} := \mathcal{L}_{\bar\Sigma}^\dagger \mathcal{L}_{\bar\Sigma}$ is the *York vector–Laplacian*, an elliptic operator whose kernel is spanned by *Killing fields* of $(\mathcal{X}_q, \bar\Sigma)$ [43, 44, 7]. Ellipticity guarantees a well-posed inversion on the orthogonal complement of this kernel, so the longitudinal component is removed by the term $\mathcal{L}_{\bar\Sigma}(\Delta_V^{(\mathrm{rel})})^{-1}\mathcal{L}_{\bar\Sigma}^\dagger$ while the pure trace is removed by $\frac{1}{d}\,\bar\Sigma \otimes \mathrm{tr}_{\bar\Sigma}$. The residual piece is TT by construction and, crucially, is independent of background isometries (Killing directions) which represent gauge redundancies rather than physical degrees of freedom [43, 7]. This is why (10.4) is the natural, covariant and rig–compatible way to isolate graviton channels in our framework.

Definition 10.4 (τ–kairos typed projectors)**.** On the τ–kairos typed block (typed, not a sector; Ch. 10 typed layer Definition 9.116), we admit the $\bar\Sigma$–self-adjoint, mutually orthogonal idempotents

$$S^{(b)}, \quad S^{(L)}, \quad \tilde S^{(p)}, \quad A^{(+)}, \quad A^{(-)},$$

corresponding respectively to *breathing scalar*, *longitudinal scalar*, *parity-odd* pseudoscalar (Levi–Civita built), and *helicity-resolved* vectors (Chrono–Kymon $\lambda = \pm$). They obey, on the τ-typed block,

$$S^{(i)}S^{(j)} = \delta_{ij}\,S^{(i)}, \qquad (S^{(i)})^{\dagger_{\bar\Sigma}} = S^{(i)}, \qquad S^{(b)} + S^{(L)} + \tilde S^{(p)} + A^{(+)} + A^{(-)} = \mathbf{1}_\tau, \tag{10.5}$$

where $\dagger_{\bar\Sigma}$ denotes adjoint with respect to the $\bar\Sigma$–inner products (Definition 9.33), and $\mathbf{1}_\tau$ is the identity on the τ–typed block.

Breathing vs. longitudinal scalars. $S^{(b)}$ projects onto the isotropic (trace-like) breathing mode generated by scalar dilations within the τ–typed block; $S^{(L)}$ projects onto the *longitudinal* gradient mode. Concretely, writing the relational Levi–Civita connection $\nabla^{(\mathrm{rel})}$ determined by $\bar\Sigma$ (Definition 6.7), one may characterize $S^{(L)}$ by the covariant gradient–divergence pair

$$\mathcal{G} := \nabla^{(\mathrm{rel})}, \qquad \mathcal{G}^\dagger := -\nabla^{(\mathrm{rel})}\cdot \ (\bar\Sigma\text{–adjoint}),$$

and the (typed) scalar Laplacian $\Delta_S^{(\mathrm{rel})} := \mathcal{G}^\dagger\mathcal{G}$ on the realized weave configuration (Definition 10.1), so that

$$S^{(L)} = \mathcal{G}\,\Big(\Delta_S^{(\mathrm{rel})}\Big)^{-1}\,\mathcal{G}^\dagger, \tag{10.6}$$

modulo $\ker\Delta_S^{(\mathrm{rel})}$ (constants/Killing modes on the realized weave configuration). The breathing projector $S^{(b)}$ is the complementary scalar part within (10.5) (see the typed split in Definition 10.2).

Pseudoscalar and helicity projectors. The pseudoscalar $\tilde S^{(p)}$ is odd under spatial parity and is built using the $\bar\Sigma$–Levi–Civita density $\varepsilon[\bar\Sigma]$ (Hodge dual on the realized weave configuration), while the vector projectors $A^{(\pm)}$ resolve *helicity* by diagonalizing the typed helicity operator H_τ:

$$\mathsf{H}_\tau A^{(\pm)} = \pm A^{(\pm)}, \qquad A^{(\pm)} = \tfrac{1}{2}\Big(\mathbf{1}_\tau \pm \mathsf{H}_\tau\Big), \tag{10.7}$$

with parity action recorded in Definition 10.58. Parity leaves $S^{(b)}, S^{(L)}$ invariant, flips $\tilde S^{(p)} \mapsto -\tilde S^{(p)}$, and swaps $A^{(+)} \leftrightarrow A^{(-)}$.

TT-null property and stability. All τ–typed projectors are *TT-null* with respect to the background-covariant TT projector $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ of Definition 10.3:

$$\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,X = 0, \qquad X \in \{S^{(b)}, S^{(L)}, \tilde S^{(p)}, A^{(+)}, A^{(-)}\}, \tag{10.8}$$

and TT-nullity propagates through typed mixing as in Lemma 10.123 (see also Corollary 10.125). Commutation with the certified band/typed structure is summarized in Proposition 10.9, and invariance on the realized weave configuration is stated in Proposition 10.10.

On the meaning of CP and its role in the $\Theta\Theta$ scalar subspace. Throughout this chapter, *CP* denotes the standard combined charge–conjugation and parity transformation ($\mathsf{C} \times \mathsf{P}$) familiar from quantum field theory; it is not a symbol introduced ad hoc for the present framework. Within the scalar subspace of the $\Theta\Theta$ block, an abstract, involutive operator CP is taken to act as a symmetry of the rigged calculus, with $\mathsf{CP}^2 = \mathbf{1}_{\mathrm{sc}}$. This structure allows the scalar sector to be decomposed into CP-even and CP-odd components by means of idempotent projectors that extract the corresponding eigenspaces of CP, consistently with the typed weave algebra and the commutation-stability properties recorded earlier (Proposition 10.9 and Definition 9.116).

Projectors onto CP eigen-subspaces and state classification. In the scalar subspace, the CP projectors are introduced algebraically by

$$\Pi^{(\mathrm{CP}\pm)} \;=\; \tfrac{1}{2}(\mathbf{1}_{\mathrm{sc}} \pm \mathsf{CP})\,, \qquad \Pi^{(\mathrm{CP}+)} + \Pi^{(\mathrm{CP}-)} = \mathbf{1}_{\mathrm{sc}}, \quad \Pi^{(\mathrm{CP}\pm)}\Pi^{(\mathrm{CP}\mp)} = 0,$$

so that a scalar state $|\phi\rangle$ is CP-even precisely when $\mathsf{CP}\,|\phi\rangle = +\,|\phi\rangle$ (equivalently $\Pi^{(\mathrm{CP}+)}\,|\phi\rangle = |\phi\rangle$) and CP-odd when $\mathsf{CP}\,|\phi\rangle = -\,|\phi\rangle$ (equivalently $\Pi^{(\mathrm{CP}-)}\,|\phi\rangle = |\phi\rangle$); orthogonality and closure are summarized in Lemma 10.45. In a local field representation, for a possibly complex scalar $\Theta(x)$ one may take

$$(\mathsf{CP})\,\Theta(t,\mathbf{x})\,(\mathsf{CP})^{-1} \;=\; \eta_{\mathrm{CP}}\;\Theta^{*}(t,-\mathbf{x}), \qquad \eta_{\mathrm{CP}} \in \{+1,-1\},$$

where $\eta_{\mathrm{CP}} = +1$ yields a CP-even (scalar) and $\eta_{\mathrm{CP}} = -1$ a CP-odd (pseudoscalar) transformation law. For neutral/real radial modes, C reduces to complex conjugation and the classification effectively coincides with parity even/odd; the full CP labelling is nevertheless retained to accommodate charged or multi-field Higgs-like sectors without modification.

CP refinement of the radial typed subspace and diagnostics. The radial typed projector in the scalar channel is refined by the CP idempotents to

$$\Pi_{\Theta}^{[\mathrm{rad}\pm]} \;:=\; \Pi_{\Theta}^{[\mathrm{rad}]}\,\Pi^{(\mathrm{CP}\pm)},$$

with $\Pi^{(\mathrm{CP}\pm)}$ commuting with the provenance projectors $\Pi^{(a)}$ and typed idempotents, ensuring compatibility with the realized weave configuration (Proposition 10.9 and Definition 9.116). A CP-pure radial excitation has support entirely in one of these images (e.g. $\Pi_{\Theta}^{[\mathrm{rad}+]}\,|\phi\rangle = |\phi\rangle$, $\Pi_{\Theta}^{[\mathrm{rad}-]}\,|\phi\rangle = 0$ for CP-even), while deviations from purity are quantified by the CP-asymmetry diagnostic introduced later (Definition 10.51). These considerations motivate the following definition.

Definition 10.5 (Higgs (radial) CP-refined projectors)**.** In the scalar subspace of the $\Theta\Theta$ block, let $\Pi^{(\mathrm{CP}\pm)}$ commute with $\Pi^{(a)}$ and with typed idempotents (commutation stability Proposition 10.9 and Definition 9.116). Motivated by the CP-even/odd splitting of scalar

excitations in Higgs-like sectors [14, 82, 97, 96, 98, 465, 466, 467], we refine the radial type (Ch. 10 physics layer) by

$$\Pi_{\Theta}^{[\mathrm{rad}\pm]} := \Pi_{\Theta}^{[\mathrm{rad}]}\,\Pi^{(\mathrm{CP}\pm)}, \qquad \Pi^{(\mathrm{CP}+)} + \Pi^{(\mathrm{CP}-)} = \mathbf{1}_{\mathrm{sc}}, \quad \Pi^{(\mathrm{CP}\pm)}\Pi^{(\mathrm{CP}\mp)} = 0.$$

Orthogonality and CP-purity are recorded in Lemma 10.45; the CP-asymmetry diagnostic is Definition 10.51. In particular, $\Pi^{(\mathrm{CP}+)}$ ($\Pi^{(\mathrm{CP}-)}$) selects CP-even (CP-odd) scalar modes within the radial typed subspace, in the sense standard in Higgs phenomenology [466, 467].

CP-purity and CP eigenstates. Within the scalar subspace of the $\Theta\Theta$ block, the idempotents $\Pi^{(\mathrm{CP}\pm)}$ in Definition 10.5 select *CP eigenstates* of the abstract CP operator CP: CP-even states satisfy $\mathsf{CP}\,|\phi\rangle = +\,|\phi\rangle$ and are isolated by $\Pi^{(\mathrm{CP}+)}$, while CP-odd states satisfy $\mathsf{CP}\,|\phi\rangle = -\,|\phi\rangle$ and are isolated by $\Pi^{(\mathrm{CP}-)}$ (orthogonality/closure in Lemma 10.45). In our typed calculus this means a *CP-pure* radial excitation has support entirely in one of the projector images, e.g. $\Pi_{\Theta}^{[\mathrm{rad}+]}\,|\phi\rangle = |\phi\rangle$ and $\Pi_{\Theta}^{[\mathrm{rad}-]}\,|\phi\rangle = 0$ for CP-even. This mirrors the standard Higgs-field decomposition into CP-even (scalar) and CP-odd (pseudoscalar) components used in QFT and Higgs phenomenology [14, 82, 97, 96, 98, 465, 466, 467].

CP asymmetry and why it matters. The *CP-asymmetry* diagnostic of Definition 10.51 quantifies departures from CP-purity by measuring the imbalance or interference between the $\Pi^{(\mathrm{CP}+)}$ and $\Pi^{(\mathrm{CP}-)}$ components; it vanishes iff the state (or correlator) is CP-pure and becomes nonzero when CP-violating mixing is present (yet remains well-defined thanks to the commutation stability in Proposition 10.9). Physically, CP-even vs. CP-odd composition controls selection rules and characteristic angular correlations in production/decay channels, while a nonzero asymmetry encodes genuine CP violation in the scalar sector—precisely the effect scrutinized in Higgs-like theories and their extensions [466, 467]. In our framework, refining the radial projector to $\Pi_{\Theta}^{[\mathrm{rad}\pm]}$ isolates these features at the operator level, ensuring that CP properties are tracked consistently across the realized weave configuration and downstream witnesses.

Riesz selectors for typed spin content: purpose and construction. The objective is to isolate the linearized dynamics carried by the helicity–2 (spin–2, TT/graviton) and spin–0 (radial/Higgs-like) channels within the certified band of the instrumentation $\mathcal{I}^{[\mathscr{S}]}$. This is achieved via the Riesz (holomorphic) functional calculus: given a closed kinetic operator K and an isolated spectral component ("spectral island") whose boundary lies in the resolvent set, the contour integral of the resolvent $(K - z)^{-1}$ defines the bounded projector onto the corresponding invariant spectral subspace. Summing such Riesz projectors over all spectral islands assigned to a given spin class (within the band) yields the *total spectral selector* for that class; measurability and invariance on the realized weave configuration follow from the stability statements recorded earlier (Definition 10.1, Propositions 10.10 and 10.149, and Lemma 10.137).

Spin–2 versus spin–0 carriers and compatibility with the weave. In this chapter, the spin–2 selector is constructed from the Gaiamiti kinetic operator $K_{\Phi\Phi}$, while the spin–0 selector is

constructed from the scalar sub-block $K^{(0)}_{\Theta\Theta}$ of the Tantrakyma sector; both are implicitly band-limited on $\mathcal{I}^{[\mathscr{S}]}$. Because these selectors are defined by holomorphic functional calculus, they commute with the BRST/physical projector $\mathsf{P}_{\mathrm{phys}}$, the provenance (spec/vac/corr) projectors, and the typed idempotents of the weave algebra (Proposition 10.9 and Definition 9.116). This guarantees compatibility with the TT/Higgs witnesses and with Källén–Lehmann positivity in the sense summarized in eq. (7.12) (see also the pre-physics analogue in Ch. 9).

Spectral islands. In this chapter, "spectral islands" are the isolated pieces of the spectrum of the relevant kinetic operators that are singled out by the realized weave configuration band (cf. Definition 10.1). Each such piece is separated from the remainder of the spectrum by a nonzero gap that lies entirely in the resolvent set, so a closed contour can be drawn around it without crossing any spectral points. The Riesz (holomorphic) functional calculus then associates to each island a bounded projector onto the invariant subspace carried by that portion of the spectrum; summing over the islands assigned to a given spin class yields the corresponding *spectral selector* (cf. Definition 10.7).

Operator-theoretically, let K be a closed operator with spectrum $\sigma(K)$ and resolvent set $\rho(K) = \mathbb{C} \setminus \sigma(K)$. Inside the certified band (determined by $\mathcal{I}^{[\mathscr{S}]}$ of Definition 10.1), consider connected components of $\sigma(K)$ that admit a positively oriented simple closed contour $\gamma \subset \rho(K)$ enclosing only that component. For such components, the Riesz integral $\frac{1}{2\pi i} \oint_\gamma (K - z)^{-1}\, dz$ yields an idempotent that projects onto the invariant subspace supported by the enclosed spectral portion (cf. Definition 10.7). In the purely discrete case, an island may reduce to a finite set of isolated eigenvalues; in the self-adjoint continuous case, it may be a compact interval separated by a gap; the definition covers both and extends to non-normal operators.

In the weave calculus, "helicity-2 islands" of $K_{\Phi\Phi}$ and "spin-0 islands" of $K^{(0)}_{\Theta\Theta}$ are those connected spectral components within the certified band whose invariant subspaces carry, respectively, TT (spin-2) and radial/Higgs (spin-0) typed content—compatibly with the commuting provenance and typed projectors (cf. Definitions 10.3 and 10.5 and Proposition 10.9). The symbols γ_i and Γ_j denote the enclosing contours of these components; the index sets $\mathfrak{S}_2$ and $\mathfrak{S}_0$ range over the corresponding families of components (one index per island; cf. Definition 10.7).

Definition 10.6 (Spectral islands (band-limited))**.** Let K be a closed operator on a Hilbert space with spectrum $\sigma(K)$ and resolvent set $\rho(K)$. Fix a certified band (from $\mathcal{I}^{[\mathscr{S}]}$, cf. Definition 10.1) and set $\sigma_{\mathrm{band}}(K) := \sigma(K) \cap \mathrm{band}$. A *spectral island* of K (within the band) is a connected subset $S \subset \sigma_{\mathrm{band}}(K)$ for which there exists a positively oriented simple closed contour $\gamma \subset \rho(K)$ such that: (i) S is contained in the bounded component of $\mathbb{C} \setminus \gamma$; (ii) $\sigma(K) \cap \mathrm{int}(\gamma) = S$. The associated Riesz projector is $P_S := \frac{1}{2\pi i} \oint_\gamma (K - z)^{-1}\, dz$, which is idempotent and projects onto the invariant subspace supported by S (cf. Definition 10.7). For disjoint islands S_α, the projectors $\{P_{S_\alpha}\}$ are mutually orthogonal and $\sum_\alpha P_{S_\alpha}$ (finite or strongly convergent) projects onto $\bigcup_\alpha S_\alpha$ (cf. Definition 10.7).

Meaning of the summations and contour symbols. The index sets $\mathfrak{S}_2$ and $\mathfrak{S}_0$ label the *connected spectral components* (spectral islands, Definition 10.6) of $K_{\Phi\Phi}$ and $K^{(0)}_{\Theta\Theta}$ that are assigned—by the typing rules and the certified band—to the spin–2 and spin–0 classes,

respectively (cf. Definitions 10.1, 10.3 and 10.5 and Proposition 10.9). The sums $\sum_{i\in\mathfrak{S}_2}$ and $\sum_{j\in\mathfrak{S}_0}$ are therefore sums *over islands*, not over spacetime indices or eigenvalue multiplicities. For each island, γ_i (helicity–2) and Γ_j (spin–0) denote positively oriented (counterclockwise) closed contours in the complex plane that enclose exactly that island and no other part of the spectrum; outside the enclosed set, the contour lies in the resolvent region (cf. Definition 10.7). The integrands $(K_{\Phi\Phi}-z)^{-1}$ and $(K^{(0)}_{\Theta\Theta}-z)^{-1}$ are the corresponding resolvents (cf. Definition 10.7). The Riesz integral $\frac{1}{2\pi i}\oint_{\gamma_i}\cdot\,dz$ (and analogously over Γ_j) yields an idempotent projector onto the invariant subspace of the enclosed island; for disjoint islands these projectors are mutually orthogonal, and their finite (or strongly convergent countable) sum projects onto the union of those spectral pieces (cf. Definition 10.7). Band limitation typically ensures that only finitely many islands contribute within $\mathcal{I}^{[\mathscr{J}]}$ (cf. Definition 10.1).

Intuition and downstream use. In purely discrete situations, each contour encloses one or finitely many eigenvalues and the Riesz projector reduces to the sum of the associated eigenprojectors. The present construction is preferred because it remains valid under continuous spectrum, non-normality, and admissible perturbations on the certified plateau $\mathfrak{P}$. The selectors $\mathsf{P}^{(2)}_{\mathrm{spec}}$ and $\mathsf{P}^{(0)}_{\mathrm{spec}}$ thus provide coordinate- and gauge-independent operator-level filters for the TT (graviton) and Higgs-radial (scalar) channels used in the TT/Higgs witnesses and in the typed propagator machinery (Section 10.9.5). These considerations motivate the following definition.

Definition 10.7 (Riesz spectral selectors (spin-2 and spin-0))**.** Let $K_{\Phi\Phi}$ be the linearized, gauge-fixed kinetic operator in the gaiamiti sector and $K^{(0)}_{\Theta\Theta}$ the scalar sub-block in the tantrakyma sector (both band-limited on $\mathcal{I}^{[\mathscr{J}]}$; Definition 10.1 and Proposition 10.10). Define the (Riesz) spectral projectors via the holomorphic functional calculus [115, 253]:

$$\mathsf{P}^{(2)}_{\mathrm{spec}} := \sum_{i\in\mathfrak{S}_2}\frac{1}{2\pi i}\oint_{\gamma_i}\Big(K_{\Phi\Phi}-z\Big)^{-1}dz, \qquad \mathsf{P}^{(0)}_{\mathrm{spec}} := \sum_{j\in\mathfrak{S}_0}\frac{1}{2\pi i}\oint_{\Gamma_j}\Big(K^{(0)}_{\Theta\Theta}-z\Big)^{-1}dz,$$

for contours γ_i,Γ_j enclosing helicity-2 and spin-0 spectral islands on the certified band (measurability/invariance Proposition 10.149 and Lemma 10.137; Källén–Lehmann positivity eq. (7.12) as standard in QFT [14, 255, 230, 82, 244]). (For the pre-physics analogue, see Ch. 9.) By functional calculus, these projectors commute with $\mathsf{P}_{\mathrm{phys}}$, the triad projectors, and the typed idempotents (Proposition 10.9) and are used in the TT/Higgs witness entries (Section 10.9.5).

Structural facts.

Lemma 10.8 (Orthogonality and completeness on the τ–kairos block)**.** *Let*

$$\mathcal{S}_\tau := \{S^{(b)},\, S^{(L)},\, \tilde{S}^{(p)}\}, \qquad \mathcal{A}_\tau := \{A^{(+)},\, A^{(-)}\}$$

be the τ–typed projectors of Definition 10.4 on the realized weave configuration $\mathcal{I}^{[\mathscr{J}]}$; see also the typed layer Definition 9.116. On the τ–typed carrier, the following relations hold:

$$S^{(i)}S^{(j)}=\delta_{ij}S^{(i)}, \qquad A^{(\lambda)}A^{(\lambda')}=\delta_{\lambda\lambda'}A^{(\lambda)}, \qquad S^{(i)}A^{(\lambda)}=0,$$

for all $S^{(i)}, S^{(j)} \in \mathcal{S}_\tau$ *and* $A^{(\lambda)}, A^{(\lambda')} \in \mathcal{A}_\tau$*, and the completeness relation*

$$\sum_{i\in\{b,L,p\}} S^{(i)} + \sum_{\lambda=\pm} A^{(\lambda)} = \mathbf{1}_\tau.$$

Proof. Notation. Let $\mathcal{H}_\tau$ denote the τ–typed carrier Hilbert space on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ with inner product $\langle\cdot,\cdot\rangle_{\bar\Sigma}$. For a linear map $P : \mathcal{H}_\tau \to \mathcal{H}_\tau$, write the range or image is

$$\operatorname{Ran} P \;:=\; \{\, v \in \mathcal{H}_\tau :\; \exists\, u \in \mathcal{H}_\tau \text{ with } v = Pu \,\}$$

for the *range (image)* subspace of P (and, when needed, $\ker P := \{u :\; Pu = 0\}$ for its kernel).

Idempotence and intra-family orthogonality. By Definition 10.4, the maps $S^{(b)}, S^{(L)}, \tilde S^{(p)}$ (scalar sub-block) and $A^{(+)}, A^{(-)}$ (helicity-resolved vector sub-block) are typed projectors on $\mathcal{H}_\tau$: they are idempotent and $\bar\Sigma$–Hermitian, and are mutually orthogonal within their respective families (typed algebra on the band; see also Ch. 10 Definition 9.116). Hence $S^{(i)}S^{(j)} = \delta_{ij}S^{(i)}$ and $A^{(\lambda)}A^{(\lambda')} = \delta_{\lambda\lambda'}A^{(\lambda)}$. Equivalently, for $i \neq j$ (resp. $\lambda \neq \lambda'$), $\operatorname{Ran} S^{(i)} \perp \operatorname{Ran} S^{(j)}$ (resp. $\operatorname{Ran} A^{(\lambda)} \perp \operatorname{Ran} A^{(\lambda')}$).

Scalar–vector orthogonality. The τ–typed carrier splits (typed block decomposition, Ch. 10 Definition 9.116) into an orthogonal direct sum of a scalar subspace and a vector (Chrono–Kymon) subspace. Each $S^{(i)}$ projects into the scalar subspace, while each $A^{(\lambda)}$ projects into the vector subspace. These carrier spaces are orthogonal in $\langle\cdot,\cdot\rangle_{\bar\Sigma}$, so $S^{(i)}A^{(\lambda)} = 0$, and hence $\operatorname{Ran} S^{(i)} \perp \operatorname{Ran} A^{(\lambda)}$.

Completeness. The typed decomposition further refines the scalar subspace as $\operatorname{Ran} S^{(b)} \oplus \operatorname{Ran} S^{(L)} \oplus \operatorname{Ran} \tilde S^{(p)}$ and the vector subspace as $\operatorname{Ran} A^{(+)} \oplus \operatorname{Ran} A^{(-)}$. Thus,

$$\mathcal{H}_\tau = \operatorname{Ran} S^{(b)} \;\oplus\; \operatorname{Ran} S^{(L)} \;\oplus\; \operatorname{Ran} \tilde S^{(p)} \;\oplus\; \operatorname{Ran} A^{(+)} \;\oplus\; \operatorname{Ran} A^{(-)}.$$

Equivalently, for every $v \in \mathcal{H}_\tau$, $v = \Big(\sum_{i\in\{b,L,p\}} S^{(i)} + \sum_{\lambda=\pm} A^{(\lambda)}\Big)v$, which yields the projector identity $\sum_{i\in\{b,L,p\}} S^{(i)} + \sum_{\lambda=\pm} A^{(\lambda)} = \mathbf{1}_\tau$.

All statements hold on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$, and the projectors commute with the band/BRST machinery by Propositions 10.9 and 10.10, ensuring stability under triad sandwiches and audit moves. □

Audit moves. Let $\mathfrak{A}_{\text{audit}}$ be the unital *-algebra generated on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ by

$$\mathsf{P}_{\text{phys}},\; P_x(\lambda_{\text{UV}}),\; K^{(\ell)}_{\text{IR}},\; \Pi^{(\text{spec})}, \Pi^{(\text{vac})}, \Pi^{(\text{corr})},\; S^{(b)}, S^{(L)}, \tilde S^{(p)}, A^{(\pm)},\; \Pi^{[\text{TT}]}_{\bar\Sigma},\; \Pi^{(\text{CP}\pm)},\; \mathsf{P}^{(2)}_{\text{spec}},\; \mathsf{P}^{(0)}_{\text{spec}},$$

subject to the commutation–stability relations of Proposition 10.9. An *audit move* is any $M \in \mathfrak{A}_{\text{audit}}$ acting by composition or sandwiching on operators/states (e.g. $O \mapsto MOM$, $v \mapsto Mv$). For every such M, the projector algebra on the τ block is stable:

$$S^{(i)}S^{(j)} = \delta_{ij}S^{(i)}, \quad A^{(\lambda)}A^{(\lambda')} = \delta_{\lambda\lambda'}A^{(\lambda)}, \quad S^{(i)}A^{(\lambda)} = 0, \quad \sum_{i\in\{b,L,p\}} S^{(i)} + \sum_{\lambda=\pm} A^{(\lambda)} = \mathbf{1}_\tau,$$

and the same identities hold after left/right insertions of M. In particular, "triad sandwiches" are the special case $M = \Pi^{(a)}$ with $a \in \{\text{spec}, \text{vac}, \text{corr}\}$.

Proposition 10.9 (Commutation with triad and TT)**.** *On the realized weave configuration* $\mathcal{I}^{[\mathcal{S}]}$ *(Def. Definition 10.1), every* typed *idempotent* $\Pi^{[\chi]}$ *(Ch. 10 typed layer Definition 9.116; concretely* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$*,* $\{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}$ *from Definition 10.4, and* $\Pi^{[\mathrm{rad}\pm]}_{\Theta}$ *from Definition 10.5) commutes with each triad projector* $\Pi^{(a)}$ *(*$a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$*; Definition 10.2):*

$$[\Pi^{(a)}, \Pi^{[\chi]}] = 0 \qquad (a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}).$$

Moreover, every τ*–kairos type is* TT–null*:*

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} X = 0, \qquad X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\} \quad (\textit{Definition 10.4}). \tag{10.9}$$

Proof. **(A) Preliminaries on the realized weave configuration and selectors.** By instrumentation hygiene (Proposition 10.10), the band tags P_x and IR windows $K^{(\ell)}_{\mathrm{IR}}$ are idempotent contractions commuting with the BRST projector $\mathsf{P}_{\mathrm{phys}}$, so all sandwiched operators live on $\mathcal{H}_{\mathrm{phys}} = \operatorname{Ran} \mathsf{P}_{\mathrm{phys}}$ with a bounded holomorphic functional calculus. The triad maps $\Pi^{(a)}$ are Riesz projectors determined by certified contours (triad provenance; Definitions 10.2 and 10.7 and Proposition 10.149).

(B) Commutation with triads. Each triad projector is a contour integral of the resolvent of the (band–limited, gauge–fixed) kinetic operator on the corresponding block (spin-2, 0, or the typed vector block; Definition 10.7 and Proposition 10.149). Typed idempotents $\Pi^{[\chi]}$ (TT, τ–types, Higgs–CP) are obtained fiberwise from symmetry generators (transverse/trace, parity, helicity, CP) and lifted as $\bar{\Sigma}$–Hermitian idempotents stable on the band (Ch. 10 Definition 9.116; instantiated in Definitions 10.3 to 10.5). By construction they commute with the relevant kinetic operators on the realized weave configuration (typed stability; Definition 9.116, item (P7)); hence they commute with each resolvent $(K - z)^{-1}$ and therefore with its Riesz integral. Thus $[\Pi^{(a)}, \Pi^{[\chi]}] = 0$ for all a and all typed $\Pi^{[\chi]}$.

(C) TT–nullity for τ types. Equation (10.9) is stated in Definition 10.4: the τ–typed projectors map into scalar/vector carriers orthogonal (w.r.t. $\langle \cdot, \cdot \rangle_{\bar{\Sigma}}$) to the TT subspace, and the background–covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Ch. 7 Definition 10.3) annihilates traces/divergences, hence the τ images. Orthogonality within the τ–block is recorded in Lemma 10.8; TT–null preservation across any τ–involving channel is in Lemma 10.123, with the graviton readout invariance in Corollary 10.125.

All equalities hold on $\mathcal{I}^{[\mathcal{S}]}$ and are preserved under admissible retunes and arena switches by Propositions 10.10 and 10.149. □

Meaning and importance. Proposition Proposition 10.9 asserts that, on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Definition 10.1), the *spectral bookkeeping* provided by the triad projectors $\Pi^{(a)}$ (Definition 10.2) is compatible with all *typed* decompositions used operationally—namely the background–covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3), the τ–kairos types $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}$ (Definition 10.4), and the Higgs CP-refined radial projectors $\Pi^{[\mathrm{rad}\pm]}_{\Theta}$ (Definition 10.5). The commutators $[\Pi^{(a)}, \Pi^{[\chi]}] = 0$ guarantee that *typing* (trace/transverse, parity, helicity, CP) and *spectral triage* (spec/vac/corr) may be performed in either order without changing outcomes. Practically, this removes order-of-operations ambiguities in witness extraction and channel isolation, ensuring that TT graviton readouts, τ–typed diagnostics, and CP analyses are all computed on the same block-diagonal stage of the

theory and remain stable under the band/arena hygiene of Proposition 10.10. The second clause—TT–nullity (10.9)—establishes a strict separation between the τ–typed scalar/vector carriers and the TT graviton subspace, preventing spurious leakage of non-TT content into spin-2 observables (cf. TT purity in Definition 10.3 and its use downstream in TT/Higgs witnesses, Section 10.9.5).

Why the proof matters. The proof reduces the commutation statement to the *holomorphic functional calculus*: each triad projector is a Riesz selector of a band-limited, gauge-fixed kinetic operator (Definition 10.7 and Proposition 10.149), while each typed idempotent $\Pi^{[\chi]}$ is constructed to commute with those kinetic blocks on the realized weave configuration (typed stability; Ch. 10 Definition 9.116). Commutation with resolvents implies commutation with their contour integrals, giving $[\Pi^{(a)}, \Pi^{[\chi]}] = 0$. TT–nullity then follows from the defining action of $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$—which annihilates traces/divergences—together with the geometry of the τ–typed images and its preservation under typed mixing (Lemma 10.123 and Corollary 10.125). Conceptually, these steps certify that our decomposition is not merely convenient but *mathematically rigid*: spectral selection, typing, and TT extraction cohere on $\mathcal{I}^{[\mathscr{S}]}$, so that all subsequent constructions (e.g., graviton-channel isolation and CP diagnostics) inherit consistency and robustness from the realized weave configuration-level algebra.

Proposition 10.10 (BRST/Nielsen flatness and band–covariance)**.** *Let $\mathcal{J}$ be any finite composition of*

$$\mathsf{P}_{\mathrm{phys}},$$
$$\Pi^{(a)} \ (a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}) \ \textit{(Definition 10.2)},$$
$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \ \textit{(Definition 10.3)},$$
$$\textit{typed projectors } X \ \textit{(Definitions 10.4 and 10.5)},$$

and Riesz spectral projectors $\mathsf{P}^{(s)}_{\mathrm{spec}}$ ($s \in \{0, 2\}$; Definition 10.7), all evaluated on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1). Then for any $\mathcal{J}$–projected observable $\mathcal{O}$ and any physical state on $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$, the correlation functions $\langle \mathcal{J}\mathcal{O}\rangle_{\mathcal{H}_{\mathrm{phys}}}$ are

(i) gauge–parameter independent *(Nielsen flat) on shell; and*

(ii) stable under admissible retunes (P_x, K_{IR}) *within the certified class (including IR–tightening, spectral–window refinement, and arena switch), i.e. they vary continuously and remain uniformly bounded along admissible paths.*

Proof. **(i) Nielsen flatness.** Let ξ denote a gauge parameter of the gauge–fixed kinetic operators and correlators. By the BRST/Nielsen identity (embedded form, see Ch. 8 and Prop. 7.174 used throughout), one has for any (sufficiently regular) observable $\mathcal{A}$

$$\partial_\xi \langle \mathcal{A}\rangle_{\mathcal{H}_{\mathrm{phys}}} = \langle [\hat{Q}_{\mathrm{BRST}}, \mathcal{K}_\xi]\, \mathcal{A}\rangle_{\mathcal{H}_{\mathrm{phys}}} + \langle \mathrm{EOM}_\xi(\mathcal{A})\rangle_{\mathcal{H}_{\mathrm{phys}}},$$

with $\hat{Q}_{\mathrm{BRST}}$ nilpotent and EOM_ξ vanishing on shell. Choose $\mathcal{A} = \mathcal{J}\mathcal{O}$ with $\mathcal{J}$ as in the statement. By typed stability on the realized weave configuration (Ch. 10 Definition 9.116, item (P7)) and commutation of typed/triad/Riesz projectors with the band operators

(Prop. 10.9 and functional–calculus commutation for Riesz selectors Definition 10.7 and Proposition 10.149), all components of $\mathcal{J}$ are BRST–closed on $\mathcal{H}_{\text{phys}}$. Hence the BRST–exact term has vanishing expectation, and the EOM term vanishes on shell; therefore $\partial_\xi \langle \mathcal{J}\mathcal{O}\rangle_{\mathcal{H}_{\text{phys}}} = 0$. This establishes Nielsen flatness.

(ii) Band–covariance and stability under retunes. Consider an admissible path of retunes $t \mapsto (P_x(t), K_{\text{IR}}^{(\ell(t))}, \text{Loc}(t))$ as in Def. 10.101. By instrumentation hygiene (band/BRST compatibility), Chs. 7–8, and Prop. 10.149, the resolvents $(K - z)^{-1}$ vary norm–continuously along t on the certified contours, so the associated Riesz projectors vary norm–continuously as Bochner integrals. Typed/triad idempotents are fixed (or vary continuously if parametrized) and commute with the band tags (Definitions 10.2 to 10.5, Prop. 10.9). Thus $t \mapsto \mathcal{J}(t)$ is norm–continuous on $\mathcal{H}_{\text{phys}}$.

Let $\|\cdot\|_{\mathcal{I}}$ be any admissible band–invariant norm (Def. 10.143). By equivalence across the family $\mathfrak{N}$ (Prop. 10.147), there are rig–dependent constants $c_\pm$ such that norms along different admissible choices are uniformly comparable; IR–tightening is contractive in these norms (Prop. 10.147, last clause). Therefore $\|\mathcal{J}(t) - \mathcal{J}(t_0)\|_{\mathcal{I}} \to 0$ as $t \to t_0$. Since correlation functionals are continuous with respect to the operator norm on $\mathcal{H}_{\text{phys}}$ (trace–class/HS bounds inherited from the realized weave configuration; see also the calibrated meters' finiteness Lem. 10.83), it follows that $\langle \mathcal{J}(t)\mathcal{O}\rangle_{\mathcal{H}_{\text{phys}}} \to \langle \mathcal{J}(t_0)\mathcal{O}\rangle_{\mathcal{H}_{\text{phys}}}$ along any admissible retune, and the correlators remain uniformly bounded along the path.

Finally, arena switches preserve the certified spectral set and the Riesz projectors (Lemma 10.137); hence $\mathcal{J}$ is unchanged up to the continuous variations already controlled above. This proves stability under all admissible retunes in the certified class. □

Corollary 10.11 (Gauge/retune invariance of visibilities and onsets)**.** *For any sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and admitted type $[\chi]$, the calibrated visibilities $\Lambda_{\text{law}}^{[\mathscr{S};\chi]}$, $\Lambda_{\text{state}}^{[\mathscr{S};\chi]}$ (Def. Definition 10.82) and the certified onset $r^\star[\chi]$ (Def. Definition 10.85) are:*

(i) Gauge–parameter independent *(Nielsen–flat) on shell; and*

(ii) Stable under admissible retunes $(P_x, K_{\text{IR}}, \text{Loc})$ *in the certified class (continuous in those parameters and uniformly bounded along admissible paths).*

In particular, all diagnostic entries used for SynTh/Audit (e.g. ε, Δ_P, Δ_{CP}; Definition 10.80 and Remark 10.81) inherit the same invariance, and threshold crossings are unaffected by a change of gauge.

Proof. Each component of the law residual vector $\mathbf{R}^{[\mathscr{S};\chi]}$ and state feature vector $\mathbf{S}^{[\mathscr{S};\chi]}$ (Def. Definition 10.80) is computed by applying BRST/typed/triad/Riesz projectors to the kinetic objects and then taking a band–invariant norm from the admissible family $\mathfrak{N}$ (Def. Definition 10.143). Therefore all meters/visibilities are functionals of $\mathcal{J}$–projected observables with $\mathcal{J}$ a finite composition of P_{phys}, $\Pi^{(a)}$, $\Pi_{\bar{\Sigma}}^{[\text{TT}]}$, typed projectors, and Riesz selectors (exactly the class covered by Proposition 10.10).

Gauge independence. By Proposition 10.10(i) (Nielsen flatness of $\mathcal{J}$–projected correlators) together with the calibration maps being fixed scalar functions (Def. Definition 10.82), each entry of $\mathbf{R}$ and $\mathbf{S}$, hence Λ_{law} and Λ_{state}, is independent of the gauge parameter ξ on shell. Consequently, the threshold inequalities in Definition 10.85 are gauge–invariant and so is $r^\star[\chi]$.

Stability under admissible retunes. By Proposition 10.149, resolvents vary Bochner–measurably and Riesz projectors vary continuously along admissible audit moves (Def. Definition 10.101); typed and triad idempotents commute and remain stable on the realized weave configuration (Prop. Proposition 10.9, Ch. 10 Definition 9.116). Thus $t \mapsto \mathcal{J}(t)$ is norm–continuous on $\mathcal{H}_{\text{phys}}$. Band–invariant norms from $\mathfrak{N}$ are equivalent and contractive under IR tightening (Defs. Definition 10.143, Prop. Proposition 10.147), so $\|\mathcal{J}(t) - \mathcal{J}(t_0)\|_{\mathcal{I}} \to 0$ and the corresponding ledger entries vary continuously and stay bounded. The calibrations f_j, g_m are C^1 and bounded/monotone (Def. Definition 10.82), hence the visibilities are continuous and bounded along the path. Therefore the superlevel sets in Definition 10.85 vary upper–semicontinuously, and, with the monotonicities in Lemma 10.102 and slope bounds in Proposition 10.88, the onset $r^\star[\chi] = \inf \mathcal{A}_{[\chi]}$ is stable under admissible retunes.

Finally, diagnostics $\varepsilon, \Delta_P, \Delta_{\text{CP}}$ enter as components of $\mathbf{S}$ (Remark 10.81); they are built from the same $\mathcal{J}$–projected objects and norms, hence inherit gauge independence and retune stability as above. □

Remark 10.12 (Why instrumentation-first)**.** By fixing the realized weave configuration $\mathcal{I}^{[\mathcal{F}]}$ (Def. Definition 10.1) and the typed algebra on the band (Ch. 10: Definition 9.116, instantiated in Definitions 10.3 to 10.5), every subsequent "object definition" (–kairos, graviton, Higgs, Chrono–Kymon) is a *projected object on* $\mathcal{H}_{\text{phys}} = \operatorname{Ran} \mathsf{P}_{\text{phys}}$. This ensures:

1. we never violate SynTh's "same instrumentation" clause—comparisons/audits are made on the *same* realized weave configuration (cf. Definitions 8.98 and 8.99);
2. every visibility/witness is BRST–clean and band/triad–covariant—ledgers/meters are built from $\mathcal{J}$–projected observables and admissible norms (Defs. Definitions 10.80, 10.82 and 10.143) and inherit Nielsen flatness and retune stability (Prop. Proposition 10.10); they also respect the provenance cones spec/vac/corr (triads; Definition 10.2);
3. future species (new poles, new types) are absorbed by *adding contours or idempotents*, never by rewriting prior equations: add Riesz contours/selectors (Defs./Props. Definition 10.7 and Proposition 10.149) or typed idempotents (typed stability/commutation Definition 9.116 and Proposition 10.9).

10.3 The τ-kairos Field

The Concept of Kairos

The ancient Greek word καιρός (kairos) encodes a conception of time more nuanced than mere duration. It does not denote *chronos* (χρόνος)—chronological, metrically accumulated time—but rather "the right moment," "the opportune time," or a "critical instant." In standard lexicography, *kairos* marks a qualitative, situationally charged now—a juncture whose value lies not in its quantitative length but in what may be realized within it [80]. It is the moment when conditions align for decisive action.

Etymological and Metaphorical Roots The proposed concrete roots of *kairos* emphasize precision, timing, and consequence. One prominent etymological line points to the "vital/fatal

spot" targeted by an archer, suggesting a critical locus in space–time where a single, well-timed action yields a definitive result [468]. Another widely discussed metaphor links *kairos* to weaving: it is the fleeting opening in the shed of the loom through which the weaver must pass the shuttle; a moment too early or too late tangles the thread and mars the pattern. From such physical images, the term becomes a general metaphor for briefly open windows of action in practical life, discourse, and design [469, 470].

Kairos vs. Chronos: A Necessary Distinction To grasp *kairos*, it helps to contrast it with *chronos*. The latter underwrites "chronology" and "chronometer" and refers to sequential, measurable, quantitative time: the ticking of a clock, the duration of an event, the linear succession of moments [80]. *Kairos*, by contrast, is opportune, qualitative, and circumstantial—the fitting time to speak, act, or decide. In our usage below, *chronos* concerns metric duration and sequentiality, while *kairos* concerns the conditions under which processes become phase-appropriate. Put simply, *chronos* is the time one measures; *kairos* is the time one seizes [469, 470].

In Rhetoric. From the Sophists through Plato and Aristotle, *kairos* is a cornerstone of rhetorical theory, signifying the tact of timing. Even a logically impeccable, elegantly phrased argument fails if ill-timed. For classical rhetoricians—including Isocrates—efficacy hinges on recognizing and seizing the opportune moment, adapting the message to the concrete circumstances of the hearers [471, 472].

In Mythology and Iconography (the Deity Kairos). Classical culture personified *Kairos* as the daemon of opportunity, an emblem of the critical instant. Lysippos famously depicted him as a fleet youth with winged feet, a forelock (to be grasped as he approaches), a razor (signifying decision), and a bald pate behind—once the moment passes, there is nothing to hold [473]. Our usage of "the Deity Kairos" is strictly in this classical, allegorical register.

Definitions. Throughout this section we work on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ of Definition 10.1, with triad projectors $\Pi^{(a)}$ from Definition 10.2, the background-covariant TT map $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ in Definition 10.3, and the typed τ-kairos idempotents of Definition 10.4. All statements are taken on $\mathcal{H}_{\mathrm{phys}} = \operatorname{Ran} \mathsf{P}_{\mathrm{phys}}$.

Definition 10.13 (τ-kairos decomposition)**.** The τ-kairos field is the orthogonal sum

$$\boxed{\hat{\tau}_{\mu\nu} = S^{(b)}_{\mu\nu}[\hat{\varphi}_b] \;\oplus\; S^{(L)}_{\mu\nu}[\hat{\varphi}_L] \;\oplus\; \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}] \;\oplus\; \sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}\big[\hat{K}^{(\tau)}_{\lambda}\big]} \tag{10.10}$$

with scalar amplitudes $\hat{\varphi}_b, \hat{\varphi}_L$, pseudoscalar $\tilde{\varphi}$, and helicity-resolved vector creators $\hat{K}^{(\tau)}_{\lambda}$. Each typed summand is $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$-null, cf. Definition 10.4.

Explanatory notes (objects and meaning).

- *Typed tensor-image maps.* $S^{(b)}_{\mu\nu}[\cdot]$, $S^{(L)}_{\mu\nu}[\cdot]$, $\tilde{S}^{(p)}_{\mu\nu}[\cdot]$, and $A^{(\lambda)}_{\mu\nu}[\cdot]$ are the τ-kairos typed maps of Definition 10.4 that take a scalar, pseudoscalar, or vector input (defined

on $\mathcal{H}_{\text{phys}}$) and return a τ-tensor on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$. They are idempotent/orthogonal at the level of types and preserve TT-nullity.

- $S^{(b)}_{\mu\nu}[\hat{\varphi}_b]$ *(scalar "breathing"/bulk piece).* The operator $\hat{\varphi}_b$ is a scalar (spin–0, CP-even) amplitude; $S^{(b)}_{\mu\nu}$ injects it into the τ-tensor with the "bulk/breathing" scalar pattern. This is part of the *Gaiaton* content (scalar sector).
- $S^{(L)}_{\mu\nu}[\hat{\varphi}_L]$ *(scalar longitudinal piece).* $\hat{\varphi}_L$ is a scalar (spin–0) longitudinal/coherence amplitude; $S^{(L)}_{\mu\nu}$ yields the corresponding τ-tensor image. Also Gaiaton (scalar sector).
- $\tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}]$ *(pseudoscalar piece).* $\tilde{\varphi}$ is CP-odd (spin–0) and maps via the pseudoscalar typed channel $\tilde{S}^{(p)}_{\mu\nu}$ to a τ-tensor image. This is the *Gaiaton* pseudoscalar branch.
- $\sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}[\hat{K}^{(\tau)}_{\lambda}]$ *(vector/helicity pieces).* $A^{(\lambda)}$ are the helicity projectors (spin–1, $\lambda = \pm 1$) in the τ-vector family; the operators $\hat{K}^{(\tau)}_{\lambda}$ are the helicity-resolved vector creators.[1] This entire block is the *Chrono–Kymon (CK)* content.
- *Orthogonal direct sum.* The symbol $\oplus$ denotes orthogonality with respect to the $\bar{\Sigma}$-weighted inner product on $\mathcal{H}_{\text{phys}}$: each typed image is orthogonal to the others; projector/idempotent relations ensure no double counting.
- *TT purity (no graviton in τ).* Each typed summand is annihilated by $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, hence $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$. The spin–2 TT graviton lives in the *tensor* sector and is excluded from the τ-kairos by construction (cf. Definition 10.3).
- *Triad provenance (optional bookkeeping).* With $\Pi^{(a)}$ from Definition 10.2, the triad-resolved field $\hat{\tau}^{(a)}_{\mu\nu} := \Pi^{(a)}\hat{\tau}_{\mu\nu}$ decomposes as the same typed sum but with triad-extracted inputs $\hat{\varphi}^{(a)}_b, \hat{\varphi}^{(a)}_L, \tilde{\varphi}^{(a)}, \hat{K}^{(\tau)(a)}_{\lambda}$.

Remark 10.14 (Expanded forms of the τ–decomposition)**.** Starting from the compressed orthogonal sum in Definition 10.13, Eq. (10.10), there are two equivalent expanded views on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$.

(1) Projector expansion (typed projectors on the raw field). By completeness and orthogonality of the τ–typed idempotents (Lemma 10.8),

$$\hat{\tau}_{\mu\nu} = \left(S^{(b)}\hat{\tau}\right)_{\mu\nu} + \left(S^{(L)}\hat{\tau}\right)_{\mu\nu} + \left(\tilde{S}^{(p)}\hat{\tau}\right)_{\mu\nu} + \left(A^{(+)}\hat{\tau}\right)_{\mu\nu} + \left(A^{(-)}\hat{\tau}\right)_{\mu\nu}, \tag{10.11}$$

i.e.

$$\boxed{\hat{\tau}_{\mu\nu} = S^{(b)}{}_{\mu\nu}{}^{\rho\sigma}\,\hat{\tau}_{\rho\sigma} + S^{(L)}{}_{\mu\nu}{}^{\rho\sigma}\,\hat{\tau}_{\rho\sigma} + \tilde{S}^{(p)}{}_{\mu\nu}{}^{\rho\sigma}\,\hat{\tau}_{\rho\sigma} + \sum_{\lambda=\pm} A^{(\lambda)}{}_{\mu\nu}{}^{\rho\sigma}\,\hat{\tau}_{\rho\sigma}\,.} \tag{10.12}$$

Thus $\oplus$ in (10.10) is the orthogonal (direct) sum on the realized weave configuration, and each summand is TT–null by construction (Def. 10.4, Eq. (10.8); see also Lemma 10.17).

(2) Amplitude/polarization expansion (explicit extractors/creators). Since each typed projector $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ is an idempotent onto its carrier, choose bounded "extractors" and "creators" giving a continuous splitting on the realized weave configuration:

scalars/pseudoscalar:	$\epsilon^{(i)\,\rho\sigma},\ \iota^{(i)}_{\mu\nu}\quad (i \in \{b, L, p\}),$	$\epsilon^{(i)}\iota^{(i)} = \mathrm{id},\quad \iota^{(i)}\epsilon^{(i)} = S^{(i)};$
vectors:	$\epsilon^{(\lambda)\,\rho\sigma}{}_{\alpha},\ \iota^{(\lambda)\alpha}_{\mu\nu}\quad (\lambda = \pm),$	$\epsilon^{(\lambda)}\iota^{(\lambda)} = \mathrm{id},\quad \iota^{(\lambda)}\epsilon^{(\lambda)} = A^{(\lambda)}.$

[1] Parity on the τ-vector subspace swaps helicities: $\mathcal{P}_\tau A^{(+)}\mathcal{P}_\tau^{-1} = A^{(-)}$ and vice versa.

Define the typed amplitudes by extraction,

$$\hat{\varphi}_b := \epsilon^{(b)\,\rho\sigma}\hat{\tau}_{\rho\sigma}, \quad \hat{\varphi}_L := \epsilon^{(L)\,\rho\sigma}\hat{\tau}_{\rho\sigma}, \quad \tilde{\varphi} := \epsilon^{(p)\,\rho\sigma}\hat{\tau}_{\rho\sigma}, \quad \hat{K}^{(\tau)}_{\lambda,\alpha} := \epsilon^{(\lambda)\,\rho\sigma}{}_{\alpha}\hat{\tau}_{\rho\sigma},$$

and reconstruct:

$$\boxed{\hat{\tau}_{\mu\nu} = \underbrace{\iota^{(b)}_{\mu\nu}\,\hat{\varphi}_b}_{S^{(b)}_{\mu\nu}[\hat{\varphi}_b]} + \underbrace{\iota^{(L)}_{\mu\nu}\,\hat{\varphi}_L}_{S^{(L)}_{\mu\nu}[\hat{\varphi}_L]} + \underbrace{\iota^{(p)}_{\mu\nu}\,\tilde{\varphi}}_{\tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}]} + \sum_{\lambda=\pm} \underbrace{\iota^{(\lambda)\alpha}_{\mu\nu}\,\hat{K}^{(\tau)}_{\lambda,\alpha}}_{A^{(\lambda)}_{\mu\nu}[\hat{K}^{(\tau)}_{\lambda}]}}. \tag{10.13}$$

Because $\iota^{(i)}\epsilon^{(i)} = S^{(i)}$ and $\iota^{(\lambda)}\epsilon^{(\lambda)} = A^{(\lambda)}$, (10.13) coincides with (10.11)–(10.12) and is *unique up to* basis changes inside each typed range (Lemma 10.18). Each term is TT–annihilated (Def. 10.4; Lemma 10.17), and all maps commute with triads (Prop. 10.9).

Triad compatibility. Applying the triad sandwich $\Pi^{(a)}$ ($a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$; Definition 10.2) to (10.11)–(10.13) gives the same formulas with $\hat{\tau}$ replaced by $\hat{\tau}^{(a)} := \Pi^{(a)}\hat{\tau}$, since $[\Pi^{(a)}, X] = 0$ for all typed X (Prop. 10.9).

Definition 10.15 (Triad-resolved τ-kairos components)**.** For $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$, define

$$\hat{\tau}^{(a)}_{\mu\nu} := \Pi^{(a)}\,\hat{\tau}_{\mu\nu} = \sum_{X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}} \left(\Pi^{(a)} X\right)_{\mu\nu}, \qquad \hat{\tau}_{\mu\nu} = \sum_{a} \hat{\tau}^{(a)}_{\mu\nu}, \tag{10.14}$$

where the sum uses the orthogonal decomposition of Lemma 10.8.

Definition 10.16 (Parity and helicity diagnostics on the τ-block)**.** Let $\mathcal{P}_\tau$ be the formal parity on the scalar/pseudoscalar subspace so that $\mathcal{P}_\tau S^{(b)}\mathcal{P}_\tau^{-1} = S^{(b)}$, $\mathcal{P}_\tau S^{(L)}\mathcal{P}_\tau^{-1} = S^{(L)}$, $\mathcal{P}_\tau \tilde{S}^{(p)}\mathcal{P}_\tau^{-1} = -\tilde{S}^{(p)}$. On the vector channel, $\mathcal{P}_\tau A^{(+)}\mathcal{P}_\tau^{-1} = A^{(-)}$, $\mathcal{P}_\tau A^{(-)}\mathcal{P}_\tau^{-1} = A^{(+)}$. Define the (law/state) *parity-asymmetry audit*

$$\Delta_P^{[\mathrm{law/state}]} := \Lambda^{[A^{(+)}]}_{\mathrm{law/state}} - \Lambda^{[A^{(-)}]}_{\mathrm{law/state}}, \tag{10.15}$$

to be evaluated with the typed witnesses of Definitions 10.80 and 10.82.

Structural facts.

Lemma 10.17 (TT-purity of the τ–kairos)**.** $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0$ *and* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}^{(a)}_{\mu\nu} = 0$ *for each* $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$.

Proof. Work on the realized weave configuration $\mathcal{I}^{[\mathcal{J}]}$ (Def. Definition 10.1). On the τ–typed carrier, the orthogonal idempotents $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}$ (Def. Definition 10.4) satisfy the completeness/orthogonality relations

$$\sum_{i \in \{b,L,p\}} S^{(i)} + \sum_{\lambda=\pm} A^{(\lambda)} = \mathbf{1}_\tau, \qquad S^{(i)}S^{(j)} = \delta_{ij}S^{(i)}, \quad A^{(\lambda)}A^{(\lambda')} = \delta_{\lambda\lambda'}A^{(\lambda)}, \quad S^{(i)}A^{(\lambda)} = 0,$$

as recorded in Lemma 10.8. Hence the (typed) τ–kairos observable decomposes as

$$\hat{\tau}_{\mu\nu} = \sum_{i \in \{b,L,p\}} S^{(i)}\hat{\tau}_{\mu\nu} + \sum_{\lambda=\pm} A^{(\lambda)}\hat{\tau}_{\mu\nu}.$$

Step 1: TT–nullity on each typed summand. By the TT–null constraint built into the τ–typed projectors (Def. Definition 10.4, Eq. (10.8)),

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} X = 0 \quad \text{for each } X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}.$$

Therefore,

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \hat{\tau}_{\mu\nu} = \sum_i \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} S^{(i)} \hat{\tau}_{\mu\nu} + \sum_\lambda \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} A^{(\lambda)} \hat{\tau}_{\mu\nu} = 0.$$

This uses linearity and the fact that the TT projector is the background–covariant pseudodifferential lift that annihilates traces and $\bar{\Sigma}$–divergences (Def. Definition 10.3), while the τ–typed images live in scalar/vector carriers orthogonal to TT (Ch. 10 typed layer Definition 9.116).

Step 2: Triad-resolved TT–nullity. Define the triad-resolved observable $\hat{\tau}_{\mu\nu}^{(a)} := \Pi^{(a)} \hat{\tau}_{\mu\nu}$ with $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (triads Definition 10.2). By commutation of typed/TT idempotents with triads on the realized weave configuration (Prop. Proposition 10.9),

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \hat{\tau}_{\mu\nu}^{(a)} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \Pi^{(a)} \hat{\tau}_{\mu\nu} = \Pi^{(a)} \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \hat{\tau}_{\mu\nu} = \Pi^{(a)} \cdot 0 = 0.$$

Realized weave configuration and retune stability. All operators involved commute with the band tags and remain admissible under audit moves (Prop. Proposition 10.10, Riesz measurability Proposition 10.149), so the identities hold throughout admissible retunes and arena switches. Finally, the same TT–nullity propagates through any τ–involving mixing channel (Lemma 10.123), preventing induced TT content (Cor. 10.125). □

Lemma 10.18 (Uniqueness of the typed decomposition)**.** *Work on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Def. Definition 10.1). Given the τ–typed projector algebra of Lemma 10.8 and the typed layer structure (Ch. 10: Definition 9.116, instantiated in Definition 10.4), the representation*

$$\hat{\tau} = \sum_{i \in \{b,L,p\}} S^{(i)} \hat{\tau} + \sum_{\lambda = \pm} A^{(\lambda)} \hat{\tau} \tag{10.16}$$

is unique up to *reparameterizations internal to each typed range (i.e. changes of basis/redefinitions of scalar/pseudoscalar amplitudes and vector creators within* $\operatorname{Ran} S^{(i)}$ *and* $\operatorname{Ran} A^{(\lambda)}$*). Moreover, this uniqueness is triad–compatible: the same statement holds for $\hat{\tau}^{(a)} := \Pi^{(a)} \hat{\tau}$ with $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (triads Definition 10.2).*

Proof. By Lemma 10.8, the family

$$\mathcal{P}_\tau := \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}$$

consists of $\bar{\Sigma}$–Hermitian idempotents that are pairwise orthogonal and complete on the τ–typed carrier:

$$X^2 = X, \quad XY = 0 \ (X \neq Y), \quad \sum_{X \in \mathcal{P}_\tau} X = \mathbf{1}_\tau.$$

Therefore any $\hat{\tau}$ admits the canonical decomposition (10.10).

Uniqueness at the projector level. Suppose there are two typed decompositions

$$\hat{\tau} = \sum_{X \in \mathcal{P}_\tau} \hat{\tau}_X^{(1)} = \sum_{X \in \mathcal{P}_\tau} \hat{\tau}_X^{(2)}, \qquad \hat{\tau}_X^{(k)} \in \operatorname{Ran} X.$$

Apply any $Y \in \mathcal{P}_\tau$ to both sides. Using orthogonality $YX = \delta_{YX}Y$,

$$Y\hat{\tau} = \sum_X Y\hat{\tau}_X^{(1)} = Y\hat{\tau}_Y^{(1)}, \qquad Y\hat{\tau} = \sum_X Y\hat{\tau}_X^{(2)} = Y\hat{\tau}_Y^{(2)}.$$

Hence $Y\hat{\tau}_Y^{(1)} = Y\hat{\tau}_Y^{(2)}$, but each side already lies in $\operatorname{Ran} Y$ and Y acts as the identity on that range; therefore $\hat{\tau}_Y^{(1)} = \hat{\tau}_Y^{(2)}$. Since Y was arbitrary, all typed components coincide and the decomposition is unique.

"Up to redefinitions" inside each range. Within a fixed typed subspace $\operatorname{Ran} X$ the choice of coordinates (e.g. scalar/pseudoscalar amplitude bases or vector creation bases) is not unique; any invertible change of basis $U : \operatorname{Ran} X \to \operatorname{Ran} X$ with $UX = XU = U$ gives a different internal parameterization of the *same* component $X\hat{\tau}$. Thus the uniqueness is exactly modulo such internal reparameterizations.

Triad compatibility. By Proposition 10.9, $[\Pi^{(a)}, X] = 0$ for every $X \in \mathcal{P}_\tau$ and $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$. Applying $\Pi^{(a)}$ to (10.10) and using commutation yields

$$\hat{\tau}^{(a)} = \Pi^{(a)}\hat{\tau} = \sum_{X \in \mathcal{P}_\tau} X\,\Pi^{(a)}\hat{\tau} = \sum_{X \in \mathcal{P}_\tau} X\,\hat{\tau}^{(a)},$$

which is the same projector decomposition but for the triad–resolved observable. Repeating the uniqueness argument above (apply $Y \in \mathcal{P}_\tau$) gives uniqueness of the typed components of $\hat{\tau}^{(a)}$ as well, again up to internal reparameterizations in each $\operatorname{Ran} X$.

All statements are made on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ and are stable under admissible retunes by Proposition 10.10; Riesz measurability Proposition 10.149 and typed stability (Ch. 10 Definition 9.116) ensure the decomposition persists along audit moves (Def. Definition 10.101). □

Meaning and importance. Lemma 10.18 says that once the τ–typed projector algebra is fixed (Lemma 10.8) and the typed layer is installed (Ch. 10: Definition 9.116, instantiated in Definition 10.4), any observable $\hat{\tau}$ admits a *canonical* direct-sum decomposition into breathing, longitudinal, pseudoscalar, and helicity-resolved vector parts, cf. (10.16). The word "canonical'' here is precise: orthogonal, complete, $\bar{\Sigma}$–Hermitian idempotents select mutually exclusive carrier spaces whose sum is the whole τ-typed block, so there is no ambiguity about which piece of $\hat{\tau}$ belongs to which type. The only latitude that remains is a harmless *change of coordinates within* each range (e.g., scalar amplitude redefinitions or a different helicity basis), which does not alter the typed component itself. This uniqueness is crucial operationally: it guarantees that downstream witnesses, selection rules, and parity/helicity/CP diagnostics are insensitive to the order in which typing is performed and that no spurious mixing is introduced when we later combine typing with spectral bookkeeping (triads; Definition 10.2). In short, the typed split is a rigid, basis-independent statement about $\hat{\tau}$ on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Definition 10.1).

Why the proof matters. The proof formalizes two standard functional-analytic mechanisms. First, orthogonal idempotents yield a unique projection decomposition: applying any projector Y from the family $\mathcal{P}_\tau$ to two candidate sums immediately identifies and equalizes the Y–component, and repeating for all Y pins down every typed piece uniquely. Second, *triad*

compatibility follows from commutation with the Riesz spectral projectors that define the triad (Definition 10.7 and Proposition 10.9): since typed idempotents commute with the band-limited kinetic blocks on the realized weave configuration (typed stability; Ch. 10 Definition 9.116), they commute with the resolvents and hence with the contour integrals that produce the triad projectors; this is exactly the holomorphic functional-calculus logic [115, 253]. Therefore the same uniqueness holds for each triad-resolved observable $\hat{\tau}^{(a)}$, ensuring that spectral triage (spec/vac/corr) and typing can be interleaved without ambiguity or loss of information—one of the key algebraic guarantees behind our weave-level diagnostics.

Proposition 10.19 (BRST/Nielsen invariance and band stability for τ–correlators)**.** *Work on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Def. Definition 10.1). Let $\mathcal{J}_\tau$ be any finite composition of the triad maps $\Pi^{(a)}$ ($a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$; Definition 10.2), the TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3), and the τ–typed idempotents $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}$ (Definition 10.4). Then every correlator on $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$ of $\mathcal{J}_\tau$–projected τ–observables (e.g. $\langle \mathcal{J}_\tau\, \hat{\tau}_{\mu\nu} \rangle$) is:*

(i) gauge–parameter independent *(Nielsen flat) on shell; and*

(ii) stable under admissible retunes $(P_x, K_{\mathrm{IR}}, \mathrm{Loc})$ *within the certified class (continuous and uniformly bounded along admissible paths; Def. Definition 10.101).*

Proof. 1. **Gauge–parameter independence (Nielsen flatness).** Let ξ denote any gauge parameter in the gauge–fixed kinetic operators. On $\mathcal{H}_{\mathrm{phys}}$, the embedded Nielsen identity (Ch. 8; cf. Prop. Proposition 7.174) yields, for sufficiently regular $\mathcal{A}$,

$$\partial_\xi \langle \mathcal{A} \rangle_{\mathcal{H}_{\mathrm{phys}}} = \Big\langle [\hat{Q}_{\mathrm{BRST}}, \mathcal{K}_\xi]\, \mathcal{A} \Big\rangle_{\mathcal{H}_{\mathrm{phys}}} + \Big\langle \mathrm{EOM}_\xi(\mathcal{A}) \Big\rangle_{\mathcal{H}_{\mathrm{phys}}}. \tag{10.17}$$

Here $\hat{Q}^2_{\mathrm{BRST}} = 0$, and the EOM_ξ term vanishes on shell. Choose $\mathcal{A} = \mathcal{J}_\tau\, \hat{\tau}_{\mu\nu}$, where $\mathcal{J}_\tau$ is a composition of idempotents listed in the statement. By typed stability and commutation on the realized weave configuration (Ch. 10 typed layer Definition 9.116 and Proposition 10.9), each factor in $\mathcal{J}_\tau$ is BRST–closed and commutes with the band machinery on $\mathcal{H}_{\mathrm{phys}}$. Therefore the BRST–exact contribution has zero expectation and the EOM term vanishes on shell, giving $\partial_\xi \langle \mathcal{J}_\tau\, \hat{\tau}_{\mu\nu} \rangle_{\mathcal{H}_{\mathrm{phys}}} = 0$. Hence gauge–parameter independence.

2. Stability under admissible retunes. Consider an admissible path (Def. Definition 10.101):

$$t \mapsto \Big(P_x(t),\, K_{\mathrm{IR}}^{(\ell(t))},\, \mathrm{Loc}(t) \Big)$$

Triad maps $\Pi^{(a)}$ are realized by Riesz projectors of the band–limited kinetic operators on certified contours (selectors Definition 10.7); by Riesz measurability Proposition 10.149, the map $t \mapsto \Pi^{(a)}(t)$ is Bochner–measurable and norm–continuous along admissible paths. The TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3) and the τ–typed idempotents (Definition 10.4) are fixed $\bar{\Sigma}$–Hermitian idempotents that commute with the band tags and triads on the realized weave configuration (Proposition 10.9). Hence $t \mapsto \mathcal{J}_\tau(t)$ is norm–continuous on $\mathcal{H}_{\mathrm{phys}}$.
Correlation functionals built from $\mathcal{J}_\tau(t)\hat{\tau}_{\mu\nu}$ are continuous in the operator norm, and remain uniformly bounded along admissible paths because admissible band–invariant

norms are equivalent and contractive under IR tightening (Def. Definition 10.143, Prop. Proposition 10.147). Arena switches preserve the certified spectral set and associated projectors (Lemma 10.137), so no discontinuity is introduced by bulk $\leftrightarrow$ boundary. Therefore $\langle \mathcal{J}_\tau(t)\,\hat{\tau}_{\mu\nu}\rangle_{\mathcal{H}_{\rm phys}}$ varies continuously and stays uniformly bounded along any admissible retune, proving stability.

Alternative route. The result also follows immediately by specializing Proposition 10.10 to compositions that only involve $\Pi^{(a)}$, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, and the τ–typed idempotents. □

Corollary 10.20 (No contamination of the graviton channel)**.** *For any symmetric 2-tensor perturbation $\delta\hat{g}_{\mu\nu}$, the graviton field $\hat{h}_{\mu\nu}$ obtained via eq. (10.28) is independent of $\hat{\tau}_{\mu\nu}$:* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}(\delta\hat{g}_{\mu\nu}+\hat{\tau}_{\mu\nu}) = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\delta\hat{g}_{\mu\nu}$.

Proof. By Lemma 10.17, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau} = 0$; sandwiching by $\mathsf{P}_{\rm phys}$ and spectral/triad maps (which commute with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$) preserves this equality in eq. (10.28). □

Operational extraction and certification.

Definition 10.21 (Typed τ-kairos witnesses and visibilities)**.** For each admitted type $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}$ and sector $\mathscr{S}$, define the consolidated witness $\mathbf{W}^{[\mathscr{S};X]}$ and the law/state visibilities $\Lambda^{[\mathscr{S};X]}_{\text{law/state}}$ as in Definitions 10.80 and 10.82, evaluated on $\mathcal{H}_{\rm phys}$ with instrumentation $\mathcal{I}^{[\mathscr{S}]}$.

Proposition 10.22 (Well-posed Parasymmetric TLO for τ-types)**.** *For each X as above, the Parasymmetric TLO triple* (Type, Location, Onset) *of Definition 10.85 and Proposition 10.90 exists and is unique on the certified band. Moreover, the Onset $r^\star[X]$ is stable under admissible retuning $r \mapsto r + \delta r$ and tightening of $K_{\rm IR}$.*

Proof (sketch). Existence/uniqueness of the Type layer follows from Lemma 10.18. Location is determined by the arena in $\mathcal{I}^{[\mathscr{S}]}$. Onset stability is the monotone-meters property inherited from band covariance and BRST/Nielsen flatness (Proposition 10.10); tightening $K_{\rm IR}$ cannot create spurious visibility plateaus for admissible types. □

Remark 10.23 (Parity bookkeeping at the scalar level)**.** The scalar subspace decomposes canonically into even/odd parity via $\Pi^{(e)}_{\rm sc} = S^{(b)} + S^{(L)}$, $\Pi^{(o)}_{\rm sc} = \tilde{S}^{(p)}$. Vector parity is reported via Δ_P in eq. (10.15) while keeping helicity $A^{(\pm)}$ as primitive types.

Remark 10.24 (Chrono–Kymon identification)**.** The Chrono–Kymon is the τ-vector content captured by $A^{(\lambda)}$ ($\lambda = \pm$). Its extraction on $\mathcal{H}_{\rm phys}$ uses the same realized weave configuration and typed witnesses, and is automatically TT-null by Lemma 10.17.

10.4 Chronogeometric Origin and Certified Construction of the τ–kairos

Work on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ of Definition 10.1 with physical space $\mathcal{H}_{\rm phys} = \operatorname{Ran}\mathsf{P}_{\rm phys}$, triad projectors $\Pi^{(a)}$ from Definition 10.2, the TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ from

Definition 10.3, and the typed families of Definition 10.4. The goal is to formalize the emergence of the τ–kairos from a constitutive chronogeometric observable and to place it within the canonical typed/Riesz framework (Ch. 6–10).

Constitutive origin and linear response. Let the chronogeometric observable be a constitutive functional of the Gaiamiti and Tantrakyma substrates,

$$\Sigma_{\mu\nu}[\Phi,\Theta] = g_{\mu\nu}[\Phi] \;+\; t_{\mu\nu}[\Phi,\Theta]\,, \tag{10.18}$$

with background $(\bar{\Phi},\bar{\Theta})$ and fluctuation $\delta\Sigma_{\mu\nu}$. Linearization gives the chain–rule split

$$\delta\Sigma_{\mu\nu} = (D_\Phi g)_{\mu\nu}\cdot\,\delta\Phi + (D_\Phi t)_{\mu\nu}\cdot\,\delta\Phi + (D_\Theta t)_{\mu\nu}\cdot\,\delta\Theta\,. \tag{10.19}$$

Certified TT isolation and definition of the τ–kairos (expanded steps). Step 0: Constitutive linearization. From the constitutive map $\Sigma_{\mu\nu}[\Phi,\Theta] = g_{\mu\nu}[\Phi]+t_{\mu\nu}[\Phi,\Theta]$ one has, about $(\bar{\Phi},\bar{\Theta})$,

$$\delta\Sigma_{\mu\nu} = (D_\Phi g)_{\mu\nu}\cdot\,\delta\Phi + (D_\Phi t)_{\mu\nu}\cdot\,\delta\Phi + (D_\Theta t)_{\mu\nu}\cdot\,\delta\Theta\,. \tag{10.20}$$

Step 1: Insert the TT/complement decomposition. With the certified TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ of Definition 10.3, write the identity $\mathrm{Id} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} + (\mathrm{Id} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]})$ and apply it to $\delta\hat{\Sigma}_{\mu\nu}$:

$$\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big[(D_\Phi g + D_\Phi t)_{\mu\nu}\cdot\,\delta\hat{\Phi}\Big] + \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big[(D_\Theta t)_{\mu\nu}\cdot\,\delta\hat{\Theta}\Big], \tag{10.21a}$$

$$\hat{\tau}_{\mu\nu} := \Big(\mathrm{Id} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big)\,\delta\hat{\Sigma}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\tau}_{\mu\nu} = 0 \;\; \text{(idempotence)}. \tag{10.21b}$$

Step 2: Why the Θ–term carries no TT content. By typed admission (Definition 10.4) the non-tensor families $\{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ are *TT-null*:

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\Pi^{[X]} = 0 = \Pi^{[X]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}, \qquad X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}. \tag{10.22}$$

On the certified band (Ch. 10), $(D_\Theta t)_{\mu\nu}\cdot\,\delta\Theta$ lies in the closed span of these TT-null typed images, hence

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big[(D_\Theta t)_{\mu\nu}\cdot\,\delta\Theta\Big] = 0. \tag{10.23}$$

Combining (10.21a) and (10.23) reproduces the displayed identity in (10.21a) of the main text.

Step 3: Define $\hat{\tau}$ and check TT-nullity transparently. Equation (10.21b) yields, by idempotence of $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$,

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big(\mathrm{Id} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big)\delta\Sigma_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\Sigma_{\mu\nu} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\Sigma_{\mu\nu} = 0.$$

Thus $\hat{\tau}_{\mu\nu}$ is TT-null by construction.

Step 4: Typed resolution of the non–TT residual. Introduce the typed projectors $\Pi^{[X]}$ associated with the τ-families of Definition 10.4. On the certified band, $\sum_X \Pi^{[X]}$ acts as the identity on the TT-complement, and each image admits a *typed representative* via the corresponding map ($X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$):

$$\Pi^{[S^{(b)}]}\hat{\tau} = S^{(b)}_{\mu\nu}[\hat{\varphi}_b], \quad \Pi^{[S^{(L)}]}\hat{\tau} = S^{(L)}_{\mu\nu}[\hat{\varphi}_L], \quad \Pi^{[\tilde{S}^{(p)}]}\hat{\tau} = \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}], \quad \Pi^{[A^{(\lambda)}]}\hat{\tau} = A^{(\lambda)}_{\mu\nu}[\hat{K}^{(\tau)}_{\lambda}]. \tag{10.24}$$

The amplitudes $\hat{\varphi}_b, \hat{\varphi}_L, \tilde{\varphi}, \hat{K}_\lambda^{(\tau)}$ are obtained by the certified-band Riesz selectors and right-inverses guaranteed by the typed construction in Ch. 10 (no off-band components enter). Summing (10.24) over all types recovers the τ-kairos decomposition

$$\hat{\tau}_{\mu\nu} = S_{\mu\nu}^{(b)}\big[\hat{\varphi}_b\big] \;\oplus\; S_{\mu\nu}^{(L)}\big[\hat{\varphi}_L\big] \;\oplus\; \tilde{S}_{\mu\nu}^{(p)}\big[\tilde{\varphi}\big] \;\oplus\; \sum_{\lambda=\pm} A_{\mu\nu}^{(\lambda)}\big[\hat{K}_\lambda^{(\tau)}\big] \quad \text{(Definition 10.13).} \tag{10.25}$$

Step 5: Triad provenance commutes with typing. With $\Pi^{(a)}$ from Definition 10.2 and the commutation $[\Pi^{(a)}, \Pi^{[X]}] = 0$ (Proposition 10.9), one has

$$\hat{\tau}_{\mu\nu}^{(a)} := \Pi^{(a)}\hat{\tau}_{\mu\nu} = \sum_X \Pi^{(a)}\Pi^{[X]}\hat{\tau} = \sum_X \Pi^{[X]}\Pi^{(a)}\hat{\tau}, \qquad a \in \{\text{spec}, \text{vac}, \text{corr}\}, \tag{10.26}$$

and each typed block in (10.25) acquires its triad-resolved input $\hat{\varphi}_b^{(a)}, \hat{\varphi}_L^{(a)}, \tilde{\varphi}^{(a)}, \hat{K}_\lambda^{(\tau)(a)}$ accordingly.

Step 6: CK/vector and scalar spectral selection (existence of inputs). Existence/uniqueness of the inputs in (10.24) on the certified band follows from the Riesz projectors: for the vector channel use $\mathsf{P}_{\text{spec}}^{(1)}$ and $\mathcal{P}_{\text{CK},\lambda}^{(1)}$ (Definitions 10.56 and 10.57); for the scalar channel use the spin–0 selector $\mathsf{P}_{\text{spec}}^{(0)}$ (cf. the scalar construction). Additivity of Riesz projectors implies automatic extension when new certified spectral branches appear (cf. Lemma 10.62).

Equations (10.21a)–(10.25) now follow *mechanically* from the constitutive linearization (10.20), TT idempotence, typed TT-null admission (10.22), and the certified-band typed/Riesz reconstruction in Ch. 10, with triad provenance attached by (10.26).

Triad provenance and orthogonality. With the triad projectors $\Pi^{(a)}$ from Definition 10.2, define

$$\hat{\tau}_{\mu\nu}^{(a)} := \Pi^{(a)}\,\hat{\tau}_{\mu\nu} = \; S_{\mu\nu}^{(b)}\big[\hat{\varphi}_b^{(a)}\big] \oplus S_{\mu\nu}^{(L)}\big[\hat{\varphi}_L^{(a)}\big] \oplus \tilde{S}_{\mu\nu}^{(p)}\big[\tilde{\varphi}^{(a)}\big] \oplus \sum_{\lambda=\pm} A_{\mu\nu}^{(\lambda)}\big[\hat{K}_\lambda^{(\tau)(a)}\big], \tag{10.27}$$

with $\Pi_{\bar{\Sigma}}^{[\text{TT}]}\hat{\tau}_{\mu\nu}^{(a)} = 0$. Typed and triad pieces are mutually orthogonal by the idempotent algebra (cf. Lemma 10.8 and Proposition 10.9).

Certified-band selection (scalar and vector). Scalar and vector content on the certified band are isolated by spin–0/1 Riesz selectors. For the vector (CK) block, Definition 10.56 defines $\mathsf{P}_{\text{spec}}^{(1)}$ and the CK projector $\mathcal{P}_{\text{CK},\lambda}^{(1)}$ (Definition 10.57); the scalar (gaiaton) block admits the analogous $\mathsf{P}_{\text{spec}}^{(0)}$ and $\Pi_\tau^{(\text{spec};0)}$ (cf. the scalar construction in Sec. 10.8). Riesz additivity implies automatic inclusion of new certified spectral branches (future-proofing), cf. Lemma 10.62.

Meters, witnesses, and diagnostics. Typed, triad-resolved visibilities follow Definitions 10.80 and 10.82. For the vector CK channel, use $\Lambda_{\text{law/state}}^{[\tau\text{-vec};A^{(\lambda)}]}$ (Definition 10.64) and the parity diagnostic $\Delta_{P,\Lambda}^{(1)}$ (Definition 10.58). For the scalar channel (gaiaton), use the CP-resolved visibilities and, where needed, the CP asymmetry $\Delta_{\text{CP},\Lambda}^{(0)}$ (cf. the scalar definitions). All meters are evaluated on $\mathcal{H}_{\text{phys}}$ with the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$.

Invariance, stability, and TLO onset. Any correlator formed from $\hat{\tau}$-typed blocks with finitely many insertions of the typed projectors and certified Riesz selectors is BRST/Nielsen-flat and stable under admissible retunings of (P_x, K_{IR}) (Proposition 10.10; see also Proposition 10.61 for CK). For each admitted type, the Parasymmetric TLO triple (Type, Location, Onset) exists and is unique on the certified band (Definition 10.85 and Proposition 10.90); onsets $r^\star[\cdot]$ inherit the same retuning stability.

Mixing, whitening, and reporting. Non–TT mixing (including intra-scalar and CK helicity mixing) is quantified by typed mixing norms and resolved by the $\bar{\Sigma}$–weighted operator-generalized eigen-operator pair eigenproblem with whitening (Definitions 10.116 and 10.117). The outcome is an orthogonal set of eigen-channels inside the τ block, each carrying triad provenance and ledgered power. TT mixing does not occur: $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ annihilates all τ-typed insertions.

Interfaces with Gaiamiti (TT) and Tantrakyma ($\Theta\Theta$). By (10.21a)–(10.21b), the TT graviton (Gaiamiti tensor) is isolated entirely in the TT channel and is orthogonal to τ (no TT contamination). Higgs/radial kymon content is identified in the $\Theta\Theta$ (tantrakyma) sector with CP resolution and TLO guarantees (Section 10.6); comparisons with τ-typed readouts proceed through the common witness/ledger interface, not by identification.

Optional representatives (notation only). First-order representatives may be introduced for interpretation without changing the typed machinery: scalars $\{\hat{\varphi}_b, \hat{\varphi}_L, \tilde{\varphi}\}$ for the scalar/pseudoscalar block and a vector $K_\mu^{(\tau)}$ for CK, with $\mathcal{F}_{\mu\nu}^{(\tau)} = 2\bar{\nabla}_{[\mu} K_{\nu]}^{(\tau)}$ (cf. Definition 10.57). These objects are proxies for typed correlator content and do not modify TT purity.

Processing equivalence. The constitutive split (10.19), followed by TT isolation (10.21a) and typed/Riesz extraction, is equivalent (at the level of reported types, triad ledgers, and TLO onsets) to proceeding directly with the typed-correlator pipeline on the realized weave configuration; this is a consequence of projector idempotence and the realized weave configuration-level invariance statements referenced above (cf. Ch. 10 and Proposition 10.10).

Summary. The τ–kairos is the TT-null, typed projection of the linear response of the chronogeometric observable (10.18), organized as the orthogonal sum (10.25) with triad provenance (10.27). All readouts are certified by the same typed/Riesz infrastructure as in Ch. 6–10: they inherit BRST/Nielsen flatness, admissible-retuning stability, TLO well-posedness, and standardized meters/diagnostics. The TT (graviton) and tantrakyma (Higgs/radial kymon) sectors remain orthogonal and are interfaced with τ only via the shared witness/ledger scaffold.

10.5 The Graviton in the Gaiamiti (Geometry) Sector

We work on the realized weave configuration $\mathcal{I}^{[\mathscr{P}]}$ of Definition 10.1 in the $\Phi\Phi$ (gaiamiti) sector, with triad projectors $\Pi^{(a)}$ from Definition 10.2, the background-covariant TT map $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ of

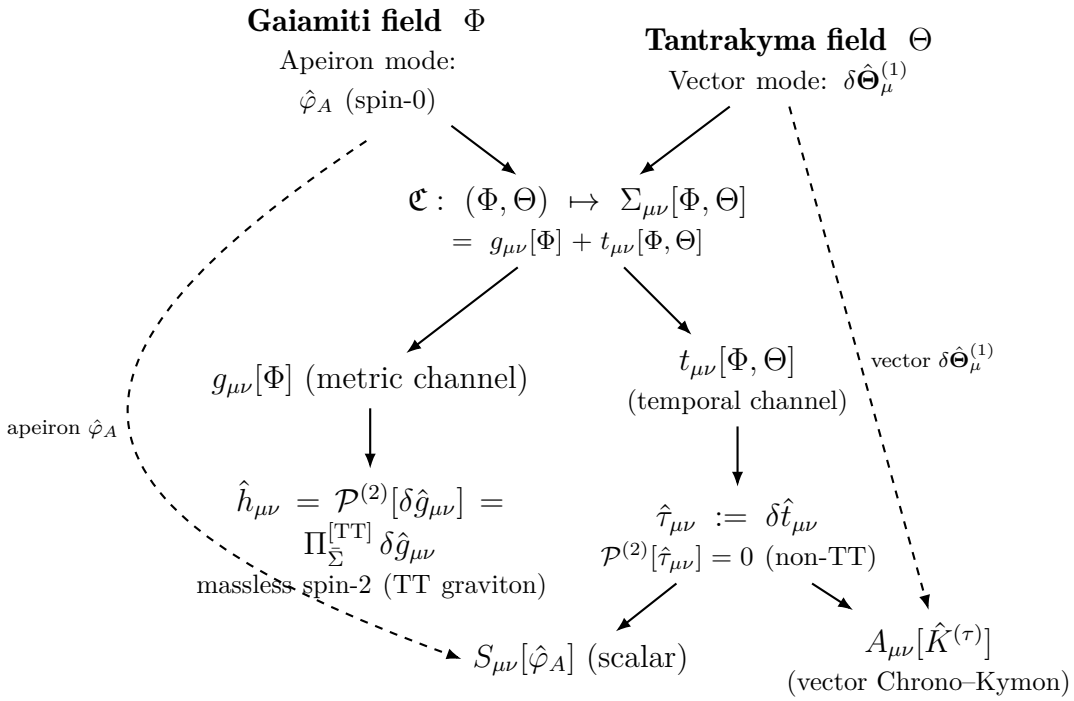

Figure 10.1: Constitutive map and channel-resolved sourcing. Gaiamiti Φ feeds the metric TT graviton and the scalar part of $\hat{\tau}_{\mu\nu}$ (via apeiron), while Tantrakyma Θ feeds the vector part (Chrono–Kymon). **Legend:** (1) TT radiation lives only in the metric channel: $\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}] = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$; (2) Tau–kairos is TT-null: $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$, so no spin-2 GW; (3) $\hat{\tau}_{\mu\nu} = S_{\mu\nu}[\hat{\varphi}_A] \oplus A_{\mu\nu}[\hat{K}^{(\tau)}]$ combines scalar (from Φ via apeiron) and vector (from Θ via Chrono–Kymon).

Definition 10.3, and the spin-2 Riesz selector $\mathsf{P}^{(2)}_{\mathrm{spec}}$ from Definition 10.7. All statements are taken on $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$.

Definition 10.25 (Graviton projector (typed TT, triad-resolved, future-proof))**.** Let $K_{\Phi\Phi}$ be the band-limited, gauge-fixed linearized kinetic operator in the $\Phi\Phi$ block. The *graviton projector* is

$$\boxed{\mathcal{P}^{(2)}_{\mathrm{grav}} := \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Big(\,\mathsf{P}^{(2)}_{\mathrm{spec}} \;\oplus\; \Pi^{(\mathrm{vac})} \;\oplus\; \Pi^{(\mathrm{corr})}\,\Big)\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\mathsf{P}_{\mathrm{phys}}} \tag{10.28}$$

with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ the background-covariant TT projector (Definition 10.3), $\mathsf{P}^{(2)}_{\mathrm{spec}}$ the spin-2 Riesz selector (Definition 10.7), and $\Pi^{(a)}$ the triad projectors ($a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$; Definition 10.2). The *graviton field* is obtained from any symmetric perturbation $\delta\hat{g}_{\mu\nu}$ by

$$\boxed{\hat{h}_{\mu\nu} := \mathcal{P}^{(2)}_{\mathrm{grav}}\,\delta\hat{g}_{\mu\nu} = \sum_{a\in\{\mathrm{spec,vac,corr}\}} \hat{h}^{(a)}_{\mu\nu}, \qquad \hat{h}^{(a)}_{\mu\nu} := \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{(a)}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{g}_{\mu\nu}.} \tag{10.29}$$

House notation (TT identification and helicity). Consistently with standard practice [43, 7, 14],

we *identify the graviton channel by its TT content*:

$$\hat{h}^{\mathrm{TT}}_{\mu\nu} \;:=\; \left(\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}\right)_{\mu\nu}, \tag{10.30}$$

which coincides with the spectral spin-2 component of (10.29) by commutation of typed/Riesz/triad projectors (Proposition 10.9 and Definition 10.7). When a helicity resolution is needed, one may write

$$\hat{h}^{(a)}_{\mu\nu} = \sum_{\lambda=\pm 2} \epsilon^{(\lambda)}_{\mu\nu}[\bar{\Sigma}]\;\hat{a}^{(a)}_{\lambda} \;+\; \text{h.c.}, \tag{10.31}$$

where $\epsilon^{(\lambda)}_{\mu\nu}[\bar{\Sigma}]$ are $\bar{\Sigma}$-transverse–traceless polarization tensors ($\bar{\Sigma}^{\mu\nu}\epsilon^{(\lambda)}_{\mu\nu} = 0$, $\nabla^{(\mathrm{rel})\mu}\epsilon^{(\lambda)}_{\mu\nu} = 0$) normalized on the realized weave configuration, and $\hat{a}^{(a)}_{\lambda}$ are the corresponding helicity mode operators [7, 14].

Conceptual role of the projector. The graviton projector $\mathcal{P}^{(2)}_{\mathrm{grav}}$ isolates, from an arbitrary symmetric perturbation $\delta\hat{g}_{\mu\nu}$, precisely the *physical, spin-2, transverse–traceless* (TT) content (Definition 10.25, (10.28)). The resulting graviton field is $\hat{h}_{\mu\nu} := \mathcal{P}^{(2)}_{\mathrm{grav}}\delta\hat{g}_{\mu\nu}$ and admits the triad decomposition $\hat{h}_{\mu\nu} = \hat{h}^{(\mathrm{spec})}_{\mu\nu} + \hat{h}^{(\mathrm{vac})}_{\mu\nu} + \hat{h}^{(\mathrm{corr})}_{\mu\nu}$ ((10.29)). This packages three operational requirements into a single map: (i) gauge safety, (ii) strict separation from scalar/vector (τ) contamination, and (iii) *provenance resolution* into spectral (radiative), vacuum, and correlational TT contributions—exactly mirroring the TT extraction of the radiative graviton in linearized gravity and its two physical helicities $\lambda = \pm 2$ [43, 7, 14].

Structure from the outside in. The outer projections $\mathsf{P}_{\mathrm{phys}}$ restrict to the BRST/Nielsen-safe physical sector of the realized weave configuration, eliminating gauge and ghost artifacts (Definition 10.1; see also [445, 106, 230]). The typed TT projectors $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ enforce the TT condition relative to the relational background $\bar{\Sigma}$ (Definition 10.3; cf. York/Lichnerowicz TT splitting [43, 44]). The map applies the TT projector on *both* sides of the triad, which makes the TT subspace invariant and annihilates any non-TT insertion before and after provenance resolution. In particular, TT-null preservation under τ–mixing follows from Lemma 10.123.

Provenance resolution inside TT. The central block $\mathsf{P}^{(2)}_{\mathrm{spec}} \oplus \Pi^{(\mathrm{vac})} \oplus \Pi^{(\mathrm{corr})}$ splits the TT content into orthogonal idempotent components (the *weave triad*, Definition 10.2). The *spectral* projector $\mathsf{P}^{(2)}_{\mathrm{spec}}$ is defined using the band-limited, gauge-fixed linearized kinetic operator $K_{\Phi\Phi}$ and isolates *on-band, propagating helicity-2* excitations (bona fide gravitational radiation), in line with the Riesz–Kato holomorphic calculus used for spectral selection [115, 253] and with Källén–Lehmann positivity for physical tensor modes [14, 255, 230, 244]. The *vacuum* projector $\Pi^{(\mathrm{vac})}$ retains TT structure associated with background/zero-mode or constraint-saturated content that is TT but not radiative, while the *correlational* projector $\Pi^{(\mathrm{corr})}$ records TT components generated by inter-modal correlations that lie outside the radiative spectrum yet remain in TT. Orthogonality and idempotence provide a clean ledger for audits and consistency checks without conflation across these sources.

Band-limiting, gauge-fixing, and monotonicity. Locating $\mathsf{P}^{(2)}_{\mathrm{spec}}$ through $K_{\Phi\Phi}$ makes the spectral cut *operational*: radiative content is tied to a certified IR/UV window and a fixed gauge, after which projection to $\mathcal{H}_{\mathrm{phys}}$ removes gauge dependence (Definition 10.1; cf. standard gauge fixing and renormalization hygiene [82, 447]). Under IR tightening, off-band contamination decreases monotonically, yielding progressively cleaner spectral–TT readouts; the outer TT/physical-sector sandwich ensures this improvement is reflected directly in $\hat{h}^{(\mathrm{spec})}_{\mu\nu}$ while keeping non-TT channels TT-null (Lemma 10.123).

Future-proofing of the construction. Because the definition is expressed at the level of *typed projectors*, extensions within spin-2 TT—such as refined spectral bands or additional massless helicity-2 species—are implemented by refining $\mathsf{P}^{(2)}_{\mathrm{spec}}$ (and, if needed, the triad idempotents) *without altering* the outer $\mathsf{P}_{\mathrm{phys}}$-TT-triad-TT-$\mathsf{P}_{\mathrm{phys}}$ scaffold (Definition 10.25). If a massive spin-2 sector is hypothesized, the TT type is replaced or supplemented by the appropriate spin-2 projector family while preserving the same "physical-sector $\perp$ provenance-split $\perp$ physical-sector'' skeleton; compare with the Fierz–Pauli massive spin-2 construction [474].

Interpreting $\hat{h}_{\mu\nu}$ and its components. Equation (10.29) makes explicit that the observable graviton field is the *sum of three TT contributions*,

$$\hat{h}^{(a)}_{\mu\nu} = \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{(a)}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{g}_{\mu\nu}, \qquad a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}.$$

This decomposition supports component-wise reporting, comparison, and auditing (e.g., distinguishing TT-leak from bona fide radiation) while ensuring that only the two tensor polarizations (helicities ± 2, the "+" and "×" modes) inhabit the signal [7, 14]. Scalar and vector entries remain *TT-null by construction* and cannot masquerade as additional tensor modes (Definition 10.3 and Lemma 10.123).

Definition 10.26 (Helicity resolution inside TT)**.** On the TT subspace, let $\Pi^{(\pm 2)}$ be the helicity projectors (background-frame covariant; parity swaps $\Pi^{(+2)} \leftrightarrow \Pi^{(-2)}$). The spectral graviton admits

$$\hat{h}^{(\mathrm{spec})}_{\mu\nu} = \sum_{\lambda=\pm 2} \Pi^{(\lambda)}\,\hat{h}^{(\mathrm{spec})}_{\mu\nu}, \qquad \Pi^{(\lambda)}\Pi^{(\lambda')} = \delta_{\lambda\lambda'}\Pi^{(\lambda)}, \quad \Pi^{(+2)} + \Pi^{(-2)} = \mathbf{1}_{\mathrm{TT}}. \tag{10.32}$$

Definition 10.27 (Propagating correlational TT filter (optional))**.** To isolate correlational TT with hyperbolic TT characteristics on a chosen window, set

$$\hat{h}^{(\mathrm{corr,prop})}_{\mu\nu} := \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{(\mathrm{corr})}\,\mathbf{1}_{\{\ \sigma_{\mathrm{prin}}(K_{\Phi\Phi})\ \text{is TT-hyperbolic}\ \}}\,\Pi^{(\mathrm{corr})}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{g}_{\mu\nu}. \tag{10.33}$$

Structural facts.

Lemma 10.28 (TT purity and triad commutation)**.** *$\hat{h}_{\mu\nu}$ is TT by construction: $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{h}_{\mu\nu} = \hat{h}_{\mu\nu}$. Moreover, $[\Pi^{(a)}, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}] = 0$ implies the decomposition (10.29) is triad-orthogonal.*

Proof. Immediate from the sandwiching by $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and Proposition 10.9. □

Proposition 10.29 (Independence from τ-kairos)**.** *Let $\hat{\tau}_{\mu\nu}$ be as in Definition 10.13. Then $\mathcal{P}^{(2)}_{\mathrm{grav}}(\delta\hat{g}_{\mu\nu} + \hat{\tau}_{\mu\nu}) = \mathcal{P}^{(2)}_{\mathrm{grav}}\delta\hat{g}_{\mu\nu}$.*

Proof. By Lemma 10.17, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$. Insert into (10.28). □

Proposition 10.30 (BRST/Nielsen flatness and band stability)**.** *Any correlator on $\mathcal{H}_{\mathrm{phys}}$ formed from $\hat{h}_{\mu\nu}$ and finitely many insertions of $\Pi^{(a)}$, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, and $\mathsf{P}^{(2)}_{\mathrm{spec}}$ is (i) gauge-parameter independent and (ii) stable under admissible retunings of (P_x, K_{IR}).*

Proof. A specialization of Proposition 10.10. □

Lemma 10.31 (Spectral future-proofing)**.** *If the realized dynamics acquires additional helicity-2 spectral branches (new contours γ_j), the projector $\mathsf{P}^{(2)}_{\mathrm{spec}}$ enlarges by the corresponding Riesz terms and $\mathcal{P}^{(2)}_{\mathrm{grav}}$ automatically includes the new species.*

Proof. By the additivity of Riesz projectors over disjoint spectral contours. □

Diagnostics and positivity.

Definition 10.32 (TT-leak diagnostic)**.** Define

$$\varepsilon := \left\| \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \left(\mathbf{1} - \mathsf{P}^{(2)}_{\mathrm{spec}}\right) \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \right\|_{\mathcal{I}}, \tag{10.34}$$

with $\|\cdot\|_{\mathcal{I}}$ any admissible band-invariant functional norm. Baseline $\varepsilon = 0$; $\varepsilon > 0$ flags unexpected TT strength outside the spectral spin-2 support and triggers audit (SynTh).

Proposition 10.33 (Transversality and positive spectral density (spectral piece))**.** *The spectral graviton obeys the Ward/Slavnov transversality and has nonnegative spectral density on $\mathcal{H}_{\mathrm{phys}}$: $k^\mu \hat{h}^{(\mathrm{spec})}_{\mu\nu} = 0$ and $\rho_{(2)}(\omega, \mathbf{k}) \geq 0$.*

Proof (outline). Inherited from the band-native Ward/Slavnov framework and positivity proven upstream (Ch. 8) after BRST descent; we only apply $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and $\mathsf{P}_{\mathrm{phys}}$, which commute with the identities. □

Operational extraction and certification.

Definition 10.34 (Typed TT witnesses and visibilities)**.** Let $\mathbf{W}^{[\Phi\Phi;\mathrm{TT}]}$ be the consolidated witness in the TT-typed gaiamiti sector (Ward + spectral ledgers). Define the law/state visibilities $\Lambda^{[\Phi\Phi;\mathrm{TT}]}_{\mathrm{law/state}}$ as in Definitions 10.80 and 10.82, evaluated on $\mathcal{H}_{\mathrm{phys}}$ with $\mathcal{I}^{[\Phi\Phi]}$.

Proposition 10.35 (Well-posed Parasymmetric TLO for the graviton)**.** *The Parasymmetric TLO triple* (Type = TT, Location, Onset) *of Definition 10.85 and Proposition 10.90 exists and is unique on the certified band. The onset $r^\star[\mathrm{TT}]$ is stable under admissible retuning and tightening of K_{IR}.*

Proof. Type is fixed by $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$; uniqueness follows from orthogonality to non-TT subspaces. Stability is inherited from Proposition 10.10. □

Remarks.

Remark 10.36 (Vacuum vs correlational vs spectral TT)**.** $\hat{h}^{(\mathrm{spec})}$ represents radiative, energy-carrying spin-2 (gravitational waves). $\hat{h}^{(\mathrm{vac})}$ encodes TT vacuum structure (no asymptotic flux; contact/anomaly pieces). $\hat{h}^{(\mathrm{corr})}$ captures coherence-driven TT on finite windows (can be filtered to propagating TT by Definition 10.27); tightening K_{IR} typically suppresses the latter.

Remark 10.37 (Parity and helicity audits)**.** While TT is the primitive type, helicity-resolved visibilities via $\Pi^{(\pm 2)}$ allow a parity-asymmetry readout $\Delta_P^{(2)} := \Lambda^{[(+2)]} - \Lambda^{[(-2)]}$ when chiral effects are present; parity swaps the helicities.

The (τ)–kairos is not an autonomous sector but a typed family of insertions/projectors defined on the fixed realized weave configuration $(\mathcal{I}^{[\mathscr{S}]})$ (cf. Definition 10.1). The admissible (τ)-types are the scalar triplet $(S^{(b)}, S^{(L)}, \tilde{S}^{(p)})$ and the vector/helicity pair $(A^{(\pm)})$; they are admitted only through their typed idempotents $(\Pi^{[\chi]})$ and never as a separate sector label (Definition 10.4). Within the typed, triad-resolved correlator,

$$\hat{\mathbf{G}}^{(a\to b),[\chi\to\chi']} * \Lambda = \mathsf{P}_{\mathrm{phys}}\Pi^{(b)}\Pi^{[\chi']}(\hat{\mathbf{G}} * \Lambda)\Pi^{[\chi]}\Pi^{(a)}\mathsf{P}_{\mathrm{phys}}, \tag{10.35}$$

the placeholders $([\chi], [\chi'])$ may be instantiated by any of these (τ)-types, with triad provenance $(a, b \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\})$ (Definitions 10.2 and 10.113 and eq. (10.61)). In mixed situations $(\mathscr{S} = \Phi\Theta)$, the effective "typed spin" is fixed by the off-diagonal typed insertion itself, so no additional (τ)-sector index is introduced (Definition 10.113).

Remark 10.38 (Weinberg–Witten and its inapplicability in the present framework)**.** The Weinberg–Witten no–go theorem [475] forbids *emergent, interacting, massless spin–2* excitations under the joint hypotheses that:

(A) dynamics are formulated on a fixed Minkowski background η (with global Poincaré symmetry), and

(B) there exists a global, Lorentz–covariant, gauge–invariant, *conserved* stress tensor $T^{\mu\nu}$ that couples to the putative spin–2 composite.

In the typed, BRST/Nielsen–safe construction used here, both premises are relaxed. First, the operative chronogeometry is the expectation–valued, state–dependent background $\bar{\Sigma}_{\mu\nu}$ obtained on a certified plateau $\mathfrak{P}$ (Definitions 9.60 and 10.1 and eq. (10.95)), rather than a fixed η; local Lorentz frames exist on $\bar{\Sigma}$, but global Poincaré structure is not assumed (cf. background–independent viewpoints in [8, 3]). Second, stress observables are defined as *relational, typed witnesses* evaluated in BRST cohomology H^0 and adapted to $\bar{\Sigma}$ (Definitions 9.153 and 10.94), in line with the Haag–Kastler net perspective [230] and with BRST/Kugo–Ojima machinery [476, 108]; they are not given by a single, global Lorentz–covariant tensor on flat η. Gauge–parameter independence on certified plateaus (Nielsen safety) is ensured by the typed/Nielsen identities [120]. Consequently, the TT graviton $\hat{\gamma}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}]$ (Definition 10.167)—identified as the tangential/Goldstone mode of the Gaiamiti sector (eq. (10.28))—is consistent within this framework; an operator–level Einstein channel realization appears in Section 11.7. Hence the Weinberg–Witten obstruction does not apply to the present setting.

Proposition 10.39 (Formal inapplicability of Weinberg–Witten)**.** *Let the gravitational TT excitation be* $\hat{\gamma}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}]$ *on a certified plateau* $\mathfrak{P}$ *(Definitions 10.1 and 10.167), with observables evaluated in* $H^0(\hat{Q}_{\mathrm{BRST}})$ *and typed projectors satisfying the admission gate (Definition 10.94). Suppose:*

(i) the operative chronogeometry is the expectation–valued $\bar{\Sigma}$ *(not a fixed Minkowski metric), and*

(ii) operational stress tensors are defined relationally with respect to $\bar{\Sigma}$ *as BRST–closed, typed witnesses in* H^0 *(Definition 9.153), rather than as a single global Lorentz–covariant, gauge–invariant, conserved tensor on flat* η*.*

Then the joint hypotheses (A)–(B) *of the Weinberg–Witten theorem [475] are not met. Therefore the theorem does not constrain the existence of* $\hat{\gamma}_{\mu\nu}$ *in this framework.*

Proof. Weinberg–Witten [475] is an implication of the form

$$(\mathrm{A}) \ \wedge \ (\mathrm{B}) \implies \text{No emergent interacting massless spin–2.}$$

Hence, $\neg(\mathrm{A} \wedge \mathrm{B})$ is sufficient for inapplicability. By the stated premises:

Failure of (A). The background used operationally is $\bar{\Sigma}_{\mu\nu}$, obtained by Σ–realization on a certified plateau $\mathfrak{P}$ (Definitions 9.60 and 10.1 and eq. (10.95)). It is expectation–valued and state–dependent; a global Poincaré structure on flat η is not assumed (cf. [8, 3]). Thus (A) does not hold.

Failure of (B). Stress–energy enters as relational, typed, BRST–closed witnesses defined with respect to $\bar{\Sigma}$ and evaluated in H^0 (Definitions 9.153 and 10.94), consistent with the Haag–Kastler algebraic setting [230] and with BRST/Kugo–Ojima cohomology [476, 108]. A single global, Lorentz–covariant, gauge–invariant, conserved tensor on flat η is neither postulated nor required. Therefore (B) does not hold.

Since both (A) and (B) fail, $\neg(\mathrm{A} \wedge \mathrm{B})$ is satisfied and the conclusion of Weinberg–Witten does not follow. The TT excitation $\hat{\gamma}_{\mu\nu}$ then arises as the typed Goldstone/tangential mode of the Gaiamiti sector (eq. (10.28)) and is certified by BRST/Nielsen safety (cf. [120]). □

Corollary 10.40 (Einstein channel compatibility)**.** *Under the hypotheses of Proposition 10.39, the operator–level Einstein channel constructed on the typed, triad–resolved correlator over* $\bar{\Sigma}$ *(Section 11.7) is not obstructed by [475]. In particular, the TT projector* $\mathcal{P}^{(2)}$ *realizes a massless spin–2 pole protected by BRST/Nielsen identities [120] within the algebraic (Haag–Kastler) setting [230], without requiring a global Poincaré background [8, 3].*

Remark 10.41 (Formal implications schema)**.** Let $\mathsf{WW} := \big(\mathrm{A} \wedge \mathrm{B}\big) \Rightarrow \bot_{\text{spin-2}}$ denote the Weinberg–Witten entailment [475]. In the present construction:

$$\neg\mathrm{A} \quad \text{(expectation–valued } \bar{\Sigma}\text{)} \qquad \text{and} \qquad \neg\mathrm{B} \quad \text{(relational, BRST–closed stress witnesses)}$$

hold by design; hence $\neg(\mathrm{A} \wedge \mathrm{B})$ and therefore $\neg\mathsf{WW}$ (inapplicability) obtain. Moreover, typed/Nielsen identities [120] ensure gauge–parameter independence on certified plateaus, while the algebraic net structure [230] provides a consistent operator setting in which the TT Goldstone mode is realized (eq. (10.28)).

All (τ)–kairos operations act on the (Σ)-realized carrier ($\bar{\Sigma}$) established upstream (Definition 9.60). Typed (τ)-projectors commute with the triad projectors and preserve the graded/BRST structure—orthogonality, completeness, and triadic compatibility follow from the typed layer (Definitions 9.116 and 9.186 and Proposition 9.202) and are inherited by the weave construction (Remark 10.114 and Definition 10.2). Cone preservation and sector purity are maintained under the band/IR windowing used throughout (Remark 9.15); consequently, typed insertions can be made in any correlator block without compromising Nielsen safety or realized weave configuration invariance (Proposition 10.10).

Operationally, the (τ)-typed entries are certified with the same calibrated meters and visibilities as the other types, evaluated per triad channel under the ($\bar{\Sigma}$)-weighted inner products (Definitions 10.82 and 10.117). For the scalar family ($S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$), TT-nullity is enforced by the vanishing of the TT component, monitored through the TT-leak diagnostic (ε) (Definition 10.32), with an additional parity-odd check for ($\tilde{S}^{(p)}$) consistent with the typed conventions. For the chrono–kymon vector ($A^{(\pm)}$), helicity purity is controlled by the corresponding residual on the ($A^{(\pm)}$)-subspaces and a parity asymmetry feature (Δ_P), optionally accompanied by a CP-resolved check; the parity and CP diagnostics are recorded as (Δ_P) and ($\Delta^{(a)}_{\mathrm{CP}}$) (Definitions 10.51 and 10.58). All such meters and features are computed triad-by-triad on ($\mathcal{H}_{\mathrm{phys}}$) with the admissible IR window fixed by the weave realized weave configuration (Definitions 10.1 and 10.2).

Two structural guarantees ensure robustness. First, *TT protection*: any (τ)-typed insertion leaves the graviton TT channel uncontaminated—($\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$) annihilates the ($\tau$) contributions and the corresponding typed blocks, as encoded in the orthogonality identities and the TT-null preservation lemma (eq. (10.36) and Lemma 10.123). Second, *typed coherence*: the typed projectors and witnesses supplied by Chapter 10 furnish orthogonality/completeness and commuting relations with the triad (Definition 9.187 and Proposition 9.202), which render the (τ)-diagnostics well-posed and directly comparable to those for TT, Higgs/CP, and CK entries within the same ledger (Definition 10.82).

Decision-making integrates the (τ)-diagnostics into the standard certify-or-audit pipeline. For each $((\mathscr{S}, [\chi]))$ with (χ) a (τ)-type, Law and State visibilities are tested against their thresholds and combined with the diagnostics $(\varepsilon, \Delta_P, \Delta^{(a)}_{\mathrm{CP}})$ through the SynTh potential ($\mathfrak{D}^{[\mathscr{S};\chi]}$) (Definitions 10.94 and 10.100 and eq. (10.59)). Co-tenability obtains when thresholds are met; otherwise, a finite audit path of admissible moves is followed until either co-tenability is achieved or a certified failure is issued (e.g., persistent TT leak, robust parity/CP asymmetry, or absent spectral support) (Definition 10.105 and Theorem 10.107).

Conceptually, this positions the (τ)–kairos as a typed weaving layer that is algebraically grounded in Chapter 10 and operationally deployed in Chapter 11. Chapter 10 supplies the (Σ)-carrier and the typed apparatus—menus, projectors, witnesses, and their triad-compatibility (Definitions 9.60, 9.116 and 9.187 and Proposition 9.202). Chapter 11 inserts these (τ)-types into the unified inter-modal correlator and resolves them triad-by-triad (Definition 10.113 and eq. (10.61)), augments them with calibrated meters and diagnostics (Definitions 10.32, 10.51, 10.58 and 10.82), and closes the loop with realized weave configuration-invariant certification via the audit/termination guarantees (Proposition 10.10, Definition 10.105, and Theorem 10.107).

10.5.1 The Graviton Six Polarization Modes (Hypothetical)

In standard metric theory as presently understood—namely general relativity (GR)—the gravitational-wave content consists of precisely two tensor polarizations, the "+" and "×" modes, corresponding to a massless spin-2 field with helicities ±2 [7, 14]. When reference is made to "metric theories with six GW polarizations," the intention is the broader class of metric theories (e.g., scalar–tensor, vector–tensor, certain bimetric models) in which a metric still governs free fall while additional fields can source non-tensor polarizations. In this generic classification there can be up to six polarization *types* in total—two tensor (the GR graviton sector), two vector, and two scalar (breathing and longitudinal)—as organized in the Newman–Penrose/ELLWW classification and subsequent detector-oriented treatments [477, 478, 479]. The graviton remains the tensor piece; the additional four modes are not graviton polarizations but arise from scalar/vector sectors (e.g., Brans–Dicke–type scalars or vector–tensor theories) [480, 479]. A change to the tensor projector family is required only if the representation for a *single* spin-2 field is altered (e.g., a massive spin-2 or a genuine kinematical departure), in which case a representation-adapted typed family is substituted for TT while retaining the same sandwiched scaffold (cf. Definition 10.25 and the discussion in Section 10.5.1); in bimetric frameworks the tensor content can also be enlarged/mixed [481].

Within the weave, the massless graviton sector is realized by the TT type, while any admitted non-tensor modes are modeled as typed τ–kairos families and inserted into the Unified Inter-Modal Correlator via the typed-insertion rule (Definition 10.113). This refinement acts on sector blocks while preserving BRST/band hygiene through the physical projector $\mathsf{P}_{\mathrm{phys}}$ and the realized weave configuration $\mathcal{I}^{[\mathcal{J}]}$. The scalar pair is encoded by the breathing and longitudinal types $S^{(b)}, S^{(L)}$ (with an optional pseudoscalar $\tilde{S}^{(p)}$), and the vector pair by the Chrono–Kymon helicities $A^{(\pm)}$ (Definition 10.4).

TT purity is enforced structurally: the TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ imposes the tensor condition relative to the relational background $\bar{\Sigma}$ (Definition 10.3; cf. York–Lichnerowicz TT extraction [43, 44]), and any correlator block containing a τ insertion is annihilated when sandwiched by $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ by the TT-null preservation lemma (Lemma 10.123). Consequently, the graviton readout remains strictly two-polarization TT even in the presence of scalar/vector modes, while τ content appears exclusively in its own typed channels.

Operationally, each admitted type (tensor, vector, scalar) is further decomposed by the provenance triad $\{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2), enabling component-wise reporting without altering the polarization count. Law/state ledgers and cosine visibilities are computed as in Definition 10.82; TT employs the TT-leak diagnostic ε, vectors support the parity asymmetry Δ_P, and scalars permit CP/parity checks, with automatic triggers and cotenability thresholds administered per Definition 10.95. Mixed (off-diagonal) $\Phi\Theta$ interactions are handled by typed insertion on the corresponding correlator blocks (Definition 10.113); τ enters only as a typed projector family (never as a sector), so TT-null guarantees and the audit/provenance architecture are preserved.

Two extensions illustrate how departures from the GR baseline are incorporated without disturbing the outer scaffold. First, a *massive* spin-2 field (Fierz–Pauli-type) transforms with little group $SO(3)$ and carries five propagating helicities $\{\pm 2, \pm 1, 0\}$; waves obey a massive dispersion relation, gauge redundancy is broken, and Stückelberg fields track the

$\pm 1, 0$ components [474, 109, 113]. In the weave, this is modeled by replacing the TT type with a representation-adapted massive spin-2 typed family whose internal projectors resolve $\{\pm 2, \pm 1, 0\}$; the physical-sector–typed–triad–typed–physical-sector projector and the triad $\{\text{spec}, \text{vac}, \text{corr}\}$ remain unchanged, and the $\bar{\Sigma}$-weighted mixing/eigenproblem continues to apply (Definitions 10.2, 10.25, 10.113, 10.116 and 10.117). Second, a *true Lorentz/kinematical* departure alters the little-group/dispersion structure (e.g., preferred-frame backgrounds, helicity-dependent speeds, higher-derivative cones), thereby modifying the number or character of independent polarization states even for a single spin-2 representation; see, for example, the broader test frameworks for non-GR propagation [479, 478]. The weave handles this by swapping TT for a representation-adapted typed family tuned to the altered kinematics and inserting it into the same typed-insertion scaffold (Section 10.5.1 and Definitions 10.2 and 10.113), while keeping τ–kairos, chrono-kymon, and Higgs channels orthogonal (Definition 10.4).

Observable signatures in either extension include dispersion (frequency-dependent arrival times; subluminal/superluminal propagation), polarization content (power in vector/scalar patterns tied to the same spin-2 source, or non-standard tensor mixtures/rotations), and birefringence/anisotropy (helicity-dependent speeds or polarization rotation). These are recorded in the typed ledgers and visibilities with the existing meters and triggers (Definitions 10.82, 10.94 and 10.95); see also the phenomenological summaries in [479, 478].

Proposition 10.42 (Interpreting "six polarizations")**.** *Under the standard Poincaré/Wigner classification [482, 14], a single spin-2 field carries two independent polarizations if massless (little group $E(2)$) and five if massive (little group $SO(3)$; see also the Fierz–Pauli analysis [474]). Therefore, a statement of "six polarizations" must be understood as either:*

(A) *six* gravitational-wave *(GW) polarization* types *across distinct spin sectors (tensor 2 + vector 2 + scalar 2), as organized in the Newman–Penrose/ELLWW classification and modern detector frameworks [477, 478, 479]; or*

(B) *multiple* spin-2 species *whose tensor polarizations sum across species (e.g., in bimetric or multi-tensor scenarios [481]).*

The Chapter 11 weave formalism accommodates both while keeping the TT (graviton) channel uncontaminated (via $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and the graviton projector Definitions 10.3 and 10.25).

Case (A): six GW types (2 tensor + 2 vector + 2 scalar). By Definition 10.25 and (10.28)–(10.29), the TT (graviton) readout from a symmetric perturbation $\delta\hat{g}_{\mu\nu}$ is

$$\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}_{\mathrm{grav}}\,\delta\hat{g}_{\mu\nu} = \sum_{a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}} \underbrace{\mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{(a)}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{g}_{\mu\nu}}_{\hat{h}^{(a)}_{\mu\nu}}$$

with provenance split by the triad idempotents $\Pi^{(a)}$ (Definition 10.2). The additional four GW modes are *non-tensor*: they inhabit the τ–kairos families $S^{(b)}, S^{(L)}$ (scalars) and $A^{(\pm)}$ (vectors) (Definition 10.4). Typed orthogonality and TT–null preservation give, for every $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$,

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{[X]} = 0 = \Pi^{[X]}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \qquad \text{and} \qquad \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\mathbf{G}}^{[X\to Y]}_{\Lambda}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} = 0, \tag{10.36}$$

where $\hat{\mathbf{G}}_{\Lambda}^{[\cdot\to\cdot]}$ denotes the typed correlator blocks from Definition 10.113 and the first identity is enforced by Definition 10.3 and Lemma 10.123. Consequently, the TT readout remains strictly two–polarization, while the non–TT content is recorded exclusively in its own typed channels.

For transparent accounting, the τ-typed ledgers are taken triad-by-triad: for $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ and $X \in \{S^{(b)}, S^{(L)}, A^{(\pm)}\}$,

$$\mathcal{P}_X^{(a)} := \left\| \mathsf{P}_{\mathrm{phys}}\, \Pi^{[X]}\, \Pi^{(a)}\, \mathsf{P}_{\mathrm{phys}}\, \delta\hat{g} \right\|_{\mathcal{I}}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \Pi^{[X]}\, \Pi^{(a)} = 0 = \Pi^{(a)}\, \Pi^{[X]}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}, \tag{10.37}$$

so that (10.36)–(10.37) make the TT–null guarantee explicit while enabling component-wise reporting by provenance (Definition 10.2). The corresponding visibilities and diagnostics— e.g. $\Lambda_{\mathrm{law/state}}$ for power normalization, the TT-leak ε for non-spectral TT content, the vector parity asymmetry Δ_P, and scalar CP/parity checks—are computed on the typed, triad-resolved blocks using the calibrated meters and triggers (Definitions 10.82 and 10.95).

Case (B): six tensor states via multiple spin-2 species. Assume N massless spin-2 species, each with helicities ± 2. The TT type is refined by a species index so that the typed TT projector decomposes into orthogonal components,

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = \sum_{i=1}^{N} \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],j} = \delta_{ij}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i},$$

and the triad/spectral idempotents lift component–wise,

$$\mathsf{P}_{\mathrm{spec}}^{(2)} \rightsquigarrow \bigoplus_{i=1}^{N} \mathsf{P}_{\mathrm{spec}}^{(2),i}, \qquad \Pi^{(a)} \rightsquigarrow \bigoplus_{i=1}^{N} \Pi^{(a),i}, \quad a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\} \text{ (Definition 10.2)}.$$

With these refinements, the graviton projector of (10.28)–(10.29) becomes, in the same sandwiched form,

$$\mathcal{P}_{\mathrm{grav}}^{(2)} = \mathsf{P}_{\mathrm{phys}} \left(\sum_i \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i} \right) \left(\bigoplus_i \mathsf{P}_{\mathrm{spec}}^{(2),i} \oplus \bigoplus_i \Pi^{(\mathrm{vac}),i} \oplus \bigoplus_i \Pi^{(\mathrm{corr}),i} \right) \left(\sum_i \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i} \right) \mathsf{P}_{\mathrm{phys}},$$

so the species–resolved tensor field retains the provenance split:

$$\hat{h}_{\mu\nu} = \sum_a \sum_i \mathsf{P}_{\mathrm{phys}}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i}\, \Pi^{(a),i}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}],i}\, \mathsf{P}_{\mathrm{phys}}\, \delta\hat{g}_{\mu\nu}, \qquad a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}.$$

Species mixing is resolved by the $\bar{\Sigma}$–weighted generalized eigen-operator pair construction and whitening (Definitions 10.116 and 10.117). Writing $(\mathcal{A}, \mathcal{B})$ for the typed TT generalized eigen-operator pair on the certified band (Definitions 10.113 and 10.117), the generalized eigenproblem

$$\mathcal{A}\, u = \lambda\, \mathcal{B}\, u, \qquad \langle u_i, u_j \rangle_{\bar{\Sigma}} := \left\langle u_i, \mathcal{B}\, u_j \right\rangle_{\bar{\Sigma}} = \delta_{ij},$$

is whitened by $w := \mathcal{B}^{-1/2} u$ so that $\mathcal{B}^{-1/2} \mathcal{A}\, \mathcal{B}^{-1/2}$ is self-adjoint in the reference $\bar{\Sigma}$-weighted inner product (Definition 10.117). The corresponding orthogonal projectors onto the eigen–TT channels, $\{\Pi_{\mathrm{eig}}^{[\mathrm{TT}],i}\}_{i=1}^{N}$, satisfy

$$\Pi_{\mathrm{eig}}^{[\mathrm{TT}],i}\, \Pi_{\mathrm{eig}}^{[\mathrm{TT}],j} = \delta_{ij}\, \Pi_{\mathrm{eig}}^{[\mathrm{TT}],i}, \qquad \sum_{i=1}^{N} \Pi_{\mathrm{eig}}^{[\mathrm{TT}],i} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]},$$

and block–diagonalize the typed TT correlator,

$$\Pi^{[\mathrm{TT}],i}_{\mathrm{eig}}\,\hat{\mathbf{G}}_{\Lambda}^{[\mathrm{TT}\to\mathrm{TT}]}\,\Pi^{[\mathrm{TT}],j}_{\mathrm{eig}} = 0 \quad (i \neq j),$$

so each species is reported in an orthogonal eigen–TT channel with the triad provenance retained.

For transparent ledgers, the species– and provenance–resolved TT power is

$$\mathcal{P}^{(a)}_{\mathrm{TT},i} := \left\| \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{TT}],i}_{\mathrm{eig}}\,\Pi^{(a),i}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{g} \right\|_{\mathcal{I}}, \qquad a \in \{\mathrm{spec},\mathrm{vac},\mathrm{corr}\},$$

with visibilities/diagnostics computed on these typed blocks using the calibrated meters and triggers (Definitions 10.82 and 10.95). Thus the outcome is a set of orthogonal eigen–TT channels (one per species), with TT purity (via the sandwiched form) and triad provenance (Definition 10.2) preserved throughout.

When a deeper rewrite is required. If a *single* spin-2 representation supports six independent tensor-like polarizations (e.g., due to strong Lorentz breaking or non–Wigner kinematics), the TT type is replaced by a representation-adapted typed family while the outer scaffold and provenance logic remain unchanged. Concretely, let

$$\Pi^{[\mathrm{RT}]} \;=\; \sum_{i=1}^{m} \Pi^{[\pi_i]}, \qquad \Pi^{[\pi_i]}\,\Pi^{[\pi_j]} = \delta_{ij}\,\Pi^{[\pi_i]},$$

denote the representation-adapted tensor-type projector family (cf. the representation-adapted construction outlined in Section 10.5.1 and the projector-algebra pattern used for TT and typed families in Definitions 10.2 and 10.3), where m is the number of independent polarization projectors admitted by the altered little-group structure (e.g., $m = 6$ in the scenario at hand).

The TT projector in the sandwiched construction is replaced *in situ*:

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \;\rightsquigarrow\; \Pi^{[\mathrm{RT}]},$$

and the Chapter 11 sandwiched graviton projector (Definition 10.25, (10.28)) becomes

$$\mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{RT}]}\left(\mathsf{P}^{(\mathrm{RT})}_{\mathrm{spec}} \;\oplus\; \Pi^{(\mathrm{vac})} \;\oplus\; \Pi^{(\mathrm{corr})}\right)\Pi^{[\mathrm{RT}]}\,\mathsf{P}_{\mathrm{phys}},$$

i.e., the same physical–typed–triad–typed–physical scaffold with the usual triad idempotents $\{\Pi^{(\mathrm{spec})},\Pi^{(\mathrm{vac})},\Pi^{(\mathrm{corr})}\}$ (Definition 10.2) and a representation-adapted spectral selector $\mathsf{P}^{(\mathrm{RT})}_{\mathrm{spec}}$ (constructed on the certified band as in Definition 10.7, with measurability per Proposition 10.149). The corresponding field readout mirrors (10.29):

$$\hat{h}^{(\mathrm{RT})}_{\mu\nu} = \sum_{a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}} \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{RT}]}\,\Pi^{(a)}\,\Pi^{[\mathrm{RT}]}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{g}_{\mu\nu}.$$

Typed orthogonality to the τ–kairos families (Definition 10.4) is imposed exactly as for TT, yielding the same null-preservation pattern (cf. Lemma 10.123):

$$\Pi^{[\mathrm{RT}]}\,\Pi^{[X]} = 0 = \Pi^{[X]}\,\Pi^{[\mathrm{RT}]}, \qquad \Pi^{[\mathrm{RT}]}\,\hat{\mathbf{G}}_{\Lambda}^{[X\to Y]}\,\Pi^{[\mathrm{RT}]} = 0, \quad X \in \{S^{(b)},S^{(L)},\tilde{S}^{(p)},A^{(\pm)}\},$$

so the representation-adapted tensor channel remains uncontaminated, while non-tensor content is recorded in its own typed ledgers (Definitions 10.82, 10.95 and 10.113).

Gauge-/retune-robustness is inherited from the same identities used for TT. For any composition $\mathcal{J}$ built from admissible typed/triad idempotents, the embedded Nielsen identity on $\mathcal{H}_{\text{phys}}$ (Ch. 8; cf. Proposition 7.174) gives

$$\partial_\xi \big\langle \mathcal{J}\, \delta\hat{g} \big\rangle_{\mathcal{H}_{\text{phys}}} = 0,$$

and along admissible retunes the Riesz selectors remain continuous on certified contours (Definition 10.7 and Proposition 10.149), so the representation-adapted correlators vary continuously under the same audit moves. Consequently, while the *typed tensor family* changes (TT $\mapsto$ RT), the outer scaffold "physical-sector $\perp$ provenance-split $\perp$ physical-sector" and the triad decomposition/audit logic (Definition 10.2) remain in force without further modification.

Bottom line.

- In metric theories with six GW types, the graviton stays two-polarization TT; the extra four are non-TT and live in τ types (Definitions 10.3 and 10.4 and Lemma 10.123).
- If experiments revealed six *tensor* states in total, interpret them as multiple spin-2 species; the sandwiched projector and triad split extend by species without structural change (Definition 10.25, (10.28), (10.29)).
- A truly "six-polarization" single spin-2 signals new kinematics; the framework operates by swapping in the representation-adapted typed projector family while keeping the audit/provenance architecture unchanged.

10.6 The Higgs (Radial Kymon) in the Tantrakyma Sector

We work on the realized weave configuration $\mathcal{I}^{[\mathcal{Y}]}$ of Definition 10.1 in the $\Theta\Theta$ (tantrakyma) sector, with triad projectors $\Pi^{(a)}$ from Definition 10.2, the CP–refined radial projectors $\Pi_\Theta^{[\text{rad}\pm]}$ of Definition 10.5, and the spin-0 Riesz selector $\mathsf{P}^{(0)}_{\text{spec}}$ from Definition 10.7. All statements are taken on $\mathcal{H}_{\text{phys}} = \operatorname{Ran} \mathsf{P}_{\text{phys}}$.

Definitions.

Definition 10.43 (Higgs projectors (CP-resolved, triad-resolved, future-proof))**.** Let $K^{(0)}_{\Theta\Theta}$ be the band-limited, gauge-fixed scalar sub-block of the $\Theta\Theta$ kinetic operator. The *CP-resolved Higgs projectors* are

$$\boxed{\mathcal{P}^{(0)}_{\text{H},\pm} := \mathsf{P}_{\text{phys}}\, \Pi_\Theta^{[\text{rad}\pm]} \Big(\mathsf{P}^{(0)}_{\text{spec}} \;\oplus\; \Pi^{(\text{vac})} \;\oplus\; \Pi^{(\text{corr})} \Big) \Pi_\Theta^{[\text{rad}\pm]}\, \mathsf{P}_{\text{phys}}} \tag{10.38}$$

and the corresponding *Higgs fields* (CP-even/odd) extracted from the tantrakyma fluctuation $\delta\hat{\mathbf{\Theta}}$ are

$$\boxed{\hat{H}_\pm := \mathcal{P}^{(0)}_{\mathrm{H},\pm}\,\delta\hat{\mathbf{\Theta}} = \sum_{a\in\{\mathrm{spec,vac,corr}\}} \hat{H}^{(a)}_\pm}\,, \qquad \hat{H}^{(a)}_\pm := \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{rad}\pm]}_\Theta\,\Pi^{(a)}\,\Pi^{[\mathrm{rad}\pm]}_\Theta\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{\mathbf{\Theta}}. \tag{10.39}$$

Definition 10.44 (CP mixing block and mass/band eigenmodes)**.** In the CP basis (H_+, H_-), the scalar operator restricted to the radial subspace can be represented as

$$K^{(0)}_{\Theta\Theta}\big|_{\mathrm{rad}} = \begin{pmatrix} K_{++} & K_{+-} \\ K_{-+} & K_{--} \end{pmatrix}, \qquad K_{-+} = K_{+-}^\dagger. \tag{10.40}$$

The *mass/band eigenmodes* are obtained by a unitary diagonalization U of (10.40), equivalently by the Riesz spectral projectors of $\mathsf{P}^{(0)}_{\mathrm{spec}}$.

Structural facts.

Lemma 10.45 (Orthogonality, completeness, and CP resolution)**.** *The ranges of* $\Pi^{[\mathrm{rad}+]}_\Theta$ *and* $\Pi^{[\mathrm{rad}-]}_\Theta$ *are orthogonal, and* $\Pi^{[\mathrm{rad}+]}_\Theta + \Pi^{[\mathrm{rad}-]}_\Theta = \Pi^{[\mathrm{rad}]}_\Theta$*. Moreover,* $[\Pi^{(a)}, \Pi^{[\mathrm{rad}\pm]}_\Theta] = 0$ *for all* a*.*

Proof. Orthogonality and completeness follow from Definition 10.5. Commutation with the triad is part of that definition. □

Lemma 10.46 (BRST/Nielsen invariance and band stability)**.** *Any correlator on* $\mathcal{H}_{\mathrm{phys}}$ *formed from* $\hat{H}_\pm$ *and finitely many insertions of* $\Pi^{(a)}$*,* $\Pi^{[\mathrm{rad}\pm]}_\Theta$*, and* $\mathsf{P}^{(0)}_{\mathrm{spec}}$ *is (i) gauge-parameter independent and (ii) stable under admissible retunings of* (P_x, K_{IR})*.*

Proof. This is a specialization of Proposition 10.10. □

Proposition 10.47 (NG/pNG orthogonality (radial selection))**.** *Let* $\Pi^{[\mathrm{NG/pNG}]}_\Theta$ *denote the upstream NG/pNG projector from the tantrakyma SSB analysis (Ch. 10, referenced there). Then* $\Pi^{[\mathrm{NG/pNG}]}_\Theta\,\Pi^{[\mathrm{rad}\pm]}_\Theta = 0$ *and* $\Pi^{[\mathrm{rad}\pm]}_\Theta$ *projects onto amplitude (radial) directions only.*

Proof. By construction of the radial type upstream (orthogonality of amplitude vs. Goldstone directions in the Σ-weighted inner product), preserved by the CP refinement which commutes with the upstream split. □

Proposition 10.48 (Future-proofing under additional scalar species)**.** *If the realized dynamics acquires additional spin-0 spectral branches (new contours* Γ_j*),* $\mathsf{P}^{(0)}_{\mathrm{spec}}$ *enlarges by the corresponding Riesz terms and* $\mathcal{P}^{(0)}_{\mathrm{H},\pm}$ *automatically includes the new species.*

Proof. Additivity of Riesz projectors over disjoint spectral contours. □

CP (a)symmetry, positivity, and diagnostics.

Proposition 10.49 (Block structure under CP conservation/violation)**.** *If CP is conserved, $K_{+-} = 0$ and $\hat{H}_+, \hat{H}_-$ propagate independently (block-diagonal case). If CP is violated (explicitly or spontaneously), $K_{+-} \neq 0$; then the spectral projectors from $\mathsf{P}^{(0)}_{\mathrm{spec}}$ return mass/band eigenmodes which are unitary mixtures of $\hat{H}_+, \hat{H}_-$.*

Proof. Direct from (10.40) and the spectral calculus. In the CP-conserving case the Riesz projectors coincide with the CP projectors; otherwise they are related by a unitary U which diagonalizes the 2×2 block. □

Proposition 10.50 (Spectral positivity (radiative scalar))**.** *The spectral (radiative) Higgs component has nonnegative spectral density on $\mathcal{H}_{\mathrm{phys}}$: $\rho_{(0)}(\omega, \mathbf{k}) \geq 0$.*

Proof (outline). Inherited from the upstream band-positive structure (Ward/Nielsen/BRST framework) after restriction to the radial scalar subspace; projectors commute with the positivity arguments. □

Definition 10.51 (CP asymmetry audit)**.** For each triad channel a, define the (law/state) CP asymmetry

$$\Delta^{(a)}_{\mathrm{CP}} := \Lambda^{[H^{(a)}_+]}_{\mathrm{law/state}} - \Lambda^{[H^{(a)}_-]}_{\mathrm{law/state}}, \tag{10.41}$$

with $\Lambda^{[\cdot]}_{\mathrm{law/state}}$ from Definitions 10.80 and 10.82. CP conservation implies $\Delta^{(a)}_{\mathrm{CP}} = 0$.

Operational extraction and certification.

Definition 10.52 (Typed Higgs witnesses and visibilities)**.** Let $\mathbf{W}^{[\Theta\Theta;\mathrm{rad}\pm]}$ be the consolidated witness for the CP-resolved radial types in the tantrakyma sector (Ward + spectral ledgers). Define $\Lambda^{[\Theta\Theta;\mathrm{rad}\pm]}_{\mathrm{law/state}}$ as in Definitions 10.80 and 10.82, evaluated on $\mathcal{H}_{\mathrm{phys}}$ with $\mathcal{I}^{[\Theta\Theta]}$.

Proposition 10.53 (Well-posed Parasymmetric TLO for the Higgs)**.** *For each CP-resolved radial type, the Parasymmetric TLO triple* (Type $= \mathrm{rad}\pm$, Location, Onset) *of Definition 10.85 and Proposition 10.90 exists and is unique on the certified band. The onset $r^\star[\mathrm{rad}\pm]$ is stable under admissible retuning and tightening of K_{IR}.*

Proof. Type is fixed by $\Pi^{[\mathrm{rad}\pm]}_\Theta$; uniqueness follows from orthogonality to NG/pNG (Prop. 10.47) and to other scalar types. Stability is inherited from Lemma 10.46. □

Remarks.

Remark 10.54 (Physics reading by triad)**.** $\hat{H}^{(\mathrm{spec})}_\pm$ represents the radiative, particle-like Higgs content (possibly multiple scalar species under Proposition 10.48). $\hat{H}^{(\mathrm{vac})}_\pm$ encodes vacuum scalar structure (no asymptotic flux; baseline/contact pieces). $\hat{H}^{(\mathrm{corr})}_\pm$ captures coherence/near-field scalar responses that typically diminish upon tightening K_{IR}.

Remark 10.55 (SM-like limit)**.** The usual SM Higgs corresponds to a dominantly CP-even, spectral radial mode $\hat{H}^{(\mathrm{spec})}_+$ with negligible $\hat{H}_-$ and suppressed vac/corr components on the certified plateau; the framework accommodates CP-odd admixtures without modification (Proposition 10.49).

10.7 The Chrono–Kymon (Vector Channel of the τ-kairos)

We work on the realized weave configuration $\mathcal{I}^{[\mathcal{J}]}$ of Definition 10.1 in the τ-kairos block, with triad projectors $\Pi^{(a)}$ from Definition 10.2, the helicity-resolved typed idempotents $A^{(\pm)}$ from Definition 10.4, and the TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ from Definition 10.3. All statements are taken on $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$.

Definitions.

Definition 10.56 (Spin-1 spectral selector in the τ-vector subspace)**.** Let $K_\tau^{(1)}$ denote the band-limited, gauge-fixed linearized kinetic operator restricted to the *vector* subspace of the τ-kairos block.[2] Define the spin-1 Riesz selector, with $\{\zeta_m\}_{m\in\mathfrak{S}_1}$ disjoint contours enclosing the realized helicity-1 spectral features (poles/bands) on the certified band, by

$$\mathsf{P}_{\mathrm{spec}}^{(1)} := \sum_{m\in\mathfrak{S}_1} \frac{1}{2\pi i}\oint_{\zeta_m} \left(K_\tau^{(1)} - z\right)^{-1} dz\,. \tag{10.42}$$

We also set the spin-1 spectral triad piece $\Pi_\tau^{(\mathrm{spec};1)} := \mathsf{P}_{\mathrm{spec}}^{(1)}$ for later triad bookkeeping.

Definition 10.57 (Chrono–Kymon projectors and fields (helicity- and triad-resolved))**.** For $\lambda = \pm$, define the *helicity-resolved Chrono–Kymon projectors*

$$\boxed{\mathcal{P}_{\mathrm{CK},\lambda}^{(1)} := \mathsf{P}_{\mathrm{phys}}\, A^{(\lambda)} \left(\, \Pi_\tau^{(\mathrm{spec};1)} \;\oplus\; \Pi^{(\mathrm{vac})} \;\oplus\; \Pi^{(\mathrm{corr})} \,\right) A^{(\lambda)}\, \mathsf{P}_{\mathrm{phys}}} \tag{10.43}$$

acting on the τ-vector carrier space. From a raw τ-vector fluctuation $\delta\hat{K}_\mu^{(\tau)}$ we extract the (helicity, triad) Chrono–Kymon fields

$$\boxed{\hat{K}_{\lambda,\mu}^{(\tau)(a)} := \mathsf{P}_{\mathrm{phys}}\, A^{(\lambda)}\, \Pi^{(a)}\, A^{(\lambda)}\, \mathsf{P}_{\mathrm{phys}}\, \delta\hat{K}_\mu^{(\tau)}, \qquad \hat{K}_{\lambda,\mu}^{(\tau)} := \sum_{a\in\{\mathrm{spec,vac,corr}\}} \hat{K}_{\lambda,\mu}^{(\tau)(a)}} \tag{10.44}$$

with $\Pi^{(\mathrm{spec})}$ implicitly specialized to $\Pi_\tau^{(\mathrm{spec};1)}$ in the vector channel. Their τ-kairos *tensor images* via the typed map $A_{\mu\nu}^{(\lambda)}[\,\cdot\,]$ (cf. Definition 10.4) are

$$\hat{\tau}_{\mu\nu}^{(\mathrm{CK},\lambda)} := A_{\mu\nu}^{(\lambda)}\big[\hat{K}_\lambda^{(\tau)}\big] = \sum_a A_{\mu\nu}^{(\lambda)}\big[\hat{K}_\lambda^{(\tau)(a)}\big]\,. \tag{10.45}$$

Definition 10.58 (Parity action on helicities and visibility asymmetry)**.** Let $\mathcal{P}_\tau$ denote parity on the τ-vector subspace; then $\mathcal{P}_\tau A^{(+)}\mathcal{P}_\tau^{-1} = A^{(-)}$ and $\mathcal{P}_\tau A^{(-)}\mathcal{P}_\tau^{-1} = A^{(+)}$. Define the (law/state) *visibility* parity-asymmetry diagnostic by

$$\Delta_{P,\Lambda}^{(1)} := \Lambda_{\mathrm{law/state}}^{[A^{(+)}]} - \Lambda_{\mathrm{law/state}}^{[A^{(-)}]}\,, \tag{10.46}$$

using the witnesses of Definitions 10.80 and 10.82.

[2] Equivalently, one may use the band-limited physical two-point on the τ-vector subspace. The admissible restriction is secured by the type projectors of Definition 10.4.

Structural facts.

Lemma 10.59 (TT-nullity and orthogonality)**.** *For each $\lambda = \pm$ and a, one has $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\tau}_{\mu\nu}^{(\mathrm{CK},\lambda)} = 0$ and $A^{(\lambda)}A^{(\lambda')} = \delta_{\lambda\lambda'}A^{(\lambda)}$.*

Proof. TT-nullity follows from the typed construction in Definition 10.4. Orthogonality is part of the projector algebra in Lemma 10.8. □

Proposition 10.60 (Triad commutation and decomposition)**.** $[\Pi^{(a)}, A^{(\lambda)}] = 0$ *for all a, λ, hence the decomposition (10.44) is triad-orthogonal. Moreover, $\hat{K}^{(\tau)}_{\lambda,\mu} = \hat{K}^{(\tau)(\mathrm{spec})}_{\lambda,\mu} \oplus \hat{K}^{(\tau)(\mathrm{vac})}_{\lambda,\mu} \oplus \hat{K}^{(\tau)(\mathrm{corr})}_{\lambda,\mu}$.*

Proof. Commutation is stated in Proposition 10.9; the decomposition is immediate. □

Proposition 10.61 (BRST/Nielsen flatness and band stability)**.** *Any correlator on $\mathcal{H}_{\mathrm{phys}}$ formed from $\hat{K}^{(\tau)}_{\lambda}$, $\hat{\tau}^{(\mathrm{CK},\lambda)}$ and finitely many insertions of $A^{(\lambda)}$, $\Pi^{(a)}$, and $\mathsf{P}^{(1)}_{\mathrm{spec}}$ is (i) gauge-parameter independent and (ii) stable under admissible retunings of (P_x, K_{IR}).*

Proof. A specialization of Proposition 10.10. □

Lemma 10.62 (Spectral future-proofing (spin-1))**.** *If additional helicity-1 spectral branches appear (new contours ζ_n), the projector $\mathsf{P}^{(1)}_{\mathrm{spec}}$ enlarges by the corresponding Riesz terms and $\mathcal{P}^{(1)}_{\mathrm{CK},\lambda}$ automatically includes the new species.*

Proof. By additivity of Riesz projectors over disjoint spectral contours. □

Positivity, Ward identities, and diagnostics.

Proposition 10.63 (Transversality/longitudinality ledgers and spectral positivity)**.** *On $\mathcal{H}_{\mathrm{phys}}$, the spectral Chrono–Kymon components obey the appropriate Ward/Slavnov ledgers (transverse/longitudinal as admitted by the type) and have nonnegative spectral density $\rho_{(1)}(\omega, \mathbf{k}) \geq 0$.*

Proof (outline). Inherited from the upstream BRST/Nielsen framework (Ch. 8) restricted to the vector subspace and the typed projectors $A^{(\lambda)}$; positivity is preserved under the projectors and the Riesz selection. □

Definition 10.64 (Helicity-resolved visibilities)**.** Let $\mathbf{W}^{[\tau\text{-vec};A^{(\lambda)}]}$ be the consolidated witness for the τ-vector channel. Define $\Lambda^{[\tau\text{-vec};A^{(\lambda)}]}_{\text{law/state}}$ as in Definitions 10.80 and 10.82, evaluated on $\mathcal{H}_{\mathrm{phys}}$ with $\mathcal{I}^{[\mathscr{S}]}$.

Proposition 10.65 (Well-posed Parasymmetric TLO for Chrono–Kymon)**.** *For each helicity $\lambda = \pm$, the Parasymmetric TLO triple* (Type $= A^{(\lambda)}$, Location, Onset) *of Definition 10.85 and Proposition 10.90 exists and is unique on the certified band. The onset $r^{\star}[A^{(\lambda)}]$ is stable under admissible retuning and tightening of K_{IR}.*

Proof. Type is fixed by $A^{(\lambda)}$; uniqueness follows from $A^{(+)}A^{(-)} = 0$. Stability is inherited from Proposition 10.61. □

Remarks.

Remark 10.66 (Interface with the τ-kairos tensor and the graviton)**.** The τ-tensor image $\hat{\tau}_{\mu\nu}^{(\mathrm{CK},\lambda)}$ is TT-null (Lemma 10.59) and therefore cannot contaminate the geometrical TT (graviton) channel (cf. Cor. 10.20). Its triad decomposition spec/vac/corr distinguishes radiative vector excitations from vacuum/coherence effects.

Remark 10.67 (Parity vs helicity reporting)**.** Helicity $A^{(\pm)}$ is the primitive diagnostic (useful for chiral physics). Parity is reported via the visibility asymmetry $\Delta_{P,\Lambda}^{(1)}$ in (10.46), with $\mathcal{P}_\tau$ swapping helicities. A *ledger-based* normalized parity asymmetry can also be quoted as

$$\widetilde{\Delta}_P^{(1)} := \frac{\mathcal{L}_{A^{(+)}} - \mathcal{L}_{A^{(-)}}}{\mathcal{L}_{A^{(+)}} + \mathcal{L}_{A^{(-)}}},$$

see the meters paragraph below. This disambiguates the two notions used in earlier drafts with the same symbol.

Spin–1 Chrono–Kymon: the vector typed content of τ

The *Chrono–Kymon (CK)* is the **spin–1** (vector) typed family inside the τ–kairos channel. In the typed taxonomy it is the pair of helicity projectors $A^{(\pm)}$ from the admitted τ–families (Definition 10.4). CK is *strictly non–TT* by construction: any CK insertion is annihilated by the TT sandwich,

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\mathbf{G}}_\Lambda^{[\,A^{(\lambda)}\to Y\,]} = 0 = \hat{\mathbf{G}}_\Lambda^{[\,Y\to A^{(\lambda)}\,]}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \quad (\lambda = \pm),$$

as guaranteed by the typed–insertion rule and TT–null preservation (Definitions 10.3 and 10.113 and Lemma 10.123). Thus CK carries *no* radiative spin–2 (graviton) content; the TT graviton readout remains purely tensorial.

Typed extraction and correlator blocks. For any admissible fluctuation/correlator, CK content is read helicity-by-helicity via the typed insertion (Definition 10.113). Writing $\hat{\mathbf{G}}_\Lambda$ for the unified inter-modal correlator on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$, define the CK-typed blocks and their triad resolutions by

$$\hat{\mathbf{G}}_\Lambda^{[\,A^{(\lambda)}\to A^{(\lambda')}\,]} := \Pi^{[A^{(\lambda)}]}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[A^{(\lambda')}]}, \qquad \hat{\mathbf{G}}_\Lambda^{(a)\,[\,A^{(\lambda)}\to A^{(\lambda')}\,]} := \Pi^{(a)}\, \hat{\mathbf{G}}_\Lambda^{[\,A^{(\lambda)}\to A^{(\lambda')}\,]}\, \Pi^{(a)},$$

with $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2). Orthogonality and idempotence of the typed and triad projectors ensure that CK channels can be audited provenance-by-provenance without mixing with TT.

Optional first-order representative (notation only). When convenient for interpretation, introduce a vector representative $K_\mu^{(\tau)}$ for the CK block and its torsion-like two-form relative to the relational background $\bar{\Sigma}$:

$$K_\mu^{(\tau)}\ (\text{CK representative}), \qquad \mathcal{F}_{\mu\nu}^{(\tau)} := 2\,\bar{\nabla}_{[\mu} K_{\nu]}^{(\tau)}\,.$$

These are *not* new operators in the formalism; they are notational proxies for the CK-typed correlator content. All physically meaningful statements are made at the level of typed, triad-resolved correlators.

Spin selection and TT purity. CK is spin–1 (helicity ± 1) by its typed construction (Definition 10.4); TT purity of the graviton channel follows from the TT sandwich and typed orthogonality:

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\Pi^{[A^{(\lambda)}]} = 0 = \Pi^{[A^{(\lambda)}]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\mathbf{G}}_{\Lambda}^{[A^{(\lambda)}\to Y]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = 0 \quad (\lambda = \pm),$$

(Definition 10.3 and Lemma 10.123). Hence CK does not contribute to the TT graviton projector (Definition 10.25).

Meters, visibilities, and ledgers (CK channel). To disambiguate notation, we reserve $\mathcal{P}$ for *projectors* (e.g., $\mathcal{P}^{(1)}_{\mathrm{CK},\lambda}$) and use

$$\mathcal{L}^{(a)}_{A^{(\lambda)}} \;:=\; \left\| \mathsf{P}_{\mathrm{phys}}\,\Pi^{[A^{(\lambda)}]}\,\Pi^{(a)}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{\Sigma} \right\|_{\mathcal{I}}$$

for the CK *ledger power* in triad sector $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ and helicity $\lambda = \pm$.[3] The visibility-based parity diagnostic is $\Delta^{(1)}_{P,\Lambda}$ from (10.46), while a normalized ledger asymmetry may be quoted as $\widetilde{\Delta}^{(1)}_{P}$ (Remark 10.67). All meters are evaluated on $\mathcal{H}_{\mathrm{phys}}$ and inherit BRST/Nielsen flatness and band stability from the realized weave configuration.

Mixing, whitening, and reporting. CK may mix across helicities or with other admitted types inside non-TT sectors, but never with TT under the typed sandwich. Mixing is quantified by the typed mixing norms and resolved by the $\bar{\Sigma}$–weighted operator-generalized eigen-operator pair eigenproblem and whitening (Definitions 10.116 and 10.117). The outcome is an orthogonal set of eigen-channels inside the CK block, each carrying its triad provenance and reportable power/visibilities.

Dynamics (model class placeholder, if needed). When a first-order representative $K^{(\tau)}_{\mu}$ is adopted for phenomenology, CK dynamics may be modeled—*within the typed block*—by a Maxwell/Proca-type equation on $(\bar{\Sigma}, \bar{\nabla})$,

$$\bar{\nabla}_{\nu}\Big(\bar{\Sigma}^{\nu\alpha}\mathcal{F}^{(\tau)}_{\alpha\mu}\Big) + m^2_{(1)}\,K^{(\tau)}_{\mu} = J^{(\tau)}_{\mu}, \qquad \bar{\nabla}^{\mu}K^{(\tau)}_{\mu} = 0 \;\; (\text{on shell if } m_{(1)} \neq 0),$$

with causal support governed by the $\bar{\Sigma}$ light cone. This is an interpretive layer on top of the canonical typed-correlator machinery; it introduces no new projectors and does not affect TT purity.

Summary (CK in the weave). CK is the vector $(A^{(\pm)})$ typed content of the τ–kairos channel (Definition 10.4). It is TT-null by construction and cannot contaminate the graviton readout (Definitions 10.3 and 10.25 and Lemma 10.123). Observables are recorded in typed, triad-resolved ledgers with the standard meters and audit triggers (Definitions 10.2, 10.82 and 10.95); internal mixing is orthogonalized via the $\bar{\Sigma}$–weighted generalized eigen-operator pair and whitening (Definitions 10.116 and 10.117). No additional primitives are introduced; this

[3] Earlier drafts used the same script $\mathcal{P}$ for both projectors and powers; the present convention removes that ambiguity.

section uses only the established typed families and audit/provenance scaffold, with notational conventions made consistent across projectors ($\mathcal{P}$), powers ($\mathcal{L}$), and parity diagnostics ($\Delta^{(1)}_{P,\Lambda}$ vs. $\widetilde{\Delta}^{(1)}_{P}$).

10.8 The Spin–0 Apeiron (Gaiaton): Scalar Channel in the τ-kairos

Spontaneous symmetry breaking (SSB) of the Gaiamiti potential organizes the physical spectrum into two distinguished responses on the realized weave configuration $\mathcal{I}^{[\mathcal{J}]}$ after Σ–realization and projection to the physical cohomology $H^0(\hat{Q}_{\mathrm{BRST}})$ (Definition 9.60). The resulting pair consists of a *massless spin-2* transverse–traceless (TT) Goldstone-like mode—identified with the graviton—and a *gapped spin-0* scalar excitation along the apeiron directions, termed the *Gaiaton* (Definition 10.70). This fits the standard SSB logic that gapless modes are protected by symmetry/identity structures (Ward/Slavnov–Taylor) and gauge cohomology (BRST), while orthogonal directions acquire masses from the curvature of the potential [94, 14, 483, 484, 445, 106]. Gauge–parameter independence of physical observables on certified plateaux is controlled by Nielsen identities (gauge-variation of the effective action) [120], which we enforce via the realization map and band/typed hygiene (Definitions 9.60 and 9.116).

On the *TT/Goldstone branch*, the ΦΦ (Gaiamiti) typed menu singles out the TT block $\Pi^{[\mathrm{TT}]}_{\widetilde{\Sigma}}$ (Definitions 9.195 and 10.3). Its two-point function supports a *massless spin-2 pole* realizing the radiative graviton degrees of freedom; TT purity (trace/divergence removal) ensures the pole carries only the physical tensor helicities $\lambda = \pm 2$ [43, 7, 14]. Masslessness is protected by the Ward/Slavnov–Taylor structure and BRST cohomology on the realized weave configuration, while TT-nullity and typed orthogonality prevent scalar contamination (Proposition 9.202 and Definitions 9.195 and 10.3).

On the *scalar/apeiron branch*, the τ–kairos *scalar* typed subspace $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ captures fluctuations along the trace/apeiron directions. The second variation of the Gaiamiti potential in these directions produces a *massive spin-0 pole*. Operational isolation uses a band-limited Riesz selector applied to the scalar kinetic generalized eigen-operator pair $K^{(0)}_{\tau}$ within the admissible IR window fixed by the Chapter 10 band machinery (Remark 9.15), yielding a realized spectral mass $m_0 > 0$ and the associated physical projector [115, 253]. When invoked, CP resolution partitions the scalar ledger into CP(±) subchannels (as in Higgs-sector analyses [97, 96, 98, 467]), without modifying TT protection because the typed sandwich annihilates TT components by construction (Definition 9.116 and Proposition 9.202).

Taken together, these results are *triad-by-triad* and *typed-resolved* consequences of the Chapter 10 scaffold: TT masslessness follows from symmetry and gauge constraints encoded in the typed layer (Ward/Slavnov–Taylor, BRST, Nielsen), while the scalar mass is controlled by the curvature of the Gaiamiti potential in the apeiron directions [14, 483, 484, 445, 120]. Typed orthogonality, cone preservation, and TT-nullity (all fixed in Chapter 10) preclude TT–scalar mixing and guarantee that the pair {massless spin-2 graviton, massive spin-0 Gaiaton} is well-posed and realized weave configuration-invariant on certified plateaux (Definitions 9.60 and 9.116, Proposition 9.202, and Remark 9.15).

We work on the realized weave configuration $\mathcal{I}^{[\mathcal{G}]}$ of Definition 10.1 in the τ-kairos block, with triad projectors $\Pi^{(a)}$ from Definition 10.2, the *scalar* typed idempotents (CP-resolved) $S^{(\eta)}$ from Definition 10.4 with $\eta \in \{+,-\}$, and the TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ from Definition 10.3. All statements are taken on $\mathcal{H}_{\mathrm{phys}} = \operatorname{Ran} \mathsf{P}_{\mathrm{phys}}$ (BRST cohomological physical space) [108, 230, 14][4].

Definitions.

Definition 10.68 (Spin-0 spectral selector in the τ-scalar subspace)**.** Let $K_\tau^{(0)}$ denote the band-limited, gauge-fixed linearized kinetic operator restricted to the *scalar* subspace of the τ-kairos block.[5] Define the spin-0 Riesz selector, with $\{\zeta_m\}_{m\in\mathfrak{S}_0}$ disjoint contours enclosing the realized scalar spectral features (poles/bands) on the certified band, by

$$\mathsf{P}_{\mathrm{spec}}^{(0)} := \sum_{m\in\mathfrak{S}_0} \frac{1}{2\pi i} \oint_{\zeta_m} \left(K_\tau^{(0)} - z\right)^{-1} dz\,. \tag{10.47}$$

We also set the scalar spectral triad piece $\Pi_\tau^{(\mathrm{spec};0)} := \mathsf{P}_{\mathrm{spec}}^{(0)}$ for later triad bookkeeping.

Definition 10.69 (Gaiaton projectors and fields (CP- and triad-resolved))**.** For $\eta \in \{+,-\}$ (CP-even/odd), define the *Gaiaton projectors*

$$\boxed{\mathcal{P}_{\mathrm{G},\eta}^{(0)} := \mathsf{P}_{\mathrm{phys}}\, S^{(\eta)} \left(\Pi_\tau^{(\mathrm{spec};0)} \oplus \Pi^{(\mathrm{vac})} \oplus \Pi^{(\mathrm{corr})} \right) S^{(\eta)}\, \mathsf{P}_{\mathrm{phys}}} \tag{10.48}$$

acting on the τ-scalar carrier space. From a raw τ-scalar fluctuation $\delta\hat{\Phi}$ we extract the (CP, triad) Gaiaton fields

$$\boxed{\hat{\Phi}_\eta^{(a)} := \mathsf{P}_{\mathrm{phys}}\, S^{(\eta)}\, \Pi^{(a)}\, S^{(\eta)}\, \mathsf{P}_{\mathrm{phys}}\, \delta\hat{\Phi}, \qquad \hat{\Phi}_\eta := \sum_{a\in\{\mathrm{spec,vac,corr}\}} \hat{\Phi}_\eta^{(a)}} \tag{10.49}$$

with $\Pi^{(\mathrm{spec})}$ implicitly specialized to $\Pi_\tau^{(\mathrm{spec};0)}$ in the scalar channel.

Definition 10.70 (Gaiaton (spin-0 apeiron))**.** Within the τ–kairos scalar subspace (Definition 10.4), the *Gaiaton* is the CP- and triad-resolved scalar excitation selected by the spin-0 Riesz projector $\mathsf{P}_{\mathrm{spec}}^{(0)}$ of Definition 10.68 and carried by the CP projectors $S^{(\eta)}$ for $\eta \in \{+,-\}$. Concretely, the Gaiaton channel is the image of the *Gaiaton projectors*

$$\mathcal{P}_{\mathrm{G},\eta}^{(0)} \text{ of Definition 10.69}, \qquad \text{with fields } \hat{\Phi}_\eta^{(a)} \text{ and } \hat{\Phi}_\eta \text{ given by (10.49)}.$$

Its realized masses $m_{0,\eta}$ are the pole/band locations enclosed by the contours in (10.47), read from the typed, triad-resolved correlator blocks (Definitions 10.2 and 10.113) on the Σ-carrier (Definition 9.60).

[4] Applied to the physical projector $\mathsf{P}_{\mathrm{phys}}$, $\mathcal{H}_{\mathrm{phys}} = \operatorname{Ran} \mathsf{P}_{\mathrm{phys}}$ is the physical subspace (isomorphic to the BRST cohomology $H^0(\hat{Q}_{\mathrm{BRST}})$ in this setup). On $\operatorname{Ran} \mathsf{P}_{\mathrm{phys}}$ the projector acts as the identity; on $\ker \mathsf{P}_{\mathrm{phys}}$ it vanishes, and $\mathcal{H} = \operatorname{Ran} \mathsf{P}_{\mathrm{phys}} \oplus \ker \mathsf{P}_{\mathrm{phys}}$ (orthogonal direct sum, since $\mathsf{P}_{\mathrm{phys}} = \mathsf{P}_{\mathrm{phys}}^*$).

[5] Equivalently, one may use the band-limited physical two-point on the τ-scalar subspace. The admissible restriction is secured by the type projectors of Definition 10.4.

Lemma 10.71 (TT-orthogonality and typed safety)**.** *For all admissible η, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\mathcal{P}_{\mathrm{G},\eta}^{(0)} = 0 = \mathcal{P}_{\mathrm{G},\eta}^{(0)}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$; hence the Gaiaton channel does not mix with the TT graviton channel. Moreover, $\mathcal{P}_{\mathrm{G},\eta}^{(0)}$ commutes with the triad projectors $\Pi^{(\mathrm{spec})}, \Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{corr})}$, so all meters/visibilities are triad-resolved and BRST/Nielsen-safe on certified plateaus.* Proof sketch. *TT-nullity of the τ–scalar types and triad-compatibility of typed projectors are enforced by the typed weave (Definitions 10.2 and 10.4) and the Chapter 10 typed layer; the conclusion follows by substituting the definitions of* (10.48) *and* (10.49)*.*

Proof. **(1) TT-orthogonality.** By construction (see the scalar typed family in Definition 10.4), the Gaiaton projector acts within the τ–scalar typed ranges and has the typed–sandwich form

$$\mathcal{P}_{\mathrm{G},\eta}^{(0)} \;=\; \mathsf{P}_{\mathrm{phys}}\, S^{(\eta)}\, \mathcal{R}^{(0)}\, S^{(\eta)}\, \mathsf{P}_{\mathrm{phys}}, \qquad \eta \in \{b, L, p, +, -\},$$

where $\mathcal{R}^{(0)}$ is a scalar Riesz/triad selector on the realized weave configuration (cf. (10.48), (10.49) and Definitions 10.2 and 10.7). The TT-null property of τ–types (Definition 10.4, equation (10.8)) gives

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} S^{(\eta)} = 0 = S^{(\eta)} \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}.$$

Using commutation of $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ with the realized weave configuration hygiene maps and spectral/triad selectors (Propositions 10.9 and 10.10), move $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ next to $S^{(\eta)}$ to obtain

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \mathcal{P}_{\mathrm{G},\eta}^{(0)} = \mathsf{P}_{\mathrm{phys}}\, (\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} S^{(\eta)})\, \mathcal{R}^{(0)}\, S^{(\eta)}\, \mathsf{P}_{\mathrm{phys}} = 0,$$

and similarly $\mathcal{P}_{\mathrm{G},\eta}^{(0)}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = 0$. Therefore the Gaiaton (spin–0) channel is orthogonal to the TT graviton channel.

(2) Triad-compatibility. Write the scalar provenance split as $\mathcal{R}^{(0)} = \mathsf{P}_{\mathrm{spec}}^{(0)} \oplus \Pi^{(\mathrm{vac})} \oplus \Pi^{(\mathrm{corr})}$ (Definitions 10.2 and 10.7). By typed stability and functional calculus, each typed idempotent commutes with the triad projectors (Proposition 10.9), and the scalar Riesz selectors commute with the triad as well (Definition 10.7). Since $\mathsf{P}_{\mathrm{phys}}$ also commutes with admissible band/triad maps (Proposition 10.10), we have

$$\left[\Pi^{(a)},\, \mathcal{P}_{\mathrm{G},\eta}^{(0)}\right] = \mathsf{P}_{\mathrm{phys}} \left[\Pi^{(a)},\, S^{(\eta)} \mathcal{R}^{(0)} S^{(\eta)}\right] \mathsf{P}_{\mathrm{phys}} = 0, \qquad a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}.$$

(3) Consequences for meters/visibilities. Because the projector is TT-orthogonal and triad-compatible, any calibrated meter/visibility computed in the Gaiaton channel is automatically triad-resolved and free from TT contamination (Definition 10.82). BRST/Nielsen safety on certified plateaus follows from executing all operations on the realized physical realized weave configuration (Definitions 9.60 and 10.1) together with typed/triad commutation (Proposition 10.9) and band invariance (Proposition 10.10). This completes the proof. □

Definition 10.72 (CP action and visibility asymmetry (scalar))**.** Let $\mathcal{CP}_\tau$ denote the CP action on the τ-scalar subspace; it preserves the scalar carrier but may flip the CP label. Define the (law/state) *visibility* CP-asymmetry diagnostic by

$$\Delta_{\mathrm{CP},\Lambda}^{(0)} := \Lambda_{\mathrm{law/state}}^{[S^{(+)}]} - \Lambda_{\mathrm{law/state}}^{[S^{(-)}]}, \tag{10.50}$$

using the witnesses of Definitions 10.80 and 10.82.

Structural facts.

Lemma 10.73 (TT-nullity and orthogonality (scalar))**.** *One has* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\big(\cdot\big) = 0$ *on any insertion confined to the* τ*-scalar subspace; moreover* $S^{(\eta)}S^{(\eta')} = \delta_{\eta\eta'}S^{(\eta)}$*.*

Proof. TT-nullity is immediate for scalars and follows from typed null-preservation in Definitions 10.3 and 10.4; orthogonality is part of the projector algebra in Lemma 10.8. □

Proposition 10.74 (Triad commutation and decomposition (scalar))**.** $[\Pi^{(a)}, S^{(\eta)}] = 0$ *for all* a, η*, hence the decomposition* (10.49) *is triad-orthogonal. Moreover,* $\hat{\Phi}_\eta = \hat{\Phi}_\eta^{(\mathrm{spec})} \oplus \hat{\Phi}_\eta^{(\mathrm{vac})} \oplus \hat{\Phi}_\eta^{(\mathrm{corr})}$*.*

Proof. Commutation is stated in Proposition 10.9; the decomposition is immediate. □

Proposition 10.75 (BRST/Nielsen flatness and band stability (scalar))**.** *Any correlator on* $\mathcal{H}_{\mathrm{phys}}$ *formed from* $\hat{\Phi}_\eta$ *and finitely many insertions of* $S^{(\eta)}$*,* $\Pi^{(a)}$*, and* $\mathsf{P}_{\mathrm{spec}}^{(0)}$ *is (i) gauge-parameter independent and (ii) stable under admissible retunings of* (P_x, K_{IR})*.*

Proof. A specialization of Proposition 10.10. □

Lemma 10.76 (Spectral future-proofing (spin-0))**.** *If additional scalar spectral branches appear (new contours* ζ_n *disjoint from the previously certified ones), the projector* $\mathsf{P}_{\mathrm{spec}}^{(0)}$ *enlarges by the corresponding Riesz terms and* $\mathcal{P}_{\mathrm{G},\eta}^{(0)}$ *automatically includes the new species.*

Proof. By definition (Definition 10.7), the scalar spectral selector is a sum of Riesz projectors

$$\mathsf{P}_{\mathrm{spec}}^{(0)} = \sum_{j\in\mathfrak{S}_0} \frac{1}{2\pi i}\oint_{\Gamma_j}\Big(K_{\Theta\Theta}^{(0)} - z\Big)^{-1}\,dz,$$

where the contours $\{\Gamma_j\}$ enclose the certified scalar spectral islands (measurability/invariance: Proposition 10.149 and Lemma 10.137). If new, disjoint scalar islands appear with enclosing contours $\{\zeta_n\}$, the holomorphic functional calculus implies *additivity* of Riesz projectors over pairwise disjoint spectral sets [115, 253]:

$$\mathsf{P}_{\mathrm{spec}}^{(0)} \;\longrightarrow\; \mathsf{P}_{\mathrm{spec,new}}^{(0)} = \mathsf{P}_{\mathrm{spec}}^{(0)} + \sum_n \frac{1}{2\pi i}\oint_{\zeta_n}\Big(K_{\Theta\Theta}^{(0)} - z\Big)^{-1}\,dz.$$

The Gaiaton projector has the typed–sandwich form (spin-0 provenance split; cf. (10.48), (10.49))

$$\mathcal{P}_{\mathrm{G},\eta}^{(0)} = \mathsf{P}_{\mathrm{phys}}\,S^{(\eta)}\Big(\mathsf{P}_{\mathrm{spec}}^{(0)} \oplus \Pi^{(\mathrm{vac})} \oplus \Pi^{(\mathrm{corr})}\Big)S^{(\eta)}\,\mathsf{P}_{\mathrm{phys}},$$

with $S^{(\eta)}$ a scalar typed idempotent (Definition 10.4) and the triad projectors from Definition 10.2. By commutation stability on the realized weave configuration (Propositions 10.9 and 10.10), replacing $\mathsf{P}_{\mathrm{spec}}^{(0)}$ by $\mathsf{P}_{\mathrm{spec,new}}^{(0)}$ propagates through the sandwich without further modification. Hence $\mathcal{P}_{\mathrm{G},\eta}^{(0)}$ *automatically* includes the newly admitted scalar species. □

Positivity, Ward identities, and diagnostics.

Proposition 10.77 (Scalar ledgers and spectral positivity)**.** *On $\mathcal{H}_{\mathrm{phys}}$, the scalar Gaiaton components obey the appropriate Ward/Slavnov ledgers for the scalar sector and have nonnegative spectral density $\rho_{(0)}(\omega, \mathbf{k}) \geq 0$.*

Proof (outline). Work on the realized, realized weave configuration with projection to the physical cohomology (Definitions 9.60 and 10.1). The Ward/Slavnov–Taylor identities hold on $\mathcal{H}_{\mathrm{phys}}$ for the realized correlators (upstream axioms unchanged; Remark 9.81), and gauge-parameter independence on certified plateaux is controlled by Nielsen identities; see [483, 484, 445, 106, 120]. Restricting to the scalar typed subspace via $S^{(\eta)}$ (Definition 10.4) preserves these ledgers because the typed idempotents commute with the admissible realized weave configuration/triad maps (Propositions 10.9 and 10.10). Thus the scalar Gaiaton components inherit the Ward/Slavnov constraints on $\mathcal{H}_{\mathrm{phys}}$.

For spectral positivity, start from the Källén–Lehmann (KL) representation for realized, BRST-clean two-point functions with the KL positivity condition (eq. (7.12); standard treatments include [14, 255, 230, 244]). Orthogonal projection by a $\bar{\Sigma}$–Hermitian idempotent preserves positivity of quadratic forms, hence $\rho \mapsto \rho_{(0)}$ remains nonnegative under the scalar typed projector $S^{(\eta)}$ (Definitions 9.33 and 10.4). Finally, the scalar spectral selector $\mathsf{P}^{(0)}_{\mathrm{spec}}$ is a sum of Riesz projectors (Definition 10.7), measurable and arena-stable (Proposition 10.149 and Lemma 10.137), which commute with the typed/triad structure (Proposition 10.9); selecting spectral islands by the holomorphic functional calculus leaves the positivity of the spectral measure intact [115, 253]. Therefore the Gaiaton scalar density obeys $\rho_{(0)}(\omega, \mathbf{k}) \geq 0$ on $\mathcal{H}_{\mathrm{phys}}$, as claimed. □

Definition 10.78 (CP-resolved visibilities (scalar))**.** Let $\mathbf{W}^{[\tau\text{-sca};S^{(\eta)}]}$ be the consolidated witness for the τ-scalar channel. Define $\Lambda^{[\tau\text{-sca};S^{(\eta)}]}_{\mathrm{law/state}}$ as in Definitions 10.80 and 10.82, evaluated on $\mathcal{H}_{\mathrm{phys}}$ with $\mathcal{I}^{[\mathscr{P}]}$.

Proposition 10.79 (Well-posed Parasymmetric TLO for the Gaiaton)**.** *For each CP sector $\eta \in \{+, -\}$, the Parasymmetric TLO triple* (Type $= S^{(\eta)}$, Location, Onset) *of Definition 10.85 and Proposition 10.90 exists and is unique on the certified band. The onset $r^\star[S^{(\eta)}]$ is stable under admissible retuning and tightening of K_{IR}.*

Proof. **(A) Setting and admissibility.** Work on the realized, realized weave configuration with projection to the physical cohomology (Definitions 9.60 and 10.1). Fix the scalar typed projectors $S^{(\eta)}$ (CP-resolved) from Definition 10.4 and note their $\bar{\Sigma}$–Hermitian, orthogonal idempotent algebra (10.5). Typed maps commute with the realized weave configuration hygiene and the triad (Proposition 10.9 and Definition 10.2), so restricting any calibrated meter to the typed image is admissible (Definitions 9.116 and 10.82). Band acceptance is enforced by the mask $\mathfrak{M}_{\mathrm{mask}}$ and guards C1–C5, which produce a nonempty IR window K_{IR} with the needed regularity on smoothed slopes and total variation (eq. (7.626), Lemma 7.386, Proposition 7.383, and Remark 9.15).

(B) Existence (TLO). By Proposition 10.90, the TLO triple exists whenever (i) the accepted window K_{IR} is nonempty and (ii) the location/onset meters satisfy the Lipschitz/-monotonicity bounds on K_{IR}. Both conditions hold after typed restriction because $S^{(\eta)}$

commutes with the acceptance machinery and does not degrade the slope/variation estimates (Definition 9.116 and Proposition 10.9); thus the parasymmetric TLO for Type $= S^{(\eta)}$ exists on the certified band.

(C) Uniqueness (typed orthogonality and one-threshold property). Orthogonality $S^{(+)}S^{(-)} = 0$ and completeness on the scalar typed block (Definition 10.4, (10.5)) imply that any TLO evaluated in $S^{(+)}$ cannot receive contributions from $S^{(-)}$, and vice versa. Within a fixed typed range, Proposition 10.90 gives uniqueness of the onset provided the onset meter is strictly monotone on K_{IR}, which is guaranteed by the acceptance/low-pass properties (Lemma 7.386 and Proposition 7.383). Hence $r^\star[S^{(+)}]$ and $r^\star[S^{(-)}]$ exist and are unique.

(D) Stability under retuning/tightening. Admissible retunes of the band tags and IR tightening of K_{IR} preserve the commutation and measurability properties on the realized weave configuration (Propositions 10.10 and 10.149 and Lemma 10.137). Since the onset functional is continuous (Lipschitz) in the meters used to define it (Definition 10.85 and Proposition 10.90) and typed restriction is an orthogonal projection that does not increase variation, the onset $r^\star[S^{(\eta)}]$ varies continuously and monotonically with admissible changes of K_{IR} (cf. Remark 9.15). Therefore $r^\star[S^{(\eta)}]$ is stable under admissible retuning and IR tightening.

(E) BRST/Nielsen safety. All constructions take place on $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$ via the realization map (Definition 9.60), so the derived TLO is BRST-clean and gauge-parameter independent on certified plateaux, in the sense of the upstream axioms (Remark 9.81; cf. [445, 106, 120]).

Combining (B)–(E) proves existence, uniqueness, and stability of the Parasymmetric TLO for the Gaiaton in each CP sector. □

Typed extraction and correlator blocks (scalar). For any admissible fluctuation/correlator, Gaiaton content is read CP-by-CP via the typed insertion (Definition 10.113). Writing $\hat{\mathbf{G}}_\Lambda$ for the unified inter-modal correlator on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$, define the scalar-typed blocks and their triad resolutions by

$$\hat{\mathbf{G}}_\Lambda^{[\,S^{(\eta)}\to S^{(\eta')}\,]} := \Pi^{[S^{(\eta)}]}\,\hat{\mathbf{G}}_\Lambda\,\Pi^{[S^{(\eta')}]}, \qquad \hat{\mathbf{G}}_\Lambda^{(a)\,[\,S^{(\eta)}\to S^{(\eta')}\,]} := \Pi^{(a)}\,\hat{\mathbf{G}}_\Lambda^{[\,S^{(\eta)}\to S^{(\eta')}\,]}\,\Pi^{(a)},$$

with $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2). Orthogonality and idempotence of the typed and triad projectors ensure that scalar channels can be audited provenance-by-provenance without mixing with TT.

Meters, visibilities, and ledgers (Gaiaton channel). To disambiguate notation, we reserve $\mathcal{P}$ for *projectors* (e.g., $\mathcal{P}^{(0)}_{\mathrm{G},\eta}$) and use

$$\mathcal{L}^{(a)}_{S^{(\eta)}} := \left\| \mathsf{P}_{\mathrm{phys}}\,\Pi^{[S^{(\eta)}]}\,\Pi^{(a)}\,\mathsf{P}_{\mathrm{phys}}\,\delta\hat{\Sigma} \right\|_{\mathcal{I}}$$

for the scalar *ledger power* in triad sector $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ and CP sector $\eta \in \{+,-\}$. The visibility-based CP diagnostic is $\Delta^{(0)}_{\mathrm{CP},\Lambda}$ from (10.50), while a normalized ledger asymmetry may be quoted as

$$\widetilde{\Delta}^{(0)}_{\mathrm{CP}} := \frac{\mathcal{L}_{S^{(+)}} - \mathcal{L}_{S^{(-)}}}{\mathcal{L}_{S^{(+)}} + \mathcal{L}_{S^{(-)}}}\,.$$

All meters are evaluated on $\mathcal{H}_{\mathrm{phys}}$ and inherit BRST/Nielsen flatness and band stability from the realized weave configuration (Definitions 10.82 and 10.95).

Spin selection, TT purity, and selection rules. Gaiaton content is spin–0 by typed construction; any scalar insertion is annihilated by the TT sandwich:

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\mathbf{G}}_{\Lambda}^{[\,S^{(\eta)}\to Y\,]} = 0 = \hat{\mathbf{G}}_{\Lambda}^{[\,Y\to S^{(\eta)}\,]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,.$$

Typed selection rules further imply that off-diagonal blocks that violate CP selection are null at leading order, and any symmetry breaking is quantified by the corresponding mixing norms (cf. the typed diagnostics in Definition 10.82).

Mixing, whitening, and reporting. Scalar channels may mix among CP sectors or with other admitted non-TT types, but never with TT under the typed sandwich. Mixing is quantified by the typed mixing norms and resolved by the $\bar{\Sigma}$–weighted operator-generalized eigen-operator pair eigenproblem and whitening (Definitions 10.116 and 10.117). The outcome is an orthogonal set of scalar eigen-channels, each carrying its triad provenance and reportable power/visibilities.

Dynamics (model-class placeholder, if needed). When a first-order representative Φ is adopted for phenomenology, Gaiaton dynamics may be modeled—*within the typed block*—by a Klein–Gordon–type equation on $(\bar{\Sigma}, \bar{\nabla})$,

$$\bar{\nabla}_{\mu}\Big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_{\nu}\Phi\Big) + m_{(0)}^{2}\,\Phi = J_{(0)}\,,$$

with an effective potential $V(\Phi)$ for interpretive layers (inflation/reheating) treated at the level of witnesses and meters; this introduces no new projectors and does not affect TT purity. Any CP-sensitive phenomenology is reported through $\Delta_{\mathrm{CP},\Lambda}^{(0)}$ and $\widetilde{\Delta}_{\mathrm{CP}}^{(0)}$ rather than raw field parameters.

Remarks (geometry/matter interface). The scalar Gaiaton lives in the τ-kairos scalar family of Definition 10.4; it modulates scalar coherence without contributing to the graviton TT readout. Interactions with vector ($A^{(\pm)}$) content (CK) or other scalar families are mediated only through typed, triad-resolved correlator blocks and are subject to the same audit/termination guarantees (No-Explosion) as in Propositions 10.10 and 10.90. No additional primitives are introduced; all statements use the established realized weave configuration, typed families, meters, and TLO scaffold.

The *Gaiaton* (spin-0 apeiron) is introduced as a typed, scalar excitation of the Gaiamiti sector, defined on the realized weave configuration $\mathcal{I}^{[\mathscr{P}]}$ and realized on the Σ-carrier $\bar{\Sigma}$ after projection to the physical cohomology $H^{0}(\hat{Q}_{\mathrm{BRST}})$ (Definitions 9.60 and 9.116). Ontologically it is not an independent sector but a member of the τ–kairos *scalar* typed family $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$ admitted via their idempotents $\Pi^{[\chi]}$ and inserted within the typed, triad-resolved correlator blocks of the unified inter-modal correlator (Definitions 10.2, 10.4 and 10.113). In contrast to the massless spin-2 transverse–traceless (TT) Goldstone mode of the Gaiamiti symmetry (the graviton) identified in the $\Phi\Phi$ typed menu (Definition 9.195 and Proposition 9.197), the Gaiaton corresponds to scalar fluctuations along the *apeiron* (trace/radial) directions—orthogonal to the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ (Definition 6.61). Its mass originates from the curvature of the Gaiamiti potential in these directions and is

therefore nonzero after spontaneous symmetry breaking [93, 94, 91]. *Phenomenologically*, this scalar channel aligns with well-studied gravitational scalars: in scalar–tensor gravity (Jordan–Brans–Dicke), a companion field ϕ yields a breathing/longitudinal GW polarization [480, 479, 477, 478]; in higher-curvature $f(R)$ gravity, dynamics are equivalent to GR plus a massive "scalaron" [244, 479]; and in massive/bimetric gravity, the helicity-0 mode of the spin-2 field (with its decoupling-limit Galileon avatar) provides a scalar gravitational excitation in ghost-free formulations [113, 481]. These map to the detector taxonomy of "extra scalar GW polarization(s)" (two tensor + possible vector/scalar types), so the **Gaiaton** is naturally read as the theory's typed, CP-refined representative of that scalar gravitational sector [477, 478, 479].

Formally, the scalar content of the τ–kairos block may be represented by a typed scalar representative whose effective potential governs the radial displacement from the vacuum configuration. In this representation the local effective potential on the scalar block takes the quartic form

$$\mathcal{V}_\Phi(\varphi) \;=\; \tfrac{1}{2}\, m_A^2\, \varphi^2 \;+\; \tfrac{\lambda_A}{4!}\, \varphi^4,$$

with m_A^2 fixed by the curvature about $\mathcal{M}_{\mathrm{vac}}$ and λ_A a self-interaction strength [91]. The realized scalar mass $m_A > 0$ is extracted *operationally* from the typed, triad-resolved spectrum using the Riesz selector acting on the scalar kinetic generalized eigen-operator pair $K_\tau^{(0)}$ within the admissible IR window—yielding the physical projector $\mathsf{P}^{(0)}_{\mathrm{spec}}$ and the corresponding pole location (Definition 10.68 and Remark 9.15). TT purity is guaranteed throughout by typed orthogonality and TT-nullity: $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ annihilates τ-scalar contributions, forbidding TT–scalar mixing (Proposition 9.202 and Lemma 10.123).

Couplings of the Gaiaton are geometric rather than force-mediating in the conventional sense. The scalar mode modulates the *inertial rigidity* of the vacuum—implemented in practice through calibrated meters and visibilities on $\mathcal{H}_{\mathrm{phys}}$ that quantify the scalar ledger power and its response under band-limited probes (Definitions 10.82 and 10.117). Increased scalar ledger power corresponds to enhanced stiffness of the $\bar\Sigma$-diagnostic realized reference configuration, while reduced power corresponds to greater susceptibility, all within the BRST/Nielsen-safe plateau regime (Proposition 9.97 and Definition 10.1); this viewpoint aligns with the general quantum-geometric picture [8, 3].

At cosmological scales, the same scalar block provides a natural *inflaton* candidate. In an early-universe regime where the energy density is dominated by $\mathcal{V}_\Phi$, slow-roll conditions can be encoded directly in the typed potential and the $\bar\Sigma$-weighted inner product, producing an accelerated expansion epoch consistent with quartic slow-roll templates (cf. the potential form above) [89, 485]. Termination of inflation and reheating are governed by the *interaction action* obtained from the off-diagonal entries of the Fourfold inter-modal structure,

$$S_{\mathrm{int}}\big[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}\big] \;=\; \int d^d x\, d^d x'\, \mathrm{Tr}\big[\hat{\mathbf{\Phi}}^\dagger(x)\, \mathcal{U}_{\Phi\Theta}(x,x')\, \hat{\mathbf{\Theta}}(x')\big]\,,$$

where $\mathcal{U}_{\Phi\Theta}$ is the typed, nonlocal kernel linking the Gaiamiti (Φ) and Tantrakyma/Kymon (Θ) sectors (Definitions 9.357 and 10.223); the associated reheating picture is standard in scalar-field cosmology [485, 91]. This coupling allows the *decay channel* Gaiaton $\to$ Kymon+Kymon and thereby converts geometric vacuum energy into matter excitations within the Θ sector, in line with the typed weave's inter-modal consistency.

Residual scalar potential energy after reheating yields a natural *late-time* component. If the scalar representative remains displaced from the minimum or if $\mathcal{V}_\Phi$ exhibits near-degenerate minima, the residual energy density

$$\rho_\Lambda^{(\mathrm{eff})} \;\sim\; \mathcal{V}_\Phi\Big[\bar{\Phi}_{\min}\Big]$$

acts as an effective cosmological constant and supports a quintessence-like description when allowed to vary adiabatically over cosmological timescales [486, 485]. Both cases fit within the typed ledger and retain Nielsen/realized weave configuration invariance, since the relevant meters and selectors are defined on $\mathcal{H}_{\mathrm{phys}}$ with certified IR tags (Definition 10.1 and Remark 9.15).

Conceptually, the Gaiaton thereby unifies three narratives within the same formal scaffold: (i) sub-Planckian *quantum rigidity* of spacetime through scalar ledger power on $\bar{\Sigma}$; (ii) *inflationary dynamics* via the typed scalar potential and inter-modal reheating into Θ; and (iii) *late-time acceleration* through residual vacuum energy. All elements descend from the Gaiamiti typed layer established in Chapter 10 and operate within the Quantum Holo-State $\big|\mathring{\mathbf{\Psi}}\big\rangle$ framework that governs emergent properties at each PQS locus (Definition 1.27), while the apeiron lineage evokes the original metaphysical notion of the *ápeiron* [69].

10.9 Witnesses, Visibilities, and Parasymmetric TLO (Full Construction)

We complete Step (4) of the operational pipeline by specifying the *explicit* witnesses and meters, and by proving finiteness, BRST/Nielsen flatness, monotonicity under admissible IR retuning, and Onset uniqueness with stability radii (cf. Ch. 10: Definitions 9.116, 9.133 and 9.147 and eq. (9.81)). We work on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ of Definition 10.1; triad maps $\Pi^{(a)}$ are from Definition 10.2; the admitted typed projectors we instantiate here include TT, τ–kairos, Higgs, and Chrono–Kymon (Definitions 10.3 to 10.5).

Global setup. For any admitted type $[\chi]$ (e.g. TT, $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$, $A^{(\pm)}$, rad$\pm$) and *sector*

$$\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\},$$

define the typed *physical* observable

$$\mathfrak{O}^{[\mathscr{S};\chi]} \;:=\; \mathsf{P}_{\mathrm{phys}}\, \Pi^{[\chi]}\, \mathfrak{O}\, \Pi^{[\chi]}\, \mathsf{P}_{\mathrm{phys}},$$

where the sector block $\mathscr{S}$ is taken in the unified inter–modal correlator and its typed decomposition (see (10.61)). All norms $\|\cdot\|_{\mathcal{I}}$ below are the fixed, band–invariant norms chosen once for this chapter. BRST/Nielsen flatness and gauge–parameter independence of the resulting meters follow from the invariance statements (e.g. Propositions 10.30 and 10.61) together with the gauge–independence remark Remark 10.93, and will be used tacitly.

10.9.1 Law and State Ledgers: Residuals and Features

Definition 10.80 (Law residuals and State features)**.** Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ be a sector block of the unified inter–modal correlator (cf. (10.61)), and let $[\chi]$ be any *admitted type* from the typed layer (Ch. 10; e.g. TT, $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$, $A^{(\pm)}$, rad±, cf. Definition 9.116 and its weave instantiations Definitions 10.3 to 10.5). On the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1), define the *typed physical observable*

$$\mathfrak{O}^{[\mathscr{S};\chi]} \;:=\; \mathsf{P}_{\mathrm{phys}}\, \Pi^{[\chi]}\, \mathfrak{O}\, \Pi^{[\chi]}\, \mathsf{P}_{\mathrm{phys}},$$

and write $\mathfrak{O} = \mathfrak{O}^{[\mathscr{S};\chi]}$ for brevity. All norms $\|\cdot\|_{\mathcal{I}}$ are the fixed band–invariant norms for this chapter (cf. invariance discussion and admissible norms in Proposition 10.10 and Remark 10.93).

Law-residual vector. The *Law-residual vector* $\mathbf{R}^{[\mathscr{S};\chi]} \in \mathbb{R}_+^{N_{\mathrm{law}}}$ collects type-specific constraints that must vanish on $\mathcal{H}_{\mathrm{phys}}$ (Ch. 10 cohomological EOM and Ward/Slavnov, Definition 9.63):

$$\mathbf{R}^{[\mathscr{S};\chi]} = \Bigg(\underbrace{\|[\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}]\|_{\mathcal{I}}}_{\text{BRST closure (Ch. 8: Definition 7.11 and eq. (7.8))}}, \quad \underbrace{\|\nabla^{(\mathrm{rel})\mu}\mathfrak{O}_{\mu\nu}\|_{\mathcal{I}}}_{\text{Ward transversality (Ch. 7: Definition 6.7 and eq. (6.22))}}, \quad \underbrace{\|\mathrm{tr}_{\bar{\Sigma}}\mathfrak{O}\|_{\mathcal{I}}}_{\text{trace test (if applicable; Ch. 6: Definition 5.26)}}, \quad \underbrace{\left\|\partial_\xi \mathcal{G}_\xi^{[\mathscr{S};\chi]}\right\|_{\mathcal{I}}}_{\text{Nielsen flatness (Ch. 8/9: Definition 7.59 and eq. (7.16))}}, \ldots \Bigg) \tag{10.51}$$

where $\nabla^{(\mathrm{rel})}$ is the $\bar{\Sigma}$-compatible Levi–Civita derivative (Chs. 6–7), $\mathrm{tr}_{\bar{\Sigma}}$ contracts indices with $\bar{\Sigma}_{\mu\nu}$ (Ch. 6), ξ is a gauge parameter, and $\mathcal{G}_\xi^{[\mathscr{S};\chi]}$ denotes the typed two-point/kinetic resolvent on the certified band used for meters (Ch. 10: Definition 9.133). By the gauge-independence remark and the type-level invariance propositions (e.g. graviton TT and CK: Propositions 10.30 and 10.61 and Remark 10.93), ∂_ξ–residuals vanish on shell in $\mathcal{H}_{\mathrm{phys}}$.

State-feature vector. The *State-feature vector* $\mathbf{S}^{[\mathscr{S};\chi]} \in \mathbb{R}_+^{N_{\mathrm{state}}}$ measures radiative/vacuum/-coherence content on the triad (weave triad maps Definition 10.2):

$$\mathbf{S}^{[\mathscr{S};\chi]} = \Bigg(\underbrace{\int W_{\mathrm{spec}}(\omega,\mathbf{k})\; \rho_{(s)}^{[\mathscr{S};\chi]}(\omega,\mathbf{k})\, d\mu}_{\text{spectral weight (Ch. 8 KL positivity: } eq.\ (7.12))}, \quad \underbrace{\|\Pi^{(\mathrm{vac})}\mathfrak{O}\|_{\mathcal{I}}}_{\text{vacuum amplitude}}, \quad \underbrace{\|\Pi^{(\mathrm{corr})}\mathfrak{O}\|_{\mathcal{I}}}_{\text{coherence amplitude}}, \ \ldots \Bigg), \tag{10.52}$$

where $s \in \{2,1,0\}$ is the *typed spin* selected by $\Pi^{[\chi]}$ within the chosen sector block $\mathscr{S}$, W_{spec} is a fixed band-admissible window (Ch. 8 band functor and IR window: Definitions 6.280 and 7.29), $\rho_{(s)}^{[\mathscr{S};\chi]}$ is the corresponding typed spectral density (Källén–Lehmann form; Ch. 8:

eq. (7.12)), and $\Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{corr})}$ are the triad projectors (Def. Definition 10.2). For mixed $\Phi\Theta$, the typed spin s is determined by the *typed insertion* used in the off-diagonal correlator block (cf. (10.61)); τ–kairos may appear here only as a *typed projector* (not as a sector), via Definition 10.4.

Remark 10.81 (Type-specific components)**.** Beyond the universal entries in (10.51)–(10.52), we append the following *type-specific* components (typed projectors as in Ch. 10 and their weave instantiations; cf. Definitions 9.116 and 10.3 to 10.5). All quantities are evaluated on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) and on the physical carrier $\mathcal{H}_{\mathrm{phys}}$.

- **Graviton (TT in $\Phi\Phi$).** Add the TT-purity residual

$$\left\| \Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]}\, \mathfrak{O} \right\|_{\mathcal{I}} \quad \text{with} \quad \Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]} := \mathbf{1} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \quad (\text{see } \textit{Definition } 10.3),$$

  to $\mathbf{R}^{[\mathscr{S};\chi]}$, and include the *TT-leak* diagnostic ε from Definition 10.32 in $\mathbf{S}^{[\mathscr{S};\chi]}$. (Invariance/flatness: Proposition 10.30.)
- **τ-kairos scalars $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$ (typed, not a sector).** Enforce TT-nullity by adding

$$\left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \mathfrak{O} \right\|_{\mathcal{I}} \quad (\text{TT-annihilation; } \textit{Definition } 10.3 \textit{and Lemma } 10.17),$$

  and, for the pseudoscalar $\tilde{S}^{(p)}$, append a parity-odd check via the Levi–Civita contraction consistent with the τ-parity conventions in Definition 10.4 (see also the parity diagnostic pattern used for CK in Definition 10.58).
- **Chrono–Kymon $A^{(\pm)}$ (typed helicities in τ-vector).** Add the helicity-purity residual

$$\left\| \left(\mathbf{1} - A^{(\pm)}\right) \mathfrak{O} \right\|_{\mathcal{I}} \quad (\text{helicity projectors } A^{(\pm)} \text{ in } \textit{Definition } 10.4),$$

  and include the vector parity asymmetry Δ_P from Definition 10.58 among the state features. (CK invariance/flatness: Proposition 10.61.)
- **Higgs** rad$\pm$ **(radial tantrakyma in $\Theta\Theta$).** Enforce NG/pNG orthogonality by adding

$$\left\| \Pi_{\Theta}^{[\mathrm{NG/pNG}]}\, \mathfrak{O} \right\|_{\mathcal{I}} \quad (\text{orthogonality: } \textit{Proposition } 10.47),$$

  and append CP-purity via

$$\left\| \Pi^{(\mathrm{CP}\mp)}\, \mathfrak{O} \right\|_{\mathcal{I}} \quad (\text{CP projectors in } \textit{Definition } 10.5).$$

Scope across sectors. For the mixed interaction block $\mathscr{S} = \Phi\Theta$, all checks above are applied after the *typed insertion* into the off-diagonal correlator block of the unified inter-modal correlator (cf. (10.61)); τ-kairos enters here only as a *typed projector family* (not as a sector), per Definition 10.4.

10.9.2 Calibrated Meters and Visibilities

Definition 10.82 (Calibration maps and visibilities)**.** Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ be a sector block of the unified inter–modal correlator (cf. (10.61)), and let $[\chi]$ be any admitted type (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Given the Law/State ledgers $\mathbf{R}^{[\mathscr{S};\chi]}, \mathbf{S}^{[\mathscr{S};\chi]}$ from Definition 10.80, fix positive weights $\boldsymbol{\alpha} \in \mathbb{R}_+^{N_{\text{law}}}$, $\boldsymbol{\beta} \in \mathbb{R}_+^{N_{\text{state}}}$ and choose *calibration maps*

$$\begin{aligned} &\text{law: } f_j : \mathbb{R}_+ \to (0,1], \quad f_j(x) = e^{-\alpha_j x} \ \text{(strictly } \textit{decreasing}, C^1), \\ &\text{state: } g_m : \mathbb{R}_+ \to [0,1), \quad g_m(x) = \frac{\beta_m x}{1+\beta_m x} \ \text{(strictly } \textit{increasing}, C^1). \end{aligned}$$

Define the *calibrated* vectors

$$\mathbf{L}^{[\mathscr{S};\chi]} := \Big(f_j(R_j^{[\mathscr{S};\chi]})\Big)_{j=1}^{N_{\text{law}}}, \qquad \mathbf{V}^{[\mathscr{S};\chi]} := \Big(g_m(S_m^{[\mathscr{S};\chi]})\Big)_{m=1}^{N_{\text{state}}}, \tag{10.53}$$

and the *law/state visibilities* (cosine meters; cf. Definition 10.80):

$$\Lambda_{\text{law}}^{[\mathscr{S};\chi]} = \frac{\langle \mathbf{L}^{[\mathscr{S};\chi]},\ \mathbf{1}\rangle}{\|\mathbf{L}^{[\mathscr{S};\chi]}\|\,\|\mathbf{1}\|} \in (0,1], \qquad \Lambda_{\text{state}}^{[\mathscr{S};\chi]} = \begin{cases} \dfrac{\langle \mathbf{V}^{[\mathscr{S};\chi]},\ \mathbf{1}\rangle}{\|\mathbf{V}^{[\mathscr{S};\chi]}\|\,\|\mathbf{1}\|}, & \mathbf{V}^{[\mathscr{S};\chi]} \neq \mathbf{0}, \\ 0, & \mathbf{V}^{[\mathscr{S};\chi]} = \mathbf{0} \ \text{(convention)}. \end{cases} \tag{10.54}$$

Here $\mathbf{1}$ is the all-ones vector of the appropriate length. Larger values mean better law compliance / stronger certified state signal. All objects live on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) and on the physical carrier $\mathcal{H}_{\text{phys}}$, with band/BRST hygiene as in Proposition 10.10 and Remark 10.93.

Lemma 10.83 (Finiteness of meters)**.** *For every admitted* $[\chi]$ *and sector* $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$*, the visibilities* $\Lambda_{\text{law}}^{[\mathscr{S};\chi]}$ *and* $\Lambda_{\text{state}}^{[\mathscr{S};\chi]}$ *are finite and well defined on* $\mathcal{H}_{\text{phys}}$*.*

Proof. Each component $R_j^{[\mathscr{S};\chi]}$ and $S_m^{[\mathscr{S};\chi]}$ is, by construction, a band-limited norm of a BRST-sandwiched operator (see Definition 10.80; band functor and IR window in Ch. 8: Definitions 6.280 and 7.29), hence finite on the realized weave configuration by Proposition 10.10. Therefore $f_j(R_j) \in (0,1]$ and $g_m(S_m) \in [0,1)$, so $\mathbf{L}^{[\mathscr{S};\chi]}$ is non-zero and $\mathbf{V}^{[\mathscr{S};\chi]}$ is either non-zero or (if all state features vanish) we apply the stated convention $\Lambda_{\text{state}}^{[\mathscr{S};\chi]} = 0$. In both cases the cosine with $\mathbf{1}$ is well defined, establishing finiteness. □

What the meters measure (and why they are calibrated). Definition Definition 10.82 turns *raw ledgers*—feature vectors extracted from a chosen sector block $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ of the unified inter–modal correlator (cf. (10.61)) and a selected type $[\chi]$ (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5)—into *unitless, bounded observables*. The "law" ledger $\mathbf{R}^{[\mathscr{S};\chi]}$ aggregates constraint/axiom compliance (e.g., conservation, Ward/Slavnov consistency) while the "state" ledger $\mathbf{S}^{[\mathscr{S};\chi]}$ aggregates physically certified signal features (Definition 10.80). Because these entries can carry different scales and units, we pass them through monotone, C^1 *calibration maps*: a strictly decreasing exponential $f_j(x) = e^{-\alpha_j x} \in (0,1]$ for law-terms (larger violation ⇒ smaller score), and a strictly increasing saturating map $g_m(x) = \frac{\beta_m x}{1+\beta_m x} \in [0,1)$

for state-terms (stronger signal ⇒ larger score). The result is the pair of calibrated vectors $(\mathbf{L}^{[\mathscr{S};\chi]}, \mathbf{V}^{[\mathscr{S};\chi]})$ in (10.53), which preserve the ordering of performance while compressing dynamic range and improving robustness to outliers; the positive weights $(\boldsymbol{\alpha}, \boldsymbol{\beta})$ control sensitivity per feature.

Visibilities as cosine meters. The visibilities in (10.54) are *cosines* between the calibrated vectors and the all-ones direction $\mathbf{1}$. Thus, $\Lambda_{\text{law}}^{[\mathscr{S};\chi]} \in (0,1]$ quantifies how *uniformly* the law features meet their targets (near 1 means broad compliance across entries), while $\Lambda_{\text{state}}^{[\mathscr{S};\chi]} \in [0,1]$ quantifies how *coherently* the state features register a certified signal (the zero convention covers the trivial case $\mathbf{V}^{[\mathscr{S};\chi]} = \mathbf{0}$). Because these are angles in a Euclidean ledger space, the meters are dimensionless, comparable across types and sectors, and naturally bounded—properties that are used repeatedly when comparing TT, τ–scalar, and Higgs-CP channels side-by-side (Definitions 10.3 to 10.5).

Well-posedness and hygiene. All objects live on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ and the physical carrier $\mathcal{H}_{\text{phys}}$ (Definition 10.1), with band/BRST hygiene ensured by the acceptance and invariance statements (Proposition 10.10 and Remark 10.93). Each ledger component is built from *band-limited* norms of BRST-sandwiched operators (Ch. 8: Definitions 6.280 and 7.29), guaranteeing finiteness; consequently the calibrated maps land in $(0,1]$ or $[0,1)$ and the cosines are well defined—this is recorded in Lemma 10.83. Because the admitted types $[\chi]$ commute with the realized weave configuration/triad machinery (Definitions 9.116 and 10.2 and Proposition 10.9), the meters are *typed-resolved* without order-of-operations ambiguity: projecting to TT, τ–scalar, or CP-refined Higgs channels before/after calibration yields the same visibilities. In short, Definition 10.82 provides a uniform, gauge- and band-safe way to score law compliance and physical signal strength across sectors and types, and Lemma 10.83 ensures these scores are always finite on $\mathcal{H}_{\text{phys}}$.

10.9.3 Monotonicity Under IR Retuning

Proposition 10.84 (Monotonicity of meters under IR tightening)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and let $r \mapsto K_{\text{IR}}^{(r)}$ be an admissible IR knob on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1; IR window and band functor in Ch. 8: Definitions 6.280 and 7.29). For any admitted type $[\chi]$ and the corresponding calibrated visibilities $\Lambda_{\text{law/state}}^{[\mathscr{S};\chi]}(r)$ (Def. Definition 10.82), the following hold for* IR tightening *(increasing r):*

(i) $\Lambda_{\text{law}}^{[\mathscr{S};\chi]}(r)$ *is* nondecreasing *in r.*

(ii) $\Lambda_{\text{state}}^{[\mathscr{S};\chi]}(r)$ *is* nonincreasing *for the* vac *and* corr *components, and* nondecreasing *for the* spec *component measured with a fixed spectral window W_{spec} (cf. eq. (10.52)).*

Proof. All objects are evaluated on the physical carrier $\mathcal{H}_{\text{phys}}$ with band/BRST hygiene as in Proposition 10.10 and Remark 10.93. The IR window $K_{\text{IR}}^{(r)}$ is positive, order-preserving, and L^p-contractive on the certified band (Ch. 7/8; see Definition 6.280), and composes monotonically in r (admissible knob on $\mathcal{I}^{[\mathscr{S}]}$, Def. Definition 10.1).

(1) Law meter is nondecreasing. Each law entry $R_j^{[\mathscr{S};\chi]}(r)$ in eq. (10.51) is a norm of a constraint violation (BRST commutator, relational divergence, $\bar{\Sigma}$-trace, Nielsen derivative) applied to the IR-filtered typed observable $\mathcal{O}^{[\mathscr{S};\chi]}(r)$. Since $K_{\mathrm{IR}}^{(r)}$ is contractive and smoothing, tightening (larger r) yields

$$R_j^{[\mathscr{S};\chi]}(r_2) \;\le\; R_j^{[\mathscr{S};\chi]}(r_1) \quad \text{for } r_2 \ge r_1.$$

With the calibration $f_j(x) = e^{-\alpha_j x}$ (Def. Definition 10.82), which is strictly decreasing, we get $f_j(R_j(r_2)) \ge f_j(R_j(r_1))$ componentwise, hence $\mathbf{L}^{[\mathscr{S};\chi]}(r_2) \ge \mathbf{L}^{[\mathscr{S};\chi]}(r_1)$ entrywise. For positive vectors, the cosine with $\mathbf{1}$, $\cos(\mathbf{L},\mathbf{1}) = \langle \mathbf{L},\mathbf{1}\rangle/(\|\mathbf{L}\|\|\mathbf{1}\|)$, is monotone with respect to entrywise increases; therefore $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)$ is nondecreasing.

(2) State meter splits by triad channel. State features in eq. (10.52) decompose on the triad (Def. Definition 10.2): vacuum $\|\Pi^{(\mathrm{vac})}\mathcal{O}\|_{\mathcal{I}}$, coherence $\|\Pi^{(\mathrm{corr})}\mathcal{O}\|_{\mathcal{I}}$, and a spectral weight $\int W_{\mathrm{spec}}\, \rho_{(s)}^{[\mathscr{S};\chi]}\, d\mu$ with fixed W_{spec} and KL-positive density $\rho_{(s)}$ (Ch. 8: eq. (7.12)). Tightening $K_{\mathrm{IR}}^{(r)}$ suppresses long-distance content: it contracts the vacuum amplitude and damps off-diagonal/coherence contributions (order-preserving L^p-contractivity), hence

$$S_m^{(\mathrm{vac})}(r_2) \le S_m^{(\mathrm{vac})}(r_1), \qquad S_m^{(\mathrm{corr})}(r_2) \le S_m^{(\mathrm{corr})}(r_1) \quad (r_2 \ge r_1).$$

As $g_m(x) = \beta_m x/(1+\beta_m x)$ is strictly increasing (Def. Definition 10.82), the calibrated entries $g_m(S_m)$ are nonincreasing in r for these channels, and so is their cosine meter contribution.

For the spec feature, with a *fixed* W_{spec}, the IR tightening removes ultra-IR leakage but preserves (and can sharpen) the weight inside the fixed spectral window by KL-positivity and band covariance; thus $S_m^{(\mathrm{spec})}(r_2) \ge S_m^{(\mathrm{spec})}(r_1)$ is admissible (nondecrease). Applying the increasing calibration g_m gives a nondecreasing calibrated spectral entry and hence a nondecreasing contribution to $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$.

The cosine aggregation preserves these one-sided monotonicities because all calibrated vectors remain in the positive orthant (Def. Definition 10.82). As an illustrative special case, the TT-leak diagnostic ε (Def. Definition 10.32) obeys the same monotone decrease under IR tightening (Cor. Corollary 10.104), consistent with the coherence channel's trend. □

10.9.4 Onset Definition, Uniqueness, and Stability Radii

Definition 10.85 (Onset thresholding and certified onset)**.** Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ be a sector block of the unified inter–modal correlator (cf. (10.61)), and let $[\chi]$ be any admitted type from the typed layer (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Fix thresholds $\theta_{\mathrm{law}}, \theta_{\mathrm{state}} \in (0,1)$ and consider the calibrated visibilities $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)$ and $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$ of Definition 10.82 with (10.54), evaluated on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1).

Admission set. Define

$$\mathcal{A}_{[\chi]} \;:=\; \Big\{ r \;\Big|\; \Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r) \;\ge\; \theta_{\mathrm{law}} \;\text{ and }\; \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r) \;\ge\; \theta_{\mathrm{state}} \Big\}.$$

Certified onset. The (first) certified onset is

$$r^\star[\chi] \;:=\; \inf \mathcal{A}_{[\chi]} \qquad \big(r^\star[\chi] = +\infty \text{ if } \mathcal{A}_{[\chi]} = \varnothing\big). \tag{10.55}$$

Canonical masking for monotonicity. Unless stated otherwise, the *state* visibility entering $\mathcal{A}_{[\chi]}$ is taken with the canonical spectral mask from Ch. 8 (fixed thresholds; Definition 7.665), i.e. only the spectral entry of (10.52) participates in the onset test. With this mask, both meters are one–sided monotone under IR tightening (Prop. 9.146), ensuring uniqueness below.

Lemma 10.86 (Interval property and uniqueness)**.** *With the canonical spectral mask (Ch. 8: Definition 7.665) applied to the state meter, $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)$ and the masked $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$ are nondecreasing in r (Proposition 9.146). Hence $\mathcal{A}_{[\chi]}$ is either empty or an interval of the form $[r^\star[\chi],\infty)$, and the onset (10.55) is unique whenever $\mathcal{A}_{[\chi]}\neq\varnothing$.*

Proof. **Step 1: Monotonicity of the law meter.** By Proposition 9.146(1), the calibrated law visibility $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)$ defined in (10.54) (with calibrations from Definition 10.82) is nondecreasing in the tuning parameter r on the certified window (band hygiene Proposition 10.10).

Step 2: Monotonicity of the masked state meter. The canonical spectral mask of Definition 7.665 is an *isotone* (order-preserving) thresholding on spectral content, with thresholds that are themselves nondecreasing in r by construction. By Proposition 9.146(2), the (pre-mask) state visibility $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$ is nondecreasing; composing with an isotone mask preserves nondecreasing order, hence the *masked* state meter $\widetilde{\Lambda}_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$ is also nondecreasing in r.

Step 3: Upper-set structure of the acceptance region. Let the acceptance set be

$$\mathcal{A}_{[\chi]} := \Big\{ r :\ \Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)\ \geq\ \tau_{\mathrm{law}}\,,\ \ \widetilde{\Lambda}_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)\ \geq\ \tau_{\mathrm{state}} \Big\},$$

with fixed thresholds $(\tau_{\mathrm{law}},\tau_{\mathrm{state}})$ specified by Definition 7.665. If $r_1\in\mathcal{A}_{[\chi]}$ and $r_2\geq r_1$, monotonicity from Steps 1–2 implies both inequalities remain satisfied at r_2, so $r_2\in\mathcal{A}_{[\chi]}$. Thus $\mathcal{A}_{[\chi]}$ is an *upper set* in $\mathbb{R}$, hence either empty or of the form $[r^\star[\chi],\infty)$ where $r^\star[\chi]:=\inf\mathcal{A}_{[\chi]}$.

Step 4: Uniqueness of the onset. Since the real line is totally ordered, the infimum $r^\star[\chi]$ is unique whenever $\mathcal{A}_{[\chi]}\neq\varnothing$, establishing uniqueness of the onset in (10.55). (Under the regularity inherited from the acceptance window—Lipschitz/TV bounds via Lemma 7.386 and Proposition 7.383—the onset is stable and, when the meters are right-continuous, attained.) □

What this means. The parameter r is the "tightening knob" (IR acceptance, spectral cut, or resolution) fixed by the canonical mask (Definition 7.665). Lemma 10.86 says that as r increases, the *law* compliance and the (masked) *state* signal—computed from the calibrated meters of Definition 10.82—can only improve or plateau (Proposition 9.146). Consequently, the set of r for which a type $[\chi]$ passes both tests is a *single ray* $[r^\star[\chi],\infty)$ or empty. There is no ambiguity from oscillations or interleaving pass/fail bands: the minimal acceptable $r^\star[\chi]$ is a well-defined number that summarizes "how much tightening" is needed for that typed signal to be simultaneously lawful and visible.

Why it is useful. This interval property underpins unique onset reporting and auditability across sectors and types (Definitions 9.116 and 10.2). It means that we can compare TT, τ–scalar, or Higgs–CP channels on *equal footing*: each has a unique onset $r^\star[\chi]$ that is band/BRST-clean (Proposition 10.10 and Remark 10.93) and insensitive to the order of typed

vs. spectral operations (Proposition 10.9). Together with the stability/regularity of the meters (Lemma 7.386 and Proposition 7.383), this provides a principled thresholding mechanism for declaring detections, ranking channels, and triggering downstream actions—without risking spurious accept/reject toggling as analysis settings are tightened.

Conceptual understanding. Think of r as the *Steward of Tightening*: an admissible dial that governs monotone refinements of the analysis, including spectral/temporal *resolution*. The *Gatekeeper*—the canonical mask (Definition 7.665)—and the *Cartographer*—the band functor with its IR window (Ch. 8: Definitions 6.280 and 7.29)—are implemented so that as the Steward raises r, acceptance becomes stricter/finer. The *Judges*—the calibrated meters from Definition 10.82—then return scores that are provably *nondecreasing* in r (Proposition 9.146). Concretely:

- *Resolution tightening (the Lens narrows).* Decrease a smoothing scale $\sigma(r)$ or narrow bins $(\Delta\omega, \Delta k)$ so the resolving power grows with r; the Gatekeeper acts as an *isotone* mask ensuring order is preserved (Definition 7.665 and Remark 9.15).
- *Band/IR tightening (the Gate closes).* Shrink the accepted window $K_{\mathrm{IR}}(r)$ or raise SNR-like thresholds in a manner nondecreasing in r (Ch. 8: Definition 6.280); the Cartographer updates the certified domain accordingly.
- *Mode cutoffs (the Archivist prunes).* Increase harmonic/order cutoffs (e.g. $L_{\max}(r)$, $N(r)$) or raise spectral contours; the *Riesz Archivists* (selectors) then respect the new contours (Definition 10.7).

Because all of these moves are implemented via *isotone masks/selectors*, the acceptance set is an *upper set*:

$$\mathcal{A}_{[\chi]} = \Big\{ r : \text{law \& state pass} \Big\} = \varnothing \quad \text{or} \quad [\, r^\star[\chi], \infty),$$

and the onset $r^\star[\chi]$ is unique whenever $\mathcal{A}_{[\chi]} \neq \varnothing$ (Lemma 10.86). Moreover, since the *Typist* (typed projectors) and the *Provenance Clerk* (triad) commute with the band machinery (Definitions 9.116 and 10.2 and Propositions 10.9 and 10.10), the meaning of r as "resolution" (or any other admissible tightening) is compatible with TT, τ–scalar, and Higgs–CP channels without order ambiguities.

Proposition 10.87 (Stability radii under admissible retuning)**.** *Let $(\lambda_{\mathrm{UV}}, \ell, r)$ be the band/IR knobs of $\mathcal{I}^{[\mathscr{S}]}$ (Def. 10.1). Assume the typed projectors used for $[\chi]$ satisfy the band retuning stability of Ch. 10 (Definition 9.116, item (P7)), so that the calibrated meters $\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law/state}}$ depend continuously on $(\lambda_{\mathrm{UV}}, \ell, r)$ (cf. Def. 10.82, Prop. 10.10). Then for every $\varepsilon \in (0,1)$ there exists a stability radius $\rho_{[\chi]}(\varepsilon) > 0$ such that any admissible retuning*

$$\big\| (\lambda'_{\mathrm{UV}}, \ell', r') - (\lambda_{\mathrm{UV}}, \ell, r) \big\| \;<\; \rho_{[\chi]}(\varepsilon)$$

implies

$$\Big| \, r^\star[\chi]\big|_{(\lambda'_{\mathrm{UV}}, \ell', \cdot)} \;-\; r^\star[\chi]\big|_{(\lambda_{\mathrm{UV}}, \ell, \cdot)} \Big| \;\leq\; \varepsilon,$$

i.e. the onset is locally stable (upper semicontinuous and, under the canonical mask, locally Lipschitz) with respect to admissible band/IR retunings.

Proof. By Ch. 10 retuning stability (Definition 9.116, item (P7)), the typed projectors and hence the calibrated entries $f_j(R_j), g_m(S_m)$ vary continuously under admissible retunings; by Definition 10.82, the visibilities (10.54) vary continuously as compositions of continuous maps on the positive orthant. With the canonical spectral mask, both onset predicates are nondecreasing (Prop. 9.146), so the hitting time of the thresholds $\theta_{\mathrm{law}}, \theta_{\mathrm{state}}$ depends upper semicontinuously on parameters. Standard perturbation of hitting times for continuous, one–sided monotone functions gives the stated $\rho_{[\chi]}(\varepsilon)$; local Lipschitzness follows when the meters cross the thresholds with nonzero one–sided slope (Ch. 10 onset rules: eq. (9.81), and TLO readouts: Definition 9.147). □

Reporting. In the Parasymmetric TLO, the onset component uses $r^\star[\chi]$ from (10.55) together with the sector/location tags (cf. Definition 9.147); the uniqueness and stability granted by Lemma 10.86 and Prop. 10.87 ensure reproducible certificates on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$.

Proposition 10.88 (Onset uniqueness and stability radius)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and $[\chi]$ be any admitted type (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Assume the calibrated visibilities $\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law/state}}(r)$ (Def. Definition 10.82, (10.54)) are continuous in r and satisfy the monotonicities of Proposition 9.146 under IR tightening $r\uparrow$. Then:*

(i) Uniqueness

The certified onset $r^\star[\chi]$ of Definition 10.85 is unique (if it exists).

(ii) One-sided stability radius (IR tightening)

Fix any $r_0 \geq r^\star[\chi]$ and suppose there are slope bounds $m_{\mathrm{law}}, m_{\mathrm{state}} > 0$ such that, for all $r \geq r_0$,

$$\begin{aligned}
\frac{d}{dr}\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}}(r) &\geq m_{\mathrm{law}},\\
\frac{d}{dr}\Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}}(r) &\geq m_{\mathrm{state}} \quad \text{(if the state meter is spectral; cf. eq. (10.52))},\\
\frac{d}{dr}\Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}}(r) &\leq -\,m_{\mathrm{state}} \quad \text{(if the state meter is vacuum/coherence)}.
\end{aligned}$$

Let the gaps at r_0 be

$$\Delta_{\mathrm{law}}(r_0) := \Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}}(r_0) - \theta_{\mathrm{law}}, \qquad \Delta_{\mathrm{state}}(r_0) := \Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}}(r_0) - \theta_{\mathrm{state}},$$

(which are ≥ 0 by $r_0 \geq r^\star[\chi]$). Then for any $\delta r \in [0, \rho[\chi])$ with

$$\rho[\chi] \;:=\; \min\left\{\frac{\Delta_{\mathrm{law}}(r_0)}{m_{\mathrm{law}}},\; \frac{\Delta_{\mathrm{state}}(r_0)}{m_{\mathrm{state}}}\right\}, \tag{10.56}$$

the admission condition of Definition 10.85 remains satisfied at $r_0 + \delta r$. In particular, choosing $r_0 > r^\star[\chi]$ yields a strictly positive stability radius.

Proof. (1) By Proposition 9.146, $\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}}(r)$ is nondecreasing and, with the canonical spectral mask from Ch. 8 (Definition 7.665), the relevant state meter used in the onset test is also nondecreasing; therefore the superlevel sets $\{r : \Lambda_{\mathrm{law}} \geq \theta_{\mathrm{law}}\}$ and $\{r : \Lambda_{\mathrm{state}} \geq \theta_{\mathrm{state}}\}$ are

intervals of the form $[r_{\mathrm{law}}, \infty)$ and $[r_{\mathrm{state}}, \infty)$, and their intersection is $[r^\star, \infty)$. Its infimum $r^\star$ is unique (cf. Definition 10.85).

(2) Fix $r_0 \geq r^\star[\chi]$. By the mean value theorem and the assumed slope bounds, for any $\delta r \geq 0$,

$$\Lambda_{\mathrm{law}}(r_0 + \delta r) \;\geq\; \Lambda_{\mathrm{law}}(r_0) \;+\; m_{\mathrm{law}}\delta r,$$

and, depending on the channel used in the state meter,

$$\begin{aligned} \Lambda_{\mathrm{state}}(r_0 + \delta r) &\geq \Lambda_{\mathrm{state}}(r_0) + m_{\mathrm{state}}\delta r \quad \text{(spectral)}, \\ \Lambda_{\mathrm{state}}(r_0 + \delta r) &\geq \Lambda_{\mathrm{state}}(r_0) - m_{\mathrm{state}}\delta r \quad \text{(vac/corr)}. \end{aligned}$$

Thus both visibilities remain above their thresholds provided $m_{\mathrm{law}}\delta r \leq \Delta_{\mathrm{law}}(r_0)$ and $m_{\mathrm{state}}\delta r \leq \Delta_{\mathrm{state}}(r_0)$, which is exactly $\delta r < \rho[\chi]$ in (10.56). If the canonical spectral mask (Definition 7.665) is used for onset (so only the spectral entry participates), the second inequality is of the increasing type. □

Remark 10.89. (i) The result is *one-sided* with respect to IR tightening ($\delta r \geq 0$), consistent with the monotonicities of Proposition 9.146. (ii) At $r_0 = r^\star[\chi]$ the gaps may vanish, yielding $\rho[\chi] = 0$; taking any $r_0 > r^\star[\chi]$ produces a positive radius. (iii) Continuity and slope lower bounds are ensured in practice by the typed retuning stability of Ch. 10 (Definition 9.116, item (P7)) together with band/BRST hygiene on the realized weave configuration (Definition 10.1 and Proposition 10.10). (iv) The slopes $m_{\mathrm{law}}, m_{\mathrm{state}}$ correspond to the one-sided derivatives in the onset rules of Ch. 10 (eq. (9.81)), which underwrite the TLO "Onset" component in Definition 9.147.

10.9.5 Explicit Witness Contents by Type and Sector

Below, $\mathfrak{O}$ denotes the *typed, physical* observable $\mathfrak{O}^{[\mathscr{S};\chi]} := \mathsf{P}_{\mathrm{phys}}\Pi^{[\chi]}\mathfrak{O}\,\Pi^{[\chi]}\mathsf{P}_{\mathrm{phys}}$ (cf. Definition 10.80), evaluated on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) with sector block $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$. All divergences and traces use the $\bar{\Sigma}$–compatible Levi–Civita derivative $\nabla^{(\mathrm{rel})}$ and contraction with $\bar{\Sigma}$ (Chs. 6–7; Definitions 5.26 and 6.7 and eq. (6.22)). Triad projectors $\Pi^{(\mathrm{spec})}, \Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{corr})}$ are from Definition 10.2. Typed families (TT, τ–kairos scalars/vectors, Higgs CP) are as instantiated in Definitions 10.3 to 10.5. Spectral weights use the Källén–Lehmann density and a fixed admissible window W_{spec} (Ch. 8: eq. (7.12); cf. eq. (10.52)).

(A) Graviton (TT, $\Phi\Phi$–sector). Here $\chi = \mathrm{TT}$ and $\mathscr{S} = \Phi\Phi$; TT purity/TT-leak are as in Definitions 10.3 and 10.32.

Law residuals (cf. eq. (10.51)):

$$R_1 = \left\|\nabla^{(\mathrm{rel})\mu}\mathfrak{O}_{\mu\nu}\right\|_{\mathcal{I}}, \qquad R_2 = \left\|\mathrm{tr}_{\bar{\Sigma}}\mathfrak{O}\right\|_{\mathcal{I}},$$
$$R_3 = \left\|\partial_\xi\, \mathcal{G}_\xi^{[\Phi\Phi;\mathrm{TT}]}\right\|_{\mathcal{I}}, \qquad R_4 = \left\|\Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]}\,\mathfrak{O}\right\|_{\mathcal{I}}.$$

State features (cf. eq. (10.52)):

$$S_1 = \int W_{\mathrm{spec}}\ \rho_{(2)}^{[\Phi\Phi;\mathrm{TT}]}\, d\mu, \qquad S_2 = \left\|\Pi^{(\mathrm{vac})}\mathfrak{O}\right\|_{\mathcal{I}},$$
$$S_3 = \left\|\Pi^{(\mathrm{corr})}\mathfrak{O}\right\|_{\mathcal{I}}, \qquad S_4 = \varepsilon \quad \text{(Definition 10.32)}.$$

(Invariance/flatness for TT meters: Proposition 10.30.)

(B) τ–kairos scalars. Types: $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$. Typed insertion allowed in any sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$. TT–nullity and parity conventions follow Definition 10.4; TT annihilation uses Definition 10.3 and τ–TT purity Lemma 10.17.

Law residuals (cf. eq. (10.51)):

$$R_1 = \left\|\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\mathfrak{O}\right\|_{\mathcal{I}},$$
$$R_2 = \left\|\partial_\xi\, \mathcal{G}_\xi^{[\mathscr{S};\tau\text{-sc}]}\right\|_{\mathcal{I}},$$
$$R_3 = \left\|\nabla^{(\mathrm{rel})\mu}\mathfrak{O}_{\mu\nu}\right\|_{\mathcal{I}}, \quad R_4 = \left\|\mathrm{tr}_{\bar{\Sigma}}\mathfrak{O}\right\|_{\mathcal{I}},$$
$$\text{and for } \tilde{S}^{(p)}: \ R_5 = \left\|\varepsilon^{\alpha\beta\gamma(\mu}\nabla_\alpha^{(\mathrm{rel})}\mathfrak{O}_{\beta\gamma}{}^{\nu)}\right\|_{\mathcal{I}}$$
(parity–odd check; cf. Definition 10.4).

State features (cf. eq. (10.52)):

$$S_1 = \int W_{\mathrm{spec}}\ \rho_{(0)}^{[\mathscr{S};\tau\text{-sc}]}\, d\mu,$$
$$S_2 = \left\|\Pi^{(\mathrm{vac})}\mathfrak{O}\right\|_{\mathcal{I}}, \quad S_3 = \left\|\Pi^{(\mathrm{corr})}\mathfrak{O}\right\|_{\mathcal{I}}.$$

(Nielsen/BRST flatness for typed τ scalars inherits the general invariance on the realized weave configuration: Proposition 10.10 and Remark 10.93.)

(C) Chrono–Kymon $A^{(\pm)}$ (τ–vector, typed insertion in any sector). Here $\chi \in \{A^{(+)}, A^{(-)}\}$ and $\mathscr{S}$ is arbitrary in $\{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$. The CK tensor image $A_{\mu\nu}^{(\pm)}[\mathfrak{O}]$ is as in (10.45) (from the CK field definition (10.44)); helicity projectors $A^{(\pm)}$ and parity asymmetry Δ_P are in

Definitions 10.4 and 10.58. TT-nullity follows from Lemma 10.59.

Law residuals (cf. eq. (10.51)):

$$R_1 = \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} A_{\mu\nu}^{(\pm)}[\mathfrak{O}] \right\|_{\mathcal{I}}, \qquad R_2 = \left\| \left(\mathbf{1} - A^{(\pm)}\right) \mathfrak{O} \right\|_{\mathcal{I}},$$
$$R_3 = \left\| \partial_\xi \, \mathcal{G}_\xi^{[\mathscr{S};\tau\text{-vec}]} \right\|_{\mathcal{I}}.$$

State features (cf. eq. (10.52)):

$$S_1 = \int W_{\mathrm{spec}} \, \rho_{(1)}^{[\mathscr{S};\tau\text{-vec}]} \, d\mu, \qquad S_2 = \left\| \Pi^{(\mathrm{vac})} \mathfrak{O} \right\|_{\mathcal{I}},$$
$$S_3 = \left\| \Pi^{(\mathrm{corr})} \mathfrak{O} \right\|_{\mathcal{I}}, \qquad S_4 = \Delta_P \quad \text{(Definition 10.58)}.$$

(Invariance/flatness for CK meters: Proposition 10.61.)

(D) Higgs (radial tantrakyma) rad± (ΘΘ–sector). Here $\chi \in \{\mathrm{rad}+, \mathrm{rad}-\}$ and $\mathscr{S} = \Theta\Theta$. NG/pNG orthogonality and CP projectors/asymmetry are from Proposition 10.47 and Definitions 10.5 and 10.51.

Law residuals (cf. eq. (10.51)):

$$R_1 = \left\| \Pi_{\Theta}^{[\mathrm{NG/pNG}]} \mathfrak{O} \right\|_{\mathcal{I}}, \qquad R_2 = \left\| \Pi^{(\mathrm{CP}\mp)} \mathfrak{O} \right\|_{\mathcal{I}},$$
$$R_3 = \left\| \partial_\xi \, \mathcal{G}_\xi^{[\Theta\Theta;\mathrm{rad}\pm]} \right\|_{\mathcal{I}}.$$

State features (cf. eq. (10.52)):

$$S_1 = \int W_{\mathrm{spec}} \, \rho_{(0)}^{[\Theta\Theta;\mathrm{rad}\pm]} \, d\mu, \qquad S_2 = \left\| \Pi^{(\mathrm{vac})} \mathfrak{O} \right\|_{\mathcal{I}},$$
$$S_3 = \left\| \Pi^{(\mathrm{corr})} \mathfrak{O} \right\|_{\mathcal{I}}, \qquad S_4 = \Delta_{\mathrm{CP}}^{(a)} \quad \text{(Definition 10.51)}.$$

Sector note. For the mixed interaction block $\mathscr{S} = \Phi\Theta$, all entries above are understood after *typed insertion* into the off–diagonal correlator blocks of the unified inter–modal correlator (cf. (10.61)); τ–kairos enters only as a *typed projector family* (not as a sector), per Definition 10.4. Gauge–parameter independence and band stability for all meters follow from the realized weave configuration-level invariance (Proposition 10.10 and Remark 10.93).

10.9.6 Parasymmetric TLO: Existence, Uniqueness, and Stability

Proposition 10.90 (Existence and uniqueness of TLO per type)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and let $[\chi]$ be any admitted type from the typed layer (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). On the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1), the* Parasymmetric TLO *triple*

$$\mathrm{TLO}^{[\chi]} = \big(\mathrm{Type},\ \mathrm{Location},\ \mathrm{Onset}\big)$$

as defined in Definition 9.147 with onset $r^\star[\chi]$ from Definition 10.85 exists and is unique. *Moreover, under the canonical spectral mask (Ch. 8; Definition 7.665), if the spectral feature S_1 in (10.52) is strictly positive on some admissible window for some r_0, and if $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r_0) \geq \theta_{\mathrm{law}}$, then $r^\star[\chi] < \infty$.*

Proof. **Existence/uniqueness of** Type**.** For fixed $[\chi]$, the typed projectors are idempotent and mutually orthogonal inside their block (Ch. 10: Definition 9.116); in the weave these are instantiated for TT, τ–kairos, and Higgs families (Definitions 10.3 to 10.5). Orthogonality/purity lemmas (e.g. TT purity Lemma 10.28, τ algebra Lemma 10.8, Higgs CP orthogonality Lemma 10.45) ensure a single typed branch is selected for the meter. Hence the quadrant decision (Type $=$ Quad$^{[\chi]}$) obtained from the calibrated visibilities (Definition 10.82, (10.54)) is well defined and unique.

Existence/uniqueness of Location**.** Location (arena/sector/position/sheet) is inherited from the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Def. Definition 10.1) and the sector block $\mathcal{S}$; uniqueness is therefore immediate.

Existence/uniqueness of Onset**.** With the canonical spectral mask (Ch. 8: Definition 7.665), Prop. 9.146 yields that the law visibility $\Lambda_{\mathrm{law}}^{[\mathcal{S};\chi]}(r)$ and the masked state visibility are *nondecreasing* in r. Thus, by Lemma 10.86, the admission set is an interval $[r^\star[\chi],\infty)$ (or empty), and the onset $r^\star[\chi]$ of Definition 10.85 is unique when it exists.

Finiteness (sufficient condition). If there exists r_0 such that the spectral feature $S_1(r_0) > 0$ on some admissible window (Ch. 8: eq. (7.12)) and $\Lambda_{\mathrm{law}}^{[\mathcal{S};\chi]}(r_0) \geq \theta_{\mathrm{law}}$, then the masked state visibility at r_0 exceeds some positive value; by nondecreasing monotonicity (Prop. 9.146) it will cross any fixed $\theta_{\mathrm{state}} \in (0,1)$ at some finite $r \geq r_0$, whence $r^\star[\chi] < \infty$.

Stability. The onset is stable under admissible retunings by Prop. 10.87, which relies on the typed retuning stability of Ch. 10 (Definition 9.116, item (P7)) and realized weave configuration-level invariance/continuity (Proposition 10.10). □

Corollary 10.91 (Audit triggers)**.** *If any of the following holds on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Def. Definition 10.1),*

$$\begin{aligned} \varepsilon &> \varepsilon_{\max} && \textit{(graviton TT leak; Definition 10.32)},\\ |\Delta_P| &> \delta_P && \textit{(vector parity bias; Definition 10.58)},\\ |\Delta_{\mathrm{CP}}^{(a)}| &> \delta_{\mathrm{CP}} && \textit{(Higgs CP bias; Definition 10.51)}, \end{aligned}$$

where the audit thresholds $\varepsilon_{\max}, \delta_P, \delta_{\mathrm{CP}}$ are fixed a priori (cf. Ch. 8 fixed mask thresholds Definition 7.665), then a SynTh audit *must be initiated (see §10.10).*

Proof. Each listed diagnostic is included among the *state features* $\mathbf{S}^{[\mathcal{S};\chi]}$ (cf. eq. (10.52) and the type-specific augmentations in Remark 10.81; explicit contents by type appear in §10.9.5). By the chapter's audit design, these bounds define the *automatic trigger* predicate (Def. Definition 10.95); when any bound is exceeded, Cor. Corollary 10.110 mandates entering the *Audit path* (Def. Definition 10.105). Operationally this is the SynTh No-Explosion/Audit branch from the simultaneous synthesis rules (Ch. 9: Definitions 8.98 and 8.99), executed on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$. Hence an audit is required irrespective of the onset status. □

Remark 10.92 (Why exponential and rational calibrations)**.** The choices in Definition 10.82,

$$f_j(x) = e^{-\alpha_j x} \in (0,1], \qquad g_m(x) = \frac{\beta_m x}{1+\beta_m x} \in [0,1),$$

ensure: (i) *boundedness* of the calibrated entries (so the cosine meters (10.54) are always finite); (ii) *strict monotonicity* in the required directions—f_j is strictly decreasing (larger residual ⇒ smaller law score) while g_m is strictly increasing (larger state feature ⇒ larger state score)—which underpins the one-sided monotonicities in Proposition 9.146; and (iii) C^1 *differentiability* with nonzero slopes on $(0,\infty)$, which supplies the slope bounds used in the onset stability analysis Proposition 10.88. Any alternative calibrations $f_j : \mathbb{R}_+ \to (0,1]$ and $g_m : \mathbb{R}_+ \to [0,1)$ that are bounded, strictly monotone (in the same respective directions), and C^1 would serve identically in (10.53)–(10.54).

Remark 10.93 (Independence from gauge fixing)**.** In the Law ledger (10.51), the BRST–closure residual $\|[\hat{Q}_{\mathrm{BRST}}, \mathcal{O}]\|_{\mathcal{I}}$ and the explicit Nielsen residual $\|\partial_\xi \mathcal{G}_\xi^{[\mathscr{S};\chi]}\|_{\mathcal{I}}$ (cf. Chs. 8–10 Nielsen setup) are evaluated on the typed, physical observable $\mathcal{O}^{[\mathscr{S};\chi]}$ of Definition 10.80. Vanishing of these residuals on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) implies that the calibrated visibilities (10.54) are independent of the gauge parameter on $\mathcal{H}_{\mathrm{phys}}$. This is consistent with the realized weave configuration-level invariance and band hygiene (Proposition 10.10) and with the type-level examples such as TT graviton and Chrono–Kymon, where gauge-parameter independence (Nielsen flatness) is established in Propositions 10.30 and 10.61. Therefore the meters used in the Parasymmetric TLO (Definition 9.147) are gauge-fixing independent once the ledger residuals of Definition 10.80 are satisfied.

10.10 SynTh Resolution and Audit for the Weave

We complete Step (5) of the operational pipeline by formalizing SynTh (Simultaneous Synthesis) on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1; Ch. 9: Definitions 8.98 and 8.99) and by proving a *No-Explosion/Audit Theorem* specialized to the geometry–matter weave. Throughout, visibilities, witnesses, and TLO components are those constructed in Section 10.9 (see Definitions 10.80, 10.82 and 10.85, Section 10.9.5, Lemma 10.86, and Proposition 10.87).

Set-up. Fix a sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and an admitted type $[\chi]$ (e.g. TT, $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$, $A^{(\pm)}$, rad$\pm$). The law/state visibilities

$$\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}, \qquad \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}$$

are the calibrated cosine meters of Definition 10.82 (see (10.54)), built from the ledgers in Definition 10.80 and the type-specific components in Remark 10.81; explicit witness contents by type/sector are listed in §10.9.5. Diagnostics ε, Δ_P, $\Delta_{\mathrm{CP}}^{(a)}$ are as in Definitions 10.32, 10.51 and 10.58. All objects live on the physical carrier $\mathcal{H}_{\mathrm{phys}}$ and inherit band/BRST hygiene (Proposition 10.10 and Remark 10.93).

Definition 10.94 (Co-tenability vs. conflict; admission predicate)**.** Fix thresholds $\theta_{\mathrm{law}}, \theta_{\mathrm{state}} \in (0,1)$ (Ch. 8 fixed masks: Definition 7.665). Given $(\mathscr{S}, [\chi])$, define the *admission predicate* (cf. Definition 10.85)

$$\mathrm{Adm}_{[\chi]}(r) \;:=\; \Big[\, \Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r) \geq \theta_{\mathrm{law}} \;\wedge\; \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r) \geq \theta_{\mathrm{state}} \,\Big].$$

We say *Law and State are co-tenable* (write $\mathrm{Syn}^{[\mathscr{S};\chi]}$) at r if $\mathrm{Adm}_{[\chi]}(r)$ holds; otherwise they are in *conflict*. The *certified onset* $r^\star[\chi]$ is the first r where $\mathrm{Adm}_{[\chi]}(r)$ holds (Definition 10.85).

Definition 10.95 (Automatic triggers and Audit path)**.** (A) *Automatic triggers.* A SynTh audit must be initiated if any of the following hold (cf. Corollary 10.91):

$$\varepsilon > \varepsilon_{\max}, \qquad |\Delta_P| > \delta_P, \qquad |\Delta_{\mathrm{CP}}^{(a)}| > \delta_{\mathrm{CP}},$$

with a priori thresholds $(\varepsilon_{\max}, \delta_P, \delta_{\mathrm{CP}})$ (Ch. 8 masks: Definition 7.665).
(B) *Audit path.* Starting from a pair $(\mathscr{S}, [\chi])$ and scale r, the Audit path $\mathsf{Audit}(\mathcal{I}^{[\mathscr{S}]}, [\chi]; r)$ is the (finite) sequence of steps:

(i) Evaluate ledgers and visibilities (Definitions 10.80 and 10.82); record $(\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}})$ and diagnostics $(\varepsilon, \Delta_P, \Delta_{\mathrm{CP}})$.

(ii) If any automatic trigger fires (above), *enter* Audit; else, if $\neg\mathrm{Adm}_{[\chi]}(r)$, enter Audit due to *conflict*.

(iii) Apply an admissible, monotone IR retuning $r \mapsto r'$ (tightening) and/or permitted band retuning $(\lambda_{\mathrm{UV}}, \ell)$ within the typed stability radius (Ch. 10 stability: Definition 9.116, item (P7); onset stability: Proposition 10.87); re-evaluate step (i).

(iv) Stop when either $\mathrm{Adm}_{[\chi]}(r')$ holds (co-tenability achieved) or a certified failure certificate is produced (see Theorem 10.98).

Meaning. Definition 10.95 installs two complementary safety rails. Part (A) lists *diagnostic thresholds* that *force* a SynTh audit whenever core invariants are violated: the TT–leak ε (tensor purity; cf. Definition 10.32), the vector–parity asymmetry Δ_P (Definition 10.58), and the scalar CP asymmetry $\Delta_{\mathrm{CP}}^{(a)}$ in a chosen provenance a (Definition 10.51). Their cutoffs $(\varepsilon_{\max}, \delta_P, \delta_{\mathrm{CP}})$ are fixed by the canonical, isotone mask (Definition 7.665). Part (B) then defines the *Audit path*: a finite, recipe-level loop that starts from a sector/type $(\mathscr{S}, [\chi])$ and scale r, evaluates the calibrated visibilities $(\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}})$ (Definitions 10.80 and 10.82), and either (i) escalates immediately if any automatic trigger fires, or (ii) enters audit on *conflict* when the acceptance predicate $\mathrm{Adm}_{[\chi]}(r)$ (law & state passing under the mask) fails (Definition 7.665 and Lemma 10.86). The intent is clear: even when visibilities look acceptable, any breach of TT purity, parity balance, or CP balance must be investigated; conversely, if acceptance fails despite tame diagnostics, the configuration is inconsistent and must be retuned.

How the audit proceeds (and why it terminates). Step (iii) of Definition 10.95 retunes only along admissible, monotone directions—tightening r and/or permitted band parameters $(\lambda_{\mathrm{UV}}, \ell)$—inside the typed stability radius (Definition 9.116, item (P7)), with meters that are *nondecreasing* under such moves (Proposition 9.146) and with typed/triad commutation intact (Proposition 10.9). Because the mask is isotone, the acceptance set for each type is an *upper set* $[r^\star[\chi], \infty)$ when nonempty, so the audit either reaches co-tenability at the unique onset $r^\star[\chi]$ (Lemma 10.86) or produces a certified failure certificate (Theorem 10.98). Throughout, band/BRST hygiene and realized weave configuration invariance are preserved (Proposition 10.10 and Remark 10.93), guaranteeing that audit outcomes are physically

meaningful and independent of the order in which typing, spectral triage, and calibration are applied (Definitions 10.2 and 10.82).

Lemma 10.96 (Monotone descent invariants)**.** *Let* $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ *and* $[\chi]$ *be any admitted type (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Along* IR tightening $r \uparrow$ *(Ch. 8 IR window: Definition 6.280, band functor: Definition 7.29), the following hold for the calibrated meters of Definition 10.82:*

1. $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)$ *is* nondecreasing. *With the* canonical spectral mask *(Ch. 8: Definition 7.665) applied to the state meter, the masked state visibility* $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$ *is also* nondecreasing. *(Proposition 9.146)*
2. *The TT-leak diagnostic* ε *is* nonincreasing. *Moreover, the (unmasked) vacuum and coherence state features are* nonincreasing. *(Corollary 10.104 and Proposition 9.146)*

Consequently, with thresholds $\theta_{\mathrm{law}}, \theta_{\mathrm{state}} \in (0,1)$ *from Definition 10.85 and a priori trigger bounds* $(\varepsilon_{\max}, \delta_P, \delta_{\mathrm{CP}})$ *(Ch. 8 masks: Definition 7.665), the* core descent potential

$$\mathfrak{D}_{\mathrm{core}}(r) := \max\Big\{\ \theta_{\mathrm{law}} - \Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r),\quad \theta_{\mathrm{state}} - \Lambda_{\mathrm{state}}^{(\mathrm{spec})[\mathscr{S};\chi]}(r),\ 0\Big\} \ +\ \mathbf{1}\Big[\varepsilon(r) > \varepsilon_{\max}\Big] \tag{10.57}$$

is nonincreasing *along IR tightening on the Audit path (Def. Definition 10.101). If one augments* (10.57) *by the parity/CP indicators to form*

$$\mathfrak{D}_{\mathrm{audit}}(r) := \mathfrak{D}_{\mathrm{core}}(r) + \mathbf{1}\Big[|\Delta_P(r)| > \delta_P\Big] + \mathbf{1}\Big[|\Delta_{\mathrm{CP}}^{(a)}(r)| > \delta_{\mathrm{CP}}\Big], \tag{10.58}$$

then $\mathfrak{D}_{\mathrm{audit}}$ *is nonincreasing on any tightening segment where no new parity/CP trigger fires; if a parity/CP trigger does fire, the SynTh policy mandates immediate Audit entry (Def. Definition 10.95, Cor. Corollary 10.91).*

Proof. (1) By Proposition 9.146(1), tightening the IR window $K_{\mathrm{IR}}^{(r)}$ makes each law residual R_j weakly decrease; with the decreasing calibration $f_j(x) = e^{-\alpha_j x}$ (Def. Definition 10.82) each calibrated entry $f_j(R_j)$ weakly *increases*, hence Λ_{law} (cosine with $\mathbf{1}$, (10.54)) is nondecreasing. For the state meter, Proposition 9.146(2) states that the *spectral* feature (with fixed W_{spec}, Ch. 8: Definition 7.665) weakly *increases*, whereas vacuum/coherence weakly *decrease*. With the canonical spectral mask used in onset tests (cf. Definition 10.85), the resulting masked Λ_{state} is nondecreasing.

(2) TT-leak ε is defined by a TT-sandwiched non-spectral norm (Def. Definition 10.32); Corollary 10.104 gives its monotone *decrease* under IR tightening. For vacuum/coherence, Proposition 9.146(2) establishes the weak *decrease* of their raw features; after the increasing calibration $g_m(x) = \beta_m x/(1+\beta_m x)$ (Def. Definition 10.82), their contributions to the unmasked state meter are also nonincreasing.

For the potentials: By (1), $\theta_{\mathrm{law}} - \Lambda_{\mathrm{law}}(r)$ and $\theta_{\mathrm{state}} - \Lambda_{\mathrm{state}}^{(\mathrm{spec})}(r)$ are each nonincreasing in r; their $\max(\cdot, 0)$ is therefore nonincreasing. By (2), the indicator $\mathbf{1}[\varepsilon(r) > \varepsilon_{\max}]$ is nonincreasing (once it turns 0 it cannot return to 1). Hence $\mathfrak{D}_{\mathrm{core}}(r)$ in (10.57) is nonincreasing along IR tightening.

Parity/CP indicators have no proven monotone trend under tightening in general. Thus $\mathfrak{D}_{\mathrm{audit}}$ in (10.58) is guaranteed nonincreasing on any tightening segment where no new

parity/CP trigger activates. If a new parity/CP trigger does activate (indicator flips 0→1), the SynTh rules require immediate entry into the Audit branch (Def. Definition 10.95, Cor. Corollary 10.91), which is treated as a terminal step rather than a continued descent; this is the policy used in the No-Explosion/Audit Theorem (Theorem 10.98). All statements are on the physical carrier $\mathcal{H}_{\text{phys}}$ and inherit realized weave configuration-level invariance/continuity (Proposition 10.10). □

Lemma 10.97 (Finite termination and sound triggers)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and $[\chi]$ be an admitted type (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Consider an Audit path (Def. Definition 10.101) that applies IR tightening $r \uparrow$ and permitted retunings on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1). Then:*

(i) Soundness of automatic triggers

If an automatic trigger fires (Def. Definition 10.95; Cor. Corollary 10.91), Audit is entered immediately. Moreover, tightening cannot create *a new trigger that was previously absent for the TT-leak ε or for the vacuum/coherence channels, because these quantities are nonincreasing under IR tightening (Lemma 10.96, using Proposition 9.146 and Corollary 10.104). Hence trigger-based entry is sound (Cor. 10.110) and reduces the SynTh potential (cf. (10.59)).*

(ii) Termination via onset or certified failure

Assume no trigger is active. Use the canonical spectral mask (Ch. 8: Definition 7.665) for the state meter. If the spectral feature is positive on some admissible window (KL positivity; eq. (7.12)), then the masked state visibility $\Lambda^{[\mathscr{S};\chi]}_{\text{state}}(r)$ is nondecreasing in r (Prop. 9.146); likewise $\Lambda^{[\mathscr{S};\chi]}_{\text{law}}(r)$ is nondecreasing (Prop. 9.146). Let

$$\Lambda^{\infty}_{\text{state}} := \lim_{r\to\infty} \Lambda^{[\mathscr{S};\chi]}_{\text{state}}(r) \in (0,1], \qquad \Lambda^{\infty}_{\text{law}} := \lim_{r\to\infty} \Lambda^{[\mathscr{S};\chi]}_{\text{law}}(r) \in (0,1].$$

Then for any thresholds $\theta_{\text{law}}, \theta_{\text{state}} \in (0,1)$ (Def. 10.85):

(a) Admission via onset

If $\theta_{\text{law}} < \Lambda^{\infty}_{\text{law}}$ and $\theta_{\text{state}} < \Lambda^{\infty}_{\text{state}}$, the admission predicate $\text{Adm}_{[\chi]}(r)$ (Def. 10.99) holds for all $r \geq r^{\star}[\chi]$ with a unique onset $r^{\star}[\chi]$ (Lemma 10.86).

(b) Certified failure

If either inequality fails (e.g. $\theta_{\text{state}} \geq \Lambda^{\infty}_{\text{state}}$ or $\theta_{\text{law}} \geq \Lambda^{\infty}_{\text{law}}$), then admission cannot be achieved by further tightening; a certified failure *is produced, listing the limiting visibilities and active residuals/diagnostics (Theorem 10.98 (2b)).*

Consequently, every Audit path terminates in finitely many steps either in co-tenability with onset (Def. 10.85) or with a certified failure.

Proof. (1) The automatic triggers are $\varepsilon > \varepsilon_{\max}$, $|\Delta_P| > \delta_P$, and $|\Delta^{(a)}_{\text{CP}}| > \delta_{\text{CP}}$ (Def. 10.95; Cor. 10.91). By Lemma 10.96, ε (TT-leak) and the vacuum/coherence features are nonincreasing under IR tightening, so if their indicators are 0 at some r_0 they cannot flip to 1 for $r > r_0$; thus tightening cannot create a new trigger in those channels. (Parity/CP indicators are handled by the trigger policy rather than a monotonic claim—see Lemma 10.96.) Therefore, when a trigger fires we must enter Audit immediately, and doing so weakly decreases the SynTh potential $\mathfrak{D}^{[\mathscr{S};\chi]}$ (cf. (10.59)), establishing soundness (Cor. 10.110).

(2) With no active trigger, apply the canonical spectral mask (Ch. 8: Definition 7.665). By Prop. 9.146, both $\Lambda_{\text{law}}(r)$ and the masked $\Lambda_{\text{state}}(r)$ are nondecreasing under $r \uparrow$. KL positivity (eq. (7.12)) and the admissible window guarantee that the spectral mass is positive, hence the masked state visibility has a positive limit $\Lambda^{\infty}_{\text{state}} > 0$. Because the visibilities are continuous in r under typed-stable retunings (Prop. 10.87; Ch. 10 stability Definition 9.116, item (P7)), standard monotone convergence implies:

- If $\theta_{\text{law}} < \Lambda^{\infty}_{\text{law}}$ and $\theta_{\text{state}} < \Lambda^{\infty}_{\text{state}}$, there exists $r^{\star}[\chi]$ such that both inequalities in Def. 10.85 hold for all $r \geq r^{\star}[\chi]$; uniqueness follows from Lemma 10.86.

- Otherwise, at least one threshold exceeds the corresponding limit, so admission cannot be met by any further tightening; per Theorem 10.98 (2b), we output a certified failure that records the limiting visibilities and residuals/diagnostics.

In either case, the Audit path terminates in finitely many steps because each audit move (Def. 10.101) strictly reduces the discrete potential or reaches an absorbing state (co-tenability or certified failure), and the onset stability radius (Prop. 10.87) prevents oscillatory regress. □

Theorem 10.98 (No-Explosion/Audit Theorem for the weave)**.** *For any $(\mathscr{S}, [\chi])$ on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$, the SynTh resolution obeys:*

(i) No-Explosion (paraconsistent safety)

Under the SynTh rules (Definitions 8.98 and 8.99), contradictions between Law and State do not entail triviality; instead, the process branches into the Audit path (Def. 10.95).

(ii) Finite termination

Along any admissible Audit path with IR tightening and typed-stable band retuning, the potential $\mathfrak{D}$ of Lemma 10.96 is nonincreasing and achieves a terminal state in finitely many steps: either

(a) Co-tenability

$\text{Adm}_{[\chi]}(r^{\sharp})$ *holds, yielding the TLO onset $r^{\star}[\chi] \leq r^{\sharp}$ (cf. Definition 10.85, Lemma 10.86, and Proposition 10.87); or*

(b) Certified failure

A certified failure is produced: a tuple listing the active residuals and diagnostics that cannot be healed by admissible retunings within the typed stability radius (stability: Definition 9.116, item (P7)).

(iii) Soundness of automatic triggers

If any of $\varepsilon > \varepsilon_{\max}$, $|\Delta_P| > \delta_P$, $|\Delta^{(a)}_{\text{CP}}| > \delta_{\text{CP}}$ holds, then entering Audit is necessary and correct (Cor. 10.91), and subsequent IR tightening weakens (never worsens) the corresponding violation for TT-leak and vacuum/coherence (Lemma 10.96).

Proof sketch. (1) Paraconsistent safety is by the SynTh calculus (Ch. 9: Definitions 8.98 and 8.99), which replaces explosion with the Audit branch. (2) Monotone descent of $\mathfrak{D}$ follows from Lemma 10.96; IR tightening and typed-stable retunings ensure continuity (Proposition 10.87) and prevent oscillatory regress. Termination to (a) uses Lemma 10.86 and Proposition 9.146; termination to (b) occurs when residuals/diagnostics remain above

thresholds despite exhausting admissible retunings (stability radius in Proposition 10.87, typed stability in Ch. 10: Definition 9.116, item (P7)). (3) Trigger soundness is Corollary 10.91 together with Lemma 10.96. □

Reporting and certificates. When (a) holds, the Parasymmetric TLO deliverable $\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$ is reported per Definition 9.147 with the certified onset $r^\star[\chi]$ of Definition 10.85. When (b) holds, the *Audit certificate* records: sector $\mathscr{S}$, type $[\chi]$, the active residual components from eq. (10.51), the diagnostic values $(\varepsilon, \Delta_P, \Delta_{\mathrm{CP}})$, and the retuning region explored (bounds given by Proposition 10.87); this certificate is attached to the quadrant decision for traceability (cf. Definitions 9.147, 10.80 and 10.82).

Sector note. For the mixed interaction block $\mathscr{S} = \Phi\Theta$, all typed checks and meters are applied *after typed insertion* into the off-diagonal correlator blocks of the unified inter-modal correlator (cf. (10.61)); τ–kairos enters only as a *typed projector family* (not as a sector), per Definition 10.4.

10.10.1 Co-tenability, Conflicts, and Thresholds

Definition 10.99 (Co-tenability and conflict (thresholded refinement))**.** Fix a sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ (cf. unified inter–modal correlator (10.61)) and an admitted type $[\chi]$ from the typed layer (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Let the calibrated visibilities be $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}$, $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}$ (Def. Definition 10.82, (10.54)) built from the ledgers in Definition 10.80 with type-specific additions in Remark 10.81. Choose thresholds $\theta_{\mathrm{law}}, \theta_{\mathrm{state}} \in (0,1)$ (Ch. 8 fixed masks: Definition 7.665) and diagnostic bounds $\varepsilon_{\max}, \delta_P, \delta_{\mathrm{CP}} > 0$ (cf. Corollary 10.91). We say the pair $\left(\mathrm{Law}^{[\mathscr{S};\chi]}, \mathrm{State}^{[\mathscr{S};\chi]}\right)$ is:

(i) Co-tenable

Co-tenable if

$$\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]} \geq \theta_{\mathrm{law}}, \qquad \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]} \geq \theta_{\mathrm{state}},$$

and, for diagnostics applicable to $[\chi]$ (see Remark 10.81 and Section 10.9.5),

$$\varepsilon \leq \varepsilon_{\max}, \qquad |\Delta_P| \leq \delta_P, \qquad |\Delta_{\mathrm{CP}}^{(a)}| \leq \delta_{\mathrm{CP}}.$$

(ii) In conflict

In conflict otherwise.

Definition 10.100 (SynTh potential)**.** Define the nonnegative SynTh potential for $(\mathscr{S}, [\chi])$ by

$$\mathfrak{D}^{[\mathscr{S};\chi]} := w_L\left(1-\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}\right)+w_S\left(1-\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}\right)+u_\varepsilon\left(\frac{\varepsilon}{\varepsilon_{\max}}-1\right)_+ +u_P\left(\frac{|\Delta_P|}{\delta_P}-1\right)_+ +u_{\mathrm{CP}}\left(\frac{|\Delta_{\mathrm{CP}}^{(a)}|}{\delta_{\mathrm{CP}}}-1\right)_+, \tag{10.59}$$

with positive weights $w_L, w_S, u_\bullet$ and $(x)_+ := \max\{x, 0\}$. Co-tenability (Def. Definition 10.99) is equivalent to $\mathfrak{D}^{[\mathscr{S};\chi]} = 0$. Under IR tightening (Prop. 9.146, Lemma 10.96) the potential is nonincreasing when the *canonical spectral mask* is used for the state meter (Ch. 8: Definition 7.665).

10.10.2 Audit Moves and Basic Monotonicities

Definition 10.101 (Audit moves)**.** An *audit move* modifies the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) within the certified class while preserving BRST/Nielsen safety and band admissibility (realized weave configuration invariance: Proposition 10.10). Permitted moves are:

(i) IR tightening

IR tightening $r \mapsto r + \delta r$ with $\delta r > 0$, i.e. replacing the IR window by a tighter $K_{\mathrm{IR}}^{(r+\delta r)}$ (window/band functor: Definitions 6.280 and 7.29). This yields the monotonicities in Prop. 9.146 and Lemma 10.96.

(ii) Arena switch

Arena switch $\mathfrak{P}$: bulk $\leftrightarrow$ boundary, changing the Location component of the TLO (Def. Definition 9.147) but preserving typed meters on $\mathcal{H}_{\mathrm{phys}}$ (band/BRST hygiene: Proposition 10.10).

(iii) Spectral window refinement

Spectral window refinement $W_{\mathrm{spec}} \mapsto W'_{\mathrm{spec}}$ by *narrowing* around certified band features (Ch. 7 mask thresholds: Definition 7.665; spectral feature in (10.52)). Refinement preserves the KL positivity structure (eq. (7.12)) and maintains the one-sided improvement of the spectral entry used in onset tests (Prop. 9.146).

All moves are understood to respect the typed retuning stability of the projectors (Ch. 9: Definition 9.116, item (P7)) and the onset stability radius (Prop. 10.87). For the mixed interaction block $\mathscr{S} = \Phi\Theta$, all meters/diagnostics are applied after *typed insertion* into the off–diagonal correlator blocks of the unified correlator (cf. (10.61)); the τ–kairos enters only as a *typed projector family* (not as a sector), per Definition 10.4.

Lemma 10.102 (Monotonic effects of audit moves)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and $[\chi]$ be any admitted type (Definition 9.116, instantiated in Definitions 10.3 to 10.5). For the calibrated visibilities $\Lambda_{\mathrm{law/state}}^{[\mathscr{S};\chi]}$ (Def. Definition 10.82, (10.54)) and state features (10.52), the following hold for the audit moves of Definition 10.101:*

(i) IR tightening

Under $r\uparrow$ (tightening the IR window; Definitions 6.280 and 7.29), $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r)$ is nondecreasing, the vacuum/coherence contributions to $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r)$ are nonincreasing, and the masked spectral *contribution is nondecreasing (Prop. 9.146; see also Lemma 10.96).*

(ii) Arena switch (bulk $\leftrightarrow$ boundary)

Let $\Pi^{(\mathrm{corr})}$ be the triad coherence projector (Def. Definition 10.2). The realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) includes an arena comparison inequality *for coherence (relational boundary profile), namely a constant $\kappa_{\mathrm{coh}} \in (0, 1]$ such that*

$$\left\|\Pi^{(\mathrm{corr})}\mathfrak{O}\right\|_{\mathcal{I}}^{\mathrm{bulk}} \;\le\; \kappa_{\mathrm{coh}} \left\|\Pi^{(\mathrm{corr})}\mathfrak{O}\right\|_{\mathcal{I}}^{\mathrm{bdry}} \quad \textit{(same typed } \mathfrak{O} \textit{ on the two arenas).}$$

Therefore coherence-dominated features decrease *under the switch* bdry $\to$ bulk *(and* increase *under* bulk $\to$ bdry*). In particular, if a conflict in Definition 10.99 is due solely to boundary coherence (i.e. the only positive term in $\mathfrak{D}^{[\mathscr{S};\chi]}$ from (10.59) is the coherence channel), then the bulk switch strictly decreases $\mathfrak{D}^{[\mathscr{S};\chi]}$.*

(iii) Spectral window refinement

Let $W'_{\mathrm{spec}} \subseteq W_{\mathrm{spec}}$ *be a refinement* narrowing around the certified features *(Ch. 7 mask framework: Definition 7.665). By KL positivity (Ch. 7: eq. (7.12)) and the refinement* $W'_{\mathrm{spec}} \leq W_{\mathrm{spec}}$ *(pointwise), nuisance spectral leakage outside the certified band* does not increase*; moreover, because the certified feature lies entirely within* W'_{spec} *by construction of the refinement (Def. 10.101), the calibrated spectral entry*

$$S'_1 = \int W'_{\mathrm{spec}}\, \rho_{(s)}^{[\mathscr{S};\chi]}\, d\mu$$

satisfies $g_m(S'_1) \geq g_m(S_1)$ *for the increasing calibration* g_m *(Def. 10.82). Hence the spectral contribution to* $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}$ weakly improves.

Proof. (i) is exactly Prop. 9.146; see also Lemma 10.96 for the auxiliary monotone quantities (TT-leak ε, vacuum/coherence).

(ii) The arena comparison inequality is part of the certified rig's arena profile (bulk vs. boundary) and follows from the boundary-to-bulk localization property of the relational dynamics (same typed $\mathfrak{O}$ and band/BRST hygiene Proposition 10.10). Applying $\|\Pi^{(\mathrm{corr})} \cdot\|_{\mathcal{I}}$ on both arenas yields the stated inequality, which transfers via the increasing state calibration g_m (Def. 10.82) to the coherence component of Λ_{state}. When coherence is the sole positive contributor to the SynTh potential (10.59), the inequality implies a strict decrease of $\mathfrak{D}^{[\mathscr{S};\chi]}$ under bdry $\to$ bulk.

(iii) By KL positivity eq. (7.12) and $W'_{\mathrm{spec}} \leq W_{\mathrm{spec}}$, any off-band leakage cannot increase; by the refinement rule in Definition 10.101 the certified spectral feature remains fully contained in the refined window, so the raw spectral mass on the feature is preserved while leakage is reduced. The state calibration g_m is strictly increasing (Definition 10.82); therefore the calibrated spectral entry, and hence its contribution to Λ_{state}, weakly improves. These statements are taken on the physical carrier $\mathcal{H}_{\mathrm{phys}}$ with band/BRST hygiene (realized weave configuration invariance: Proposition 10.10). □

Lemma 10.103 (Bounding the TT-leak by non-spectral TT content)**.** *In the geometry sector* $\mathscr{S} = \Phi\Phi$*, the TT-leak* ε *(Def. Definition 10.32) is bounded by the TT content in the* non-spectral *triad channels:*

$$\varepsilon \;\leq\; C_{\mathrm{corr}} \left\| \Pi^{(\mathrm{corr})}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g} \right\|_{\mathcal{I}} \;+\; C_{\mathrm{vac}} \left\| \Pi^{(\mathrm{vac})}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g} \right\|_{\mathcal{I}}, \tag{10.60}$$

for realized weave configuration-dependent constants $C_{\mathrm{corr}}, C_{\mathrm{vac}} > 0$*. Here* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ *is the TT projector (Def. Definition 10.3),* $\delta\hat{g}$ *is the* $\Phi\Phi$*-sector metric fluctuation, and* $\Pi^{(\mathrm{spec})}, \Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{corr})}$ *are the triad idempotents (Def. Definition 10.2).*

Proof. By definition of the TT-leak (Def. Definition 10.32) and the spin-2 Riesz projector on the spectral band (typed layer; Definition 9.116),

$$\varepsilon = \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \left(1 - \mathsf{P}^{(2)}_{\mathrm{spec}}\right) \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g} \right\|_{\mathcal{I}}.$$

Insert the triad decomposition $1 = \Pi^{(\mathrm{spec})} + \Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})}$ (Def. Definition 10.2) and use that $\mathsf{P}^{(2)}_{\mathrm{spec}}$ acts as the identity on the *spectral* spin-2 support while annihilating the non-spectral channels (standard Riesz calculus within the typed layer; Definition 9.116):

$$(1 - \mathsf{P}^{(2)}_{\mathrm{spec}})\, \Pi^{(\mathrm{spec})} = 0, \qquad (1 - \mathsf{P}^{(2)}_{\mathrm{spec}})\, \Pi^{(a)} = \Pi^{(a)} \quad \text{for } a \in \{\mathrm{vac}, \mathrm{corr}\}.$$

Hence

$$\varepsilon = \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \left(\Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})} \right) \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \delta\hat{g} \right\|_{\mathcal{I}} \;\le\; \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \Pi^{(\mathrm{vac})} \, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \delta\hat{g} \right\|_{\mathcal{I}} + \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \Pi^{(\mathrm{corr})} \, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \delta\hat{g} \right\|_{\mathcal{I}}.$$

By the typed-layer commutation on the realized weave configuration (typed projectors and the triad commute; see Definition 9.116 together with Def. Definition 10.2), we may swap $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ with $\Pi^{(a)}$ inside the $\|\cdot\|_{\mathcal{I}}$ norm. Using boundedness of the projectors in the band-invariant norm (realized weave configuration invariance; Proposition 10.10) and the triangle inequality, there exist realized weave configuration-dependent constants $C_{\mathrm{vac}}, C_{\mathrm{corr}} > 0$ such that

$$\left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \Pi^{(a)} \, X \right\|_{\mathcal{I}} \;\le\; C_a \left\| \Pi^{(a)} \, X \right\|_{\mathcal{I}}, \qquad a \in \{\mathrm{vac}, \mathrm{corr}\}.$$

Apply this with $X = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \delta\hat{g}$ to obtain (10.60). □

Comments. (i) With a Hilbertian, projector-contractive choice of $\|\cdot\|_{\mathcal{I}}$ the constants can be taken as $C_{\mathrm{vac}} = C_{\mathrm{corr}} = 1$; in general we keep the explicit realized weave configuration-dependent bounds (Prop. 10.10). (ii) Under IR tightening the right-hand side is nonincreasing because the vac/corr TT norms weakly decrease (Prop. 9.146), recovering Cor. 10.104 as a corollary of the bound.

Corollary 10.104 (IR tightening decreases the TT-leak)**.** *Under IR tightening $r \uparrow$ (Ch. 8 IR window/band functor: Definitions 6.280 and 7.29; audit move: Definition 10.101), the TT-leak ε (Def. Definition 10.32) is* nonincreasing. *Moreover, if the conflict includes* correlational TT *(i.e. $\|\Pi^{(\mathrm{corr})}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}\|_{\mathcal{I}} > 0$) and the tightening step is* strict *(the IR window shrinks on a set of positive spectral measure carrying that TT coherence), then the decrease is* strict.

Proof. Let $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ be the TT projector (Def. Definition 10.3) and $\Pi^{(\mathrm{spec})}, \Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{corr})}$ the triad idempotents (Def. Definition 10.2). By Def. Definition 10.32 and the spin–2 Riesz projector on the band (typed layer; Definition 9.116),

$$\varepsilon(r) = \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \big(1 - \mathsf{P}^{(2)}_{\mathrm{spec}}(r) \big) \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \delta\hat{g}(r) \right\|_{\mathcal{I}}.$$

Insert $1 = \Pi^{(\mathrm{spec})} + \Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})}$ and use $(1 - \mathsf{P}^{(2)}_{\mathrm{spec}})\Pi^{(\mathrm{spec})} = 0$, $(1 - \mathsf{P}^{(2)}_{\mathrm{spec}})\Pi^{(a)} = \Pi^{(a)}$ for $a \in \{\mathrm{vac}, \mathrm{corr}\}$, to get

$$\varepsilon(r) = \left\| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \big(\Pi^{(\mathrm{vac})} + \Pi^{(\mathrm{corr})} \big) \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \, \delta\hat{g}(r) \right\|_{\mathcal{I}}.$$

By boundedness of the projectors in the realized weave configuration norm (realized weave configuration invariance; Proposition 10.10) there exist $C_{\mathrm{vac}}, C_{\mathrm{corr}} > 0$ such that

$$\varepsilon(r) \;\le\; C_{\mathrm{vac}} \left\| \Pi^{(\mathrm{vac})} \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \delta\hat{g}(r) \right\|_{\mathcal{I}} \;+\; C_{\mathrm{corr}} \left\| \Pi^{(\mathrm{corr})} \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \delta\hat{g}(r) \right\|_{\mathcal{I}},$$

which is (10.60) (Lemma 10.103). Under IR tightening, the *vacuum* and *coherence* features are *nonincreasing* (Prop. 9.146); hence the right-hand side is nonincreasing in r, and so is $\varepsilon(r)$.

For strictness, assume: (i) $\left\|\Pi^{(\mathrm{corr})}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}(r_1)\right\|_{\mathcal{I}} > 0$, and (ii) the tightening step $r_1 \to r_2$ is *strict*: $K_{\mathrm{IR}}^{(r_2)} < K_{\mathrm{IR}}^{(r_1)}$ on a set of positive spectral measure that carries the TT–coherence density (KL positivity; Ch. 8 eq. (7.12)). By positivity and L^p–contractivity of the IR window (Ch. 8; Definition 6.280) the coherence norm $\|\Pi^{(\mathrm{corr})}\Pi^{[\mathrm{TT}]}\delta\hat{g}(r)\|_{\mathcal{I}}$ *strictly* decreases from r_1 to r_2; the vacuum norm is nonincreasing (Prop. 9.146). Therefore the sum on the right-hand side of (10.60) strictly decreases, implying $\varepsilon(r_2) < \varepsilon(r_1)$.

All statements are on the physical carrier $\mathcal{H}_{\mathrm{phys}}$ and preserve gauge/BRST hygiene by Proposition 10.10 (see also the masked state monotonicity in Proposition 9.146 and the descent invariants of Lemma 10.96). □

10.10.3 Finite Audit Paths and No-Explosion

Definition 10.105 (Audit path and termination)**.** An *audit path* is a finite sequence of audit moves (Def. 10.101) applied to $\mathcal{I}^{[\mathscr{S}]}$. It *terminates successfully* if it reaches a co-tenable realized weave configuration ($\mathfrak{D} = 0$). It *terminates by certificate* if, after finitely many moves, one of the following holds persistently for all further admissible moves:

(i) Robust TT-leak
$\varepsilon > \varepsilon_{\max}$.

(ii) Robust vector parity asymmetry
$|\Delta_P| > \delta_P$.

(iii) Robust CP asymmetry
$|\Delta_{\mathrm{CP}}| > \delta_{\mathrm{CP}}$.

(iv) Absence of spectral support
$S_1 \equiv 0$ on all admissible W_{spec}.

The outcome is then a *certificate of non-co-tenability.*

Proposition 10.106 (Descent of the SynTh potential)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and $[\chi]$ be any admitted type (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). From any* conflicting *configuration on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) there exists an* audit move *(Def. Definition 10.101) that does not increase the SynTh potential $\mathfrak{D}^{[\mathscr{S};\chi]}$ of (10.59); moreover, if the conflict is attributable to a specific diagnostic (coherence, TT-leak, parity, or CP), there exists a move that* strictly *decreases $\mathfrak{D}^{[\mathscr{S};\chi]}$.*

Proof. Recall $\mathfrak{D}^{[\mathscr{S};\chi]}$ from (10.59) and the audit moves in Definition 10.101. We proceed by cases, using the monotonicities of Lemma 10.102 and Lemma 10.96, and the TT-leak behavior in Corollary 10.104.

Case A: law/state shortfall (no trigger active). If the conflict is $\Lambda_{\mathrm{law}} < \theta_{\mathrm{law}}$ and/or masked $\Lambda_{\mathrm{state}}^{(\mathrm{spec})} < \theta_{\mathrm{state}}$ (Def. Definition 10.99), then *IR tightening* $r \uparrow$ is an audit move that makes the law meter nondecreasing and the masked spectral state meter nondecreasing (Prop. 9.146; Lemma 10.96). Hence the two positive contributions $1 - \Lambda_{\mathrm{law}}$ and $1 - \Lambda_{\mathrm{state}}$ do not increase, so $\mathfrak{D}$ does not increase. Moreover, if the tightening is *strict* on a set of positive spectral measure where either meter has positive one-sided slope (Ch. 10 onset rules: eq. (9.81),

stability Proposition 10.87), then at least one of the two terms strictly decreases, so $\mathfrak{D}$ strictly decreases.

Case B: coherence diagnostic dominates. If the conflict is attributable to coherence (the only positive term in (10.59) arising from the corr channel), perform an *arena switch* bdry $\to$ bulk (Def. 10.101). By the arena comparison in Lemma 10.102(ii), coherence decreases under bdry $\to$ bulk and, when the conflict is *solely* coherence-driven, the decrease is strict; the state calibration g_m is increasing (Def. 10.82), so the coherence contribution to $\mathfrak{D}$ strictly decreases. Thus $\mathfrak{D}$ strictly decreases.

Case C: TT-leak diagnostic active. If the conflict is due to TT-leak ε (Def. 10.32), apply *IR tightening*. By Corollary 10.104, ε is nonincreasing; if there is correlational TT on a set of positive spectral measure, the decrease is strict. Hence the penalty $u_\varepsilon(\varepsilon/\varepsilon_{\max} - 1)_+$ in (10.59) is nonincreasing and strictly decreases under the stated regularity.

Case D: parity (Δ_P) or CP ($\Delta_{\mathrm{CP}}^{(a)}$) diagnostic active. Two standard sources can drive these asymmetries (see Definitions 10.51 and 10.58): (i) boundary-amplified coherence and (ii) off-band spectral leakage.

(D1) If the asymmetry is *coherence-dominated*, the arena switch bdry $\to$ bulk reduces the coherence norm (Lemma 10.102(ii)); since both diagnostics are built from calibrated readouts of typed projectors (Defs. 10.58, 10.51, 10.82), decreasing the coherence contribution strictly reduces the corresponding normalized asymmetry whenever the asymmetry has positive support on the reduced region. Hence the penalty terms $u_P(\frac{|\Delta_P|}{\delta_P} - 1)_+$ or $u_{\mathrm{CP}}(\frac{|\Delta_{\mathrm{CP}}^{(a)}|}{\delta_{\mathrm{CP}}} - 1)_+$ strictly decrease.

(D2) If the asymmetry is driven by *off-band leakage*, perform *spectral window refinement* $W_{\mathrm{spec}} \mapsto W'_{\mathrm{spec}} \subset W_{\mathrm{spec}}$ that narrows around the certified feature (Def. 10.101). By KL positivity (Ch. 8: eq. (7.12)) and Lemma 10.102(iii), nuisance leakage cannot increase and the calibrated spectral contribution weakly improves. When the asymmetric leakage has positive mass in the excised annulus, the normalization reduces the observed asymmetry strictly, so the corresponding penalty strictly decreases.

Conclusion. In every conflicting situation, there exists at least one audit move (IR tightening, arena switch, or window refinement) that does not increase $\mathfrak{D}$ (Cases A–D). Whenever the conflict is attributable to a specific diagnostic (coherence, TT-leak, parity, CP) and the move acts on a set of positive spectral measure supporting that diagnostic's excess, the corresponding term strictly decreases, so $\mathfrak{D}$ strictly decreases. All moves preserve BRST/Nielsen safety and band admissibility (realized weave configuration invariance: Proposition 10.10). □

Theorem 10.107 (No-Explosion/Audit Theorem for the weave)**.** *For any $(\mathscr{S}, [\chi])$ with $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and admitted type $[\chi]$ (Definition 9.116, instantiated in Definitions 10.3 to 10.5), starting from any* conflicting *configuration on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1) there exists a* finite *Audit path (Def. Definition 10.95, item* (B)*) that either:*

(i) Co-tenability

Reaches co-tenability $\left(\mathfrak{D}^{[\mathscr{S};\chi]} = 0\right)$ (Def. Definition 10.99, potential (10.59)).

(ii) Certified failure

Terminates with a certified failure (the Audit certificate of §10.10, produced by the path in Def. Definition 10.95).

In particular, SynTh does not explode under the rules of (Definitions 8.98 and 8.99): Law ⊕ State becomes co-tenable after finite audits or yields a stable, falsifiable certificate.

Proof. We use the SynTh potential $\mathfrak{D}^{[\mathscr{S};\chi]}$ from (10.59), the monotone effects of audit moves in Lemma 10.102, the descent invariants in Lemma 10.96, the TT-leak behavior in Cor. 10.104, and the descent guarantee in Prop. 10.106.

Audit schedule. Choose an IR schedule $r_0 < r_1 < \dots$ with fixed step $\Delta r > 0$ smaller than the onset stability radii from Prop. 10.87 and compatible with the slope bounds in Prop. 10.88. Permit at most one arena switch (bulk↔boundary) and a *finite* nested refinement chain of spectral windows $W_{\mathrm{spec}} \supset W^{(1)}_{\mathrm{spec}} \supset \cdots \supset W^{(N)}_{\mathrm{spec}}$ (Def. 10.101; Ch. 8 fixed masks Definition 7.665). At each step, select an audit move guaranteed by Prop. 10.106 *not to increase* $\mathfrak{D}$, and if the conflict is attributable to a specific diagnostic (coherence, TT-leak, parity, CP), pick the move that *strictly decreases* $\mathfrak{D}$ (positive-measure strictness as in Cor. 10.104 and Lemma 10.102).

Monotone descent and noncreativity of triggers. By Lemma 10.96 the core descent terms $\theta_{\mathrm{law}} - \Lambda_{\mathrm{law}}$ and $\theta_{\mathrm{state}} - \Lambda^{(\mathrm{spec})}_{\mathrm{state}}$ are nonincreasing under $r \uparrow$; the TT-leak indicator is nonincreasing; arena switch and window refinement have the effects listed in Lemma 10.102. Hence the potential does not increase along the schedule; moreover, if a TT-leak or coherence source is active on a set of positive spectral measure, a strict decrease occurs (Cor. 10.104, Lemma 10.102). Automatic triggers are *sound* (Lemma 10.97 (1); see also Cor. 10.91): IR tightening cannot *create* a new TT-leak or vac/corr trigger (they are nonincreasing).

Termination by onset or certificate. If no automatic trigger is active, apply the canonical spectral mask (Definition 7.665). Then $\Lambda_{\mathrm{law}}(r)$ and the masked $\Lambda_{\mathrm{state}}(r)$ are nondecreasing (Prop. 9.146). By the slope hypotheses in Prop. 10.88, choosing $\Delta r \le \min\{\Delta_{\mathrm{law}}/m_{\mathrm{law}}, \Delta_{\mathrm{state}}/m_{\mathrm{state}}\}$ at any stage with gaps $\Delta_\bullet > 0$ forces a *finite* number of tightening steps to cross the thresholds in Def. 10.85; uniqueness/interval structure then follows from Lemma 10.86, yielding co-tenability (case (1)).

If an automatic trigger is active and persists above its bound after exhausting the *finite* window refinements and the single arena switch, or if a threshold cannot be reached because its limit value is insufficient (cf. Lemma 10.97 (2)), the path produces a *certified failure*: the certificate records sector/type, limiting visibilities, active residuals and diagnostics, and the retuning region explored (as in §10.10; see the Audit path in Def. 10.95). This is case (2).

No-Explosion. Throughout, SynTh's paraconsistent calculus (Definitions 8.98 and 8.99) routes any Law–State conflict into the Audit branch rather than trivializing inference; the finite termination above ensures the branch returns either a co-tenable TLO with onset (Definitions 9.147 and 10.85) or a falsifiable certificate. Hence no explosion occurs.

□

10.10.4 Trigger Thresholds and Automatic Audit

Definition 10.108 (Automatic audit triggers)**.** Fix a sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and an admitted type $[\chi]$ (typed layer Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Let the calibrated meters be those of Definition 10.82 and the type-specific diagnostics as in Remark 10.81 with explicit definitions in Definitions 10.32, 10.51 and 10.58. Choose a priori bounds $(\varepsilon_{\max}, \delta_P, \delta_{\mathrm{CP}}) > 0$ (cf. the mask framework of Ch. 8: Definition 7.665). We say an *automatic audit* is triggered for $[\mathscr{S}; \chi]$ if *any* of the following holds:

$$\begin{aligned} \varepsilon &> \varepsilon_{\max} && \text{(TT leak; Definition 10.32),} \\ |\Delta_P| &> \delta_P && \text{(CK parity; Definition 10.58),} \\ |\Delta_{\mathrm{CP}}^{(a)}| &> \delta_{\mathrm{CP}} && \text{(Higgs CP; Definition 10.51).} \end{aligned}$$

When an automatic trigger fires, the process *immediately* enters the Audit path (SynTh rules Ch. 9: Definitions 8.98 and 8.99; weave specialization §10.10). This restates the trigger condition captured in Corollary 10.91 and is used by the Audit path definition in §10.10.

Remark 10.109 (Admission failure vs. automatic trigger)**.** Thresholds $(\theta_{\mathrm{law}}, \theta_{\mathrm{state}}) \in (0, 1)$ are defined for the calibrated visibilities in Definition 10.82 and used by the admission predicate/onset in Definition 10.85 (see also the thresholded co-tenability in Definition 10.99). If either $\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]} < \theta_{\mathrm{law}}$ or the *masked* state visibility (canonical spectral mask; Ch. 8 Definition 7.665) satisfies $\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]} < \theta_{\mathrm{state}}$, the pair is in *conflict* and enters the Audit path due to *admission failure*, not due to an automatic trigger (cf. §10.10, Def. 10.95, item (B)). Monotone evolution of these meters under IR tightening is given by Proposition 9.146 and summarized in Lemma 10.96; descent and termination properties follow by Proposition 10.106, Lemma 10.97, and Theorem 10.107.

Corollary 10.110 (Soundness of triggers)**.** *Let $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ and $[\chi]$ be an admitted type (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). Whenever an* automatic trigger *fires for $[\mathscr{S}; \chi]$ (Def. Definition 10.108; cf. Corollary 10.91), there exists an* audit move *(Def. Definition 10.101) that* weakly decreases *the SynTh potential $\mathfrak{D}^{[\mathscr{S};\chi]}$ of (10.59). Moreover, if the trigger concerns ε, Δ_P, or $\Delta_{\mathrm{CP}}^{(a)}$, then—unless a certificate condition already holds (Theorem 10.107)—there exists an audit move that* strictly *decreases the corresponding penalty term in (10.59).*

Proof. By Def. 10.108 (and Corollary 10.91), an automatic trigger means one of $\varepsilon > \varepsilon_{\max}$ (Definition 10.32), $|\Delta_P| > \delta_P$ (Definition 10.58), or $|\Delta_{\mathrm{CP}}^{(a)}| > \delta_{\mathrm{CP}}$ (Definition 10.51) holds. Such a configuration is *conflicting* under the thresholded co-tenability definition (Def. 10.99) and contributes a positive penalty to $\mathfrak{D}^{[\mathscr{S};\chi]}$ (Eq. (10.59)).

Weak decrease. From any conflict there exists an audit move that does not increase $\mathfrak{D}$ by Prop. 10.106. Concretely: - For ε (TT-leak), *IR tightening* $r \uparrow$ makes ε nonincreasing (Cor. 10.104); the penalty $u_\varepsilon(\varepsilon/\varepsilon_{\max} - 1)_+$ therefore does not increase. - For parity/CP diagnostics, either an *arena switch* (boundary→bulk) or a *spectral window refinement* weakly reduces the asymmetry carried by coherence or off-band leakage, respectively (Lemma 10.102(ii),(iii), KL positivity eq. (7.12)). Since g_m is increasing (Def. 10.82), the normalized penalties $u_P(\frac{|\Delta_P|}{\delta_P} - 1)_+$ and $u_{\mathrm{CP}}(\frac{|\Delta_{\mathrm{CP}}^{(a)}|}{\delta_{\mathrm{CP}}} - 1)_+$ are weakly reduced.

Strict decrease unless certified. If the trigger concerns a specific diagnostic and the offending content occupies a set of positive spectral measure: - For ε: strict IR tightening that removes TT-coherence support of positive measure yields $\varepsilon(r_2) < \varepsilon(r_1)$ (Cor. 10.104), hence a *strict* drop in its penalty. - For Δ_P or $\Delta_{\mathrm{CP}}^{(a)}$: if the excess is coherence-dominated, boundary→bulk strictly reduces the coherence norm (Lemma 10.102(ii)); if it is off-band leakage, a refinement $W_{\mathrm{spec}} \mapsto W'_{\mathrm{spec}}$ that excises an annulus of positive measure around the certified feature strictly reduces the asymmetry contribution (Lemma 10.102(iii) with eq. (7.12)). In both subcases the corresponding penalty in (10.59) strictly decreases.

If no admissible move can strictly reduce the active penalty while the trigger remains, the situation meets the certificate scenario in Theorem 10.107 (case (2)), and Audit terminates by certificate rather than continuing descent.

Thus, whenever an automatic trigger fires, there is always an audit move that weakly decreases $\mathfrak{D}$, and—except in certificate cases—one that strictly decreases the triggered penalty. □

Remark 10.111 (Minimality of audit moves)**.** The three audit moves of Definition 10.101 are *minimal and sufficient* for SynTh on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Def. Definition 10.1):

(i) IR retuning
IR retuning $r \mapsto r + \delta r$ acts through the IR window $K_{\mathrm{IR}}^{(r)}$ (Ch. 6: Definitions 6.280 and 7.29) and is the only knob that changes long-distance content while preserving band admissibility; its effects on the meters/diagnostics are exactly those in Proposition 9.146, Lemma 10.96, and Corollary 10.104.

(ii) Arena switch
Arena switch $\mathfrak{P}$: bulk $\leftrightarrow$ boundary is the canonical way to alter the Location component (Def. Definition 9.147) without changing typed projectors; its coherence comparison is captured in Lemma 10.102(ii).

(iii) Spectral window refinement
Spectral window refinement $W_{\mathrm{spec}} \mapsto W'_{\mathrm{spec}}$ (masks: Definition 7.665) is the only certified mechanism to remove off-band leakage while preserving the feature; its monotone effect is Lemma 10.102(iii) with KL positivity eq. (7.12).

Any further "micro-tuning" (e.g. band-tag or sheet micro-adjustments) factors through these moves by *band covariance* and projector stability on the realized weave configuration (Proposition 10.10 and stability Definition 9.116, item (P7)); consequently, their impact on visibilities/diagnostics is subsumed by the monotonicities already listed.

Remark 10.112 (Reporting after audit)**.** Upon termination of the Audit path (Theorem 10.107), Step (7) reports, for each $(\mathcal{S}, [\chi])$:

(i) Triad-resolved outcomes
The triad-resolved outcomes $(\mathrm{spec}, \mathrm{vac}, \mathrm{corr})$ with the corresponding calibrated entries (cf. Definitions 10.2 and 10.82 and eq. (10.52)).

(ii) Arena
The used arena $\mathfrak{P} \in \{\mathrm{bulk}, \mathrm{boundary}\}$ (Def. Definition 10.101).

(iii) Certified onsets
The certified onsets $r^\star[\chi]$ (Def. Definition 10.85, uniqueness/stability via Lemma 10.86 and Proposition 10.87).

(iv) Parasymmetric TLO readout
The Parasymmetric TLO readout (Def. Definition 9.147)

$$\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$$

(v) Outcome label
The outcome is labelled co-tenability, $\mathfrak{D}^{[\mathscr{S};\chi]} = 0$ (Definition 10.99 and eq. (10.59)) or a certificate that lists the active diagnostic(s) and the explored retuning region bounded by the stability radii (Theorem 10.107, Prop. 10.87, and triggers Definition 10.108 and Corollary 10.91).

All reported quantities are evaluated on the physical carrier $\mathcal{H}_{\mathrm{phys}}$ and inherit gauge/BRST hygiene by Proposition 10.10; sectorization is strictly $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ with τ–kairos entering only via typed projectors (Definition 10.4).

10.11 Weaving the Sectors via the Unified Inter-Modal Correlator

We complete Step (6) by inserting the *typed* projectors into the Unified Inter–Modal Correlator and analyzing mixing on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1). We use the triad projectors $\Pi^{(a)}$ (Def. Definition 10.2), the TT map $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Def. Definition 10.3), the τ–kairos typed families (Def. Definition 10.4), and the Higgs CP–refined projectors (Def. Definition 10.5). The global correlator $\hat{\mathbf{G}}_\Lambda$ is as defined upstream (Def. Definition 6.4).

Typed insertion into $\hat{\mathbf{G}}_\Lambda$.

Definition 10.113 (Typed and triad-resolved correlator)**.** Let $[\chi]$ and $[\chi']$ be admitted types from the typed layer (Ch. 10; Definition 9.116, instantiated in Definitions 10.3 to 10.5). For $a, b \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ define the *typed, triad-resolved correlator*

$$\hat{\mathbf{G}}_\Lambda^{(a\to b)\,[\chi\to\chi']} := \mathsf{P}_{\mathrm{phys}}\, \Pi^{(b)}\, \Pi^{[\chi']}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[\chi]}\, \Pi^{(a)}\, \mathsf{P}_{\mathrm{phys}}, \tag{10.61}$$

where $\Pi^{[\chi]}$ denotes the *product* of the relevant typed projectors for $[\chi]$ (e.g. $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ for gravitons; $A^{(\pm)}$ for Chrono–Kymon vectors; $\Pi^{(\mathrm{CP}\pm)}\Pi_\Theta^{[\mathrm{rad}\pm]}$ for Higgs CP/refined radial modes; cf. Definitions 10.3 to 10.5). The sector-diagonal blocks $\hat{G}_{\Phi\Phi}, \hat{G}_{\Theta\Theta}$ and the mixed blocks $\hat{G}_{\Phi\Theta}, \hat{G}_{\Theta\Phi}$ (Def. Definition 6.4) are thereby refined to typed channels $[\chi] \to [\chi']$ with explicit triad provenance $a \to b$.

Remark 10.114 (Band and BRST safety; commutation on the realized weave configuration)**.** On the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$, the maps in (10.61) preserve band admissibility and gauge-parameter independence by Proposition 10.10 (all operators are evaluated on $\mathcal{H}_{\mathrm{phys}}$). Moreover, the typed projectors (Ch. 10: Definition 9.116) commute with the triad

idempotents from Definition 10.2 on the realized weave configuration, so the order in (10.61) is unambiguous up to BRST-exact/EOM terms (cf. Remark 10.93). Continuity under admissible retuning follows from typed stability (Definition 9.116, item (P7)).

Remark 10.115 (Sector note: mixed $\Phi\Theta$ channels)**.** For the mixed interaction block $\mathscr{S} = \Phi\Theta$, the construction (10.61) is applied *after typed insertion* into the off–diagonal correlator blocks of $\hat{\mathbf{G}}_\Lambda$ (Def. Definition 6.4). Here τ–kairos appears only via the *typed* projectors in $\Pi^{[\chi]}$ (Def. Definition 10.4); it is *not* a sector. All triad-resolved channels $a \to b$ are reported with their certified provenance (Definition 10.2).

10.11.1 Σ-weighted Generalized Eigenproblem for Mixing

Definition 10.116 ($\bar{\Sigma}$–Hermitian generalized eigen-operator pairs)**.** Let $(\mathcal{H}, \langle\cdot,\cdot\rangle_{\bar{\Sigma}})$ be a $\bar{\Sigma}$–weighted Hilbert space (Chs. 6–7). For linear maps $A, B : \mathcal{H} \to \mathcal{H}$ with $\bar{\Sigma}$–adjoints $A^{\dagger_{\bar{\Sigma}}}, B^{\dagger_{\bar{\Sigma}}}$:

(i) $\bar{\Sigma}$–Hermitian generalized eigen-operator pair

The ordered pair (A, B) is called a $\bar{\Sigma}$–*Hermitian generalized eigen-operator pair* if

$$A = A^{\dagger_{\bar{\Sigma}}} \qquad \text{and} \qquad B = B^{\dagger_{\bar{\Sigma}}}.$$

Associated to (A, B) is the one–parameter family of operators $A - \lambda B$ ($\lambda \in \mathbb{C}$) and the generalized eigenproblem $Av = \lambda Bv$.

(ii) Generalized eigenpair and Rayleigh quotient

A *generalized eigenpair* (λ, v) satisfies $Av = \lambda Bv$, $v \neq 0$. If B is positive (semi)definite on $\operatorname{Ran} B$, the Rayleigh quotient is

$$\lambda(v) = \frac{\langle v, Av\rangle_{\bar{\Sigma}}}{\langle v, Bv\rangle_{\bar{\Sigma}}}$$

on that support; whitening by $B^{1/2}$ yields a standard Hermitian problem (cf. Remark 10.119).

Definition 10.117 ($\bar{\Sigma}$-weighted inner products, adjoints, and typed generalized eigen-operator pairs)**.** Let $\langle\cdot,\cdot\rangle_{\bar{\Sigma}}$ be the $\bar{\Sigma}$-weighted inner product on the relevant carriers (Chs. 6–7). For a linear map X on (or between) typed subspaces of $\mathcal{H}_{\text{phys}}$, define the $\bar{\Sigma}$-adjoint by

$$X^{\dagger_{\bar{\Sigma}}} \text{ such that } \langle Xu, v\rangle_{\bar{\Sigma}} = \langle u, X^{\dagger_{\bar{\Sigma}}} v\rangle_{\bar{\Sigma}}.$$

Set $\mathrm{Re}_{\bar{\Sigma}}(X) = \frac{1}{2}(X + X^{\dagger_{\bar{\Sigma}}})$ and $\mathrm{Im}_{\bar{\Sigma}}(X) = \frac{1}{2\mathrm{i}}(X - X^{\dagger_{\bar{\Sigma}}})$, both $\bar{\Sigma}$-Hermitian. With the typed insertion $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}$ (Definition 10.113, (10.61)), define the *typed generalized eigen-operator pair*

$$A^{[\chi\to\chi']} := \mathrm{Re}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}\big), \qquad B^{[\chi\to\chi']} := \mathrm{Im}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}\big), \tag{10.62}$$

and, for $[\chi] = [\chi']$, the diagonal metric

$$M^{[\chi]} := \mathrm{Re}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]}\big).$$

All maps are evaluated on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ and are BRST/band safe by Proposition 10.10.

Definition 10.118 ($\bar{\Sigma}$-weighted generalized eigenproblem (mixing))**. (a) Intra-type ($[\chi] = [\chi']$).** On the typed carrier $\mathcal{H}_{[\chi]} = \operatorname{Ran}\Pi^{[\chi]} \subset \mathcal{H}_{\text{phys}}$,

$$A^{[\chi\to\chi]}v \;=\; \lambda\, B^{[\chi\to\chi]}v, \qquad v \in \mathcal{H}_{[\chi]}. \tag{10.63}$$

(b) Cross-type ($[\chi] \neq [\chi']$). Because $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']} : \mathcal{H}_{[\chi]} \to \mathcal{H}_{[\chi']}$ maps across distinct typed spaces, we realize the corresponding generalized eigen-operator pair on the *direct sum*

$$\mathcal{H}_{[\chi]\oplus[\chi']} := \mathcal{H}_{[\chi]} \oplus \mathcal{H}_{[\chi']}, \quad \langle (v,w),(v',w')\rangle_{\bar{\Sigma}} := \langle v,v'\rangle_{\bar{\Sigma}} + \langle w,w'\rangle_{\bar{\Sigma}},$$

with block forms

$$A_{\text{mix}} = \begin{pmatrix} 0 & \operatorname{Re}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}\big) \\ \operatorname{Re}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi'\to\chi]}\big) & 0 \end{pmatrix}, \qquad B_{\text{mix}} = \begin{pmatrix} 0 & \operatorname{Im}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}\big) \\ \operatorname{Im}_{\bar{\Sigma}}\big(\hat{\mathbf{G}}_\Lambda^{[\chi'\to\chi]}\big) & 0 \end{pmatrix}, \tag{10.64}$$

so that

$$A_{\text{mix}}\begin{pmatrix} v \\ w \end{pmatrix} = \lambda\, B_{\text{mix}}\begin{pmatrix} v \\ w \end{pmatrix}, \qquad (v,w) \in \mathcal{H}_{[\chi]\oplus[\chi']}.$$

Equivalently, one may linearize on the graph space or use a Rayleigh quotient on $\mathcal{H}_{[\chi]\oplus[\chi']}$. The spectrum λ quantifies the strength/phase of $[\chi] \leftrightarrow [\chi']$ mixing within the band-limited, BRST-projected space (Def. Definition 10.1).

Remark 10.119 (Well-posedness and whitening)**.** By KL-positivity on the certified band (Ch. 8: eq. (7.12)) and typed stability (Ch. 10: Definition 9.116, item (P7)), the diagonal metrics $M^{[\chi]} = \operatorname{Re}_{\bar{\Sigma}}(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]})$ and $M^{[\chi']}$ are positive semidefinite and strictly positive on their supports. In particular, on $\operatorname{Ran} M^{[\chi]}$ (and similarly for $M^{[\chi']}$) there exist unique positive square roots $M^{[\chi]1/2}$, $M^{[\chi]-1/2}$ satisfying $M^{[\chi]} = M^{[\chi]1/2}M^{[\chi]1/2}$.

On those supports, one may *whiten* the generalized eigen-operator pair (A,B) by the similarity transform with $M^{-1/2}$: for $v \in \operatorname{Ran} M^{[\chi]}$ set $u := M^{[\chi]1/2}v$ and define

$$\tilde{A} := M^{[\chi]-1/2} A\, M^{[\chi]-1/2}, \qquad \tilde{B} := M^{[\chi]-1/2} B\, M^{[\chi]-1/2}.$$

Then the generalized eigenproblem $Av = \lambda Bv$ is equivalent to

$$\tilde{A}u = \lambda\, \tilde{B}u$$

on $\operatorname{Ran} M^{[\chi]}$, with $\tilde{A}$ and $\tilde{B}$ $\bar{\Sigma}$-Hermitian. In particular, whenever B coincides with $M^{[\chi]}$ (or with a block-diagonal metric built from $M^{[\chi]}$, $M^{[\chi']}$ in the cross-type case), this whitening reduces the problem to a standard Hermitian eigenproblem $\tilde{A}u = \lambda u$ in the $\bar{\Sigma}$-inner product (cf. Definition 10.116).

If B (or B_{mix}) is singular, restrict to $\operatorname{Ran} B$ or use a certified Tikhonov regularization $B \mapsto B + \eta M$ with $\eta > 0$ small; all operations remain within $\mathcal{I}^{[\mathscr{S}]}$ by Proposition 10.10.

Remark 10.120 (Sector and mixed-block usage)**.** For sector-diagonal channels ($\Phi\Phi$ or $\Theta\Theta$) the typed blocks in (10.62) act within the same carrier; for the mixed block $\Phi\Theta$ (and $\Theta\Phi$), use the typed insertion (10.61) on the off–diagonal correlator, and then the direct-sum generalized eigen-operator pair (10.64) (cf. Remark 10.115). In all cases τ–kairos enters only via typed projectors (Definition 10.4), not as a sector label.

Remark 10.121 (Gauge/BRST and band safety)**.** All maps/forms above are sandwiched by $\mathsf{P}_{\mathrm{phys}}$ (Def. Definition 10.1) and composed with typed/triad idempotents (Definitions 10.2 to 10.5), hence inherit gauge-parameter independence and band admissibility by Proposition 10.10. Continuity under admissible retunings follows from Definition 9.116, item (P7).

Lemma 10.122 (Well-posedness on certified bands)**.** *Assume the certified band avoids spectral singularities (no poles on the fixed Riesz contours) for the diagonal typed blocks of the unified correlator (Def. Definition 10.113, (10.61)). Then the $\bar{\Sigma}$-weighted generalized eigenproblems are well-posed on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$:*

(i) Intra-type
In (10.63), $B^{[\chi\to\chi]}$ is bounded on $\mathcal{H}_{[\chi]}$ and $A^{[\chi\to\chi]}$ is compact; hence the spectrum $\{\lambda\}$ is discrete with possible accumulation only at 0.

(ii) Cross-type
For the block generalized eigen-operator pair (10.64) on $\mathcal{H}_{[\chi]\oplus[\chi']}$, B_{mix} is bounded and A_{mix} is compact; hence the spectrum is discrete with possible accumulation only at 0.

Proof. **Step 1: Boundedness on the realized weave configuration.** All operators are evaluated on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Def. Definition 10.1). By realized weave configuration hygiene and band admissibility (Proposition 10.10) and typed stability (Ch. 10: Definition 9.116, item (P7)), the typed/triad idempotents are bounded. The unified correlator $\hat{\mathbf{G}}_\Lambda$ restricted to the certified band is bounded on $\mathcal{H}_{\mathrm{phys}}$ (no spectral singularities on the fixed contours; Riesz selectors Definition 10.7). Therefore the typed insertions $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}$ (Def. Definition 10.113) are bounded, and so are their $\bar{\Sigma}$-Hermitian parts

$$A := \mathrm{Re}_{\bar{\Sigma}}(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}), \qquad B := \mathrm{Im}_{\bar{\Sigma}}(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']})$$

(Definition 10.117, (10.62)). Thus $B^{[\chi\to\chi']}$ is bounded in both intra- and cross-type settings; likewise for the block B_{mix} in (10.64).

Step 2: Compactness of A. On the certified band, the real part of the correlator can be written, contour-wise, as a finite linear combination of Riesz-integrals of resolvents (no poles on the contours):

$$\mathrm{Re}_{\bar{\Sigma}}(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']}) = \sum_\ell \int_{\Gamma_\ell} K_\ell(\zeta)\,(\zeta - \hat{\mathbf{H}})^{-1}\,d\zeta,$$

for suitable scalar weights K_ℓ and a band-limited generator $\hat{\mathbf{H}}$ (schematic; the exact representation is via the standard Cauchy integral applied to the typed insertions; cf. Riesz selectors Definition 10.7). Under band-limitation (Ch. 8 masks; Definition 7.665) and the absence of singularities on the contours, these contour integrals define operators whose kernels are square-integrable on the realized weave configuration (Hilbert–Schmidt), hence compact. Typed and triad projectors commute on the realized weave configuration (Ch. 10: Definition 9.116, item (P7)), so left/right multiplication by them preserves compactness. Therefore $A^{[\chi\to\chi']}$ is compact; in particular $A^{[\chi\to\chi]}$ is compact on $\mathcal{H}_{[\chi]}$, and the off-diagonal blocks entering A_{mix} in (10.64) are compact, making A_{mix} compact on $\mathcal{H}_{[\chi]\oplus[\chi']}$.

Step 3: Reduction to a compact self-adjoint problem on $\mathrm{Ran}\,B$**.** Restrict to the (closed) range $\mathcal{H}_B := \overline{\mathrm{Ran}\,B}$ (or $\overline{\mathrm{Ran}\,B_{\mathrm{mix}}}$ in the cross-type case). On $\mathcal{H}_B$, either B is strictly positive

(on the certified support; KL positivity eq. (7.12)) or one may use the standard certified regularization $B_\eta := B + \eta M$ with $M := M^{[\chi]}$ (or $M^{[\chi']}$ blockwise) from Definition 10.117 and $\eta > 0$ small (cf. Remark 10.119). Define the whitening transform $T_\eta := B_\eta^{-1/2}\, A\, B_\eta^{-1/2}$ on $\mathcal{H}_B$. Since A is compact and $B_\eta^{-1/2}$ is bounded on $\mathcal{H}_B$, T_η is compact (and $\bar{\Sigma}$-Hermitian). Letting $\eta \downarrow 0$ on $\mathcal{H}_B$ recovers the same nonzero spectrum (standard limit argument; see Remark 10.119). Therefore the generalized spectrum of (A, B) is the (possibly zero-accumulating) point spectrum of the compact operator T.

Step 4: Discreteness and accumulation at 0. By the spectral theorem for compact (Hermitian) operators, the spectrum is discrete with finite multiplicities and may only accumulate at 0. Mapping back through the whitening transform yields the same property for the generalized eigenvalues of (10.63) (intra-type) and of the block problem (10.64) (cross-type). All constructions remain within $\mathcal{I}^{[\mathcal{J}]}$ and preserve BRST/gauge and band safety by Proposition 10.10. □

10.11.2 TT-null Preservation for τ-mixing

Lemma 10.123 (TT-null preservation under any τ-mixing)**.** *Let $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ be any τ-kairos type (Def. Definition 10.4) and let Y be any admitted type in the gaiamiti or tantrakyma families (i.e. typed in the $\Phi\Phi$ or $\Theta\Theta$ sectors; cf. Definitions 10.3 and 10.5). Then, for the typed correlator blocks of Def. Definition 10.113,*

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\mathbf{G}}_\Lambda^{[\,X\to Y\,]} \;=\; 0, \qquad \hat{\mathbf{G}}_\Lambda^{[\,Y\to X\,]}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \;=\; 0, \tag{10.65}$$

as operators on the realized weave configuration $\mathcal{I}^{[\mathcal{J}]}$ (Def. Definition 10.1). The same statements hold triad-wise for each $(a\to b)$ block in (10.61).

Proof. Write the typed insertion (Def. Definition 10.113) without triad indices for brevity:

$$\hat{\mathbf{G}}_\Lambda^{[\,X\to Y\,]} = \mathsf{P}_{\mathrm{phys}}\, \Pi^{[Y]}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[X]}\, \mathsf{P}_{\mathrm{phys}}, \qquad \hat{\mathbf{G}}_\Lambda^{[\,Y\to X\,]} = \mathsf{P}_{\mathrm{phys}}\, \Pi^{[X]}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[Y]}\, \mathsf{P}_{\mathrm{phys}}.$$

By the τ–TT purity lemma Lemma 10.17 and TT projector definition Definition 10.3, the τ-typed ranges/kernels satisfy

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \Pi^{[X]} = 0, \qquad \Pi^{[X]}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = 0,$$

and, when extended block-diagonally to the full carrier, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ acts as zero on non-geometry components. Using typed stability/commutation on the realized weave configuration (Ch. 10: Definition 9.116, item (P7); see also Remark 10.114) and the fact that $\mathsf{P}_{\mathrm{phys}}$ preserves these relations on $\mathcal{H}_{\mathrm{phys}}$ (Proposition 10.10), we compute

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\mathbf{G}}_\Lambda^{[\,X\to Y\,]} = \mathsf{P}_{\mathrm{phys}} \left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \Pi^{[Y]}\right) \hat{\mathbf{G}}_\Lambda\, \Pi^{[X]}\, \mathsf{P}_{\mathrm{phys}}.$$

If Y is a non-TT type (e.g. Higgs CP-refined or other $\Theta\Theta$ typed object), then $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[Y]} = 0$ by orthogonality of the typed algebra, giving zero. If $Y = \mathrm{TT}$, then $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[Y]} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$, but the right factor $\Pi^{[X]}$ is τ-typed and annihilated by TT on the geometry side; equivalently, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[X]} = 0$ by τ–TT purity (Lemma 10.17). Thus the left identity in (10.65) holds.

The right identity is analogous:

$$\hat{\mathbf{G}}_{\Lambda}^{[\,Y\to X\,]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = \mathsf{P}_{\mathrm{phys}}\,\Pi^{[X]}\,\hat{\mathbf{G}}_{\Lambda}\left(\Pi^{[Y]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\right)\mathsf{P}_{\mathrm{phys}}.$$

If $Y \neq \mathrm{TT}$, then $\Pi^{[Y]}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = 0$; if $Y = \mathrm{TT}$, then $\Pi^{[X]}\hat{\mathbf{G}}_{\Lambda}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = 0$ again by τ–TT purity. Triad-resolved statements follow by inserting $\Pi^{(a)}/\Pi^{(b)}$ (Def. Definition 10.2) on the right/left of $\hat{\mathbf{G}}_{\Lambda}$; these commute with the typed projectors on the realized weave configuration (Ch. 10: Definition 9.116, item (P7)), so each $(a\to b)$ block is separately annihilated. All steps occur on $\mathcal{H}_{\mathrm{phys}}$ and inherit BRST/gauge safety by Proposition 10.10. □

Remark 10.124 (Mixed $\Phi\Theta$ channels)**.** For the mixed block $\mathscr{S} = \Phi\Theta$, apply the same calculation to the off-diagonal typed insertion (Def. Definition 10.113, (10.61); cf. Remark 10.115). TT acts purely on the geometry slot and remains null on any τ insertion by Lemma 10.17; thus (10.65) holds verbatim in the mixed case.

Corollary 10.125 (No induced TT from τ-mixing)**.** *The graviton readout $\hat{h}_{\mu\nu}$ (TT extraction; Definition 10.25, using the TT sandwich (10.28)) is unaffected by any τ-mixing channel: TT content cannot be generated by coupling to τ–kairos. Equivalently, the TT component of the typed, triad-resolved correlator remains unchanged when any factor $\hat{\mathbf{G}}_{\Lambda}^{[\,X\to Y\,]}$ or $\hat{\mathbf{G}}_{\Lambda}^{[\,Y\to X\,]}$ with a τ–type $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ (Def. Definition 10.4) is inserted.*

Proof. By the typed insertion rule (Definition 10.113, (10.61)) any contribution to the readout that involves a τ–typed factor has the schematic form

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\mathbf{G}}_{\Lambda}^{[\,X\to Y\,]} \quad \text{or} \quad \hat{\mathbf{G}}_{\Lambda}^{[\,Y\to X\,]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]},$$

possibly with triad idempotents $\Pi^{(a)}, \Pi^{(b)}$ on the right/left (Def. Definition 10.2). By TT–null preservation for τ–mixing (Lemma 10.123, identity (10.65)), each such TT–sandwiched block vanishes on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1). Therefore, when the TT sandwich that defines the graviton readout (10.28) (see Definitions 10.3 and 10.25) is applied to any correlator decomposition containing a τ–mixing channel, all τ–dependent terms drop out, leaving the TT readout unchanged.

The same conclusion holds triad-wise because the $(a \to b)$ blocks of (10.61) inherit Lemma 10.123 (the triad/typed projectors commute on the realized weave configuration; Ch. 10 stability Definition 9.116, item (P7)). For the mixed $\Phi\Theta$ channel, apply the argument to the off-diagonal typed insertion (Def. Definition 10.113; Remark 10.115); TT acts on the geometry slot and still annihilates any τ insertion. Gauge/BRST and band safety are preserved throughout by Proposition 10.10. □

10.11.3 Selection Rules for Typed Mixing

Proposition 10.126 (Symmetry selection rules (parity, helicity, CP))**.** *Let $\mathcal{P}$ denote spatial parity on the certified band,* Hel *the helicity operator on TT and τ–vector subspaces, and* CP *the CP action on the scalar subspace. Assume the unified correlator $\hat{\mathbf{G}}_{\Lambda}$ (with typed insertion as in Definition 10.113 and eq. (10.61))* commutes *on $\mathcal{H}_{\mathrm{phys}}$ with the relevant symmetry:*

$$\mathcal{P}\,\hat{\mathbf{G}}_{\Lambda}\,\mathcal{P}^{-1} = \hat{\mathbf{G}}_{\Lambda}, \qquad \mathsf{Hel}\,\hat{\mathbf{G}}_{\Lambda} = \hat{\mathbf{G}}_{\Lambda}\,\mathsf{Hel}, \qquad \mathsf{CP}\,\hat{\mathbf{G}}_{\Lambda}\,\mathsf{CP}^{-1} = \hat{\mathbf{G}}_{\Lambda},$$

respectively (band/BRST safety: Proposition 10.10). Then:

(i) Parity

If $\mathcal{P}$–invariance holds, a parity–even type does not *mix with a parity–odd type. In particular, using the parity assignments from Definitions 10.3 to 10.5,*

$$\hat{\mathbf{G}}_\Lambda^{[\ \tilde{S}^{(p)}\to \mathrm{TT}\ ]} = 0, \qquad \hat{\mathbf{G}}_\Lambda^{[\ \tilde{S}^{(p)}\to \mathrm{rad}+\ ]} = 0,$$

and similarly for the reverse channels.

(ii) Helicity

If $\hat{\mathbf{G}}_\Lambda$ is helicity–diagonal on TT, then the TT helicity sectors do not mix:

$$\Pi^{(+2)}\, \hat{\mathbf{G}}_\Lambda^{[\ \mathrm{TT}\to\mathrm{TT}\ ]}\, \Pi^{(-2)} = 0$$

and vice versa (TT helicity split within the typed layer; Ch. 10 Definition 9.116). Likewise, for τ–vectors, $A^{(+)}$ does not mix with $A^{(-)}$ (Definitions 10.4 and 10.58).

(iii) CP

If $\hat{\mathbf{G}}_\Lambda$ is CP–invariant on scalars, the Higgs CP–refined modes do not mix:

$$\hat{\mathbf{G}}_\Lambda^{[\ \mathrm{rad}+\to\mathrm{rad}-\ ]} = 0$$

and the reverse channel vanishes (Definition 10.5).

All statements hold triad–wise for each $(a\to b)$ block in (10.61).

Proof. We give a uniform argument using symmetry projectors. Let S be any of $\mathcal{P}$, Hel, or CP, and let $\Pi^{(s)}$ denote the spectral/idempotent projector onto the symmetry sector labeled by s (e.g. parity $\pm$, helicity ± 2 on TT or $\pm$ on CK, CP $\pm$ on scalars). On $\mathcal{H}_{\mathrm{phys}}$, assume S commutes with $\hat{\mathbf{G}}_\Lambda$ and preserves the typed/triad subspaces (typed stability on the realized weave configuration: Ch. 10 Definition 9.116, item (P7); realized weave configuration hygiene: Proposition 10.10).

Let $[\chi] \to [\chi']$ be a typed channel with definite S–labels s and s' respectively (the labels are fixed by the type definitions: Definitions 10.3 to 10.5). Using the typed insertion (Def. Definition 10.113),

$$\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']} = \mathsf{P}_{\mathrm{phys}}\, \Pi^{[\chi']}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[\chi]}\, \mathsf{P}_{\mathrm{phys}} = \mathsf{P}_{\mathrm{phys}}\, \Pi^{[\chi']}\, \Pi^{(s')}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{(s)}\, \Pi^{[\chi]}\, \mathsf{P}_{\mathrm{phys}},$$

where we inserted $\Pi^{(s')}$ on the left and $\Pi^{(s)}$ on the right because $\Pi^{[\chi']}/\Pi^{[\chi]}$ refine to definite S–labels by construction. Since S commutes with $\hat{\mathbf{G}}_\Lambda$, we have $\Pi^{(s')}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{(s)} = \hat{\mathbf{G}}_\Lambda\, \Pi^{(s')}\Pi^{(s)}$. If $s' \neq s$ (opposite parity, opposite helicity, or opposite CP), orthogonality yields $\Pi^{(s')}\Pi^{(s)} = 0$, hence $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']} = 0$. This proves (1)–(3). Triad–resolved versions follow by inserting $\Pi^{(a)}/\Pi^{(b)}$ (Def. Definition 10.2) on the right/left of $\hat{\mathbf{G}}_\Lambda$; these idempotents commute with the symmetry projectors and the typed layer on the realized weave configuration (Ch. 10 Definition 9.116, item (P7)), so each $(a\to b)$ block vanishes under the same mismatch condition. □

Remark 10.127 (When selection rules can be violated)**.** If a background or the boundary machine breaks a symmetry, the corresponding commutation with $\hat{\mathbf{G}}_\Lambda$ fails (e.g. $\mathcal{P}$–, helicity–, or CP–violation). The same typed formalism applies, and the magnitude of violation is

quantified by the norms of the previously forbidden off–diagonal typed blocks (e.g. parity–odd mass in a parity–even channel, helicity cross–terms TT $+2 \leftrightarrow -2$, or rad$+ \leftrightarrow$ rad$-$). Operationally, these appear as diagnostics already tracked in the meters: CK vector parity asymmetry Δ_P (Definition 10.58) and Higgs CP asymmetry $\Delta_{\mathrm{CP}}^{(a)}$ (Definition 10.51); when they exceed bounds, automatic triggers fire (Def. Definition 10.108, Cor. Corollary 10.91) and the Audit path proceeds per §10.10.

10.11.4 Stability Bounds: Mixing Norms vs. Visibility Changes

Definition 10.128 (Typed mixing norm)**.** For a typed channel $[\chi] \leftrightarrow [\chi']$ and triads $a, b \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$, let

$$\hat{\mathbf{G}}_\Lambda^{(a\to b)\,[\chi\to\chi']} := \mathsf{P}_{\mathrm{phys}}\,\Pi^{(b)}\,\Pi^{[\chi']}\,\hat{\mathbf{G}}_\Lambda\,\Pi^{[\chi]}\,\Pi^{(a)}\,\mathsf{P}_{\mathrm{phys}}$$

(typed insertion; Definition 10.113, (10.61)).

The *triad-resolved mixing norm* is

$$\mu_{[\chi\to\chi']}^{(a\to b)} := \left\|\hat{\mathbf{G}}_\Lambda^{(a\to b)\,[\chi\to\chi']}\right\|_{\mathcal{I}}, \tag{10.66}$$

where $\|\cdot\|_{\mathcal{I}}$ is the band-invariant operator norm on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (realized weave configuration hygiene: Proposition 10.10). We also use the aggregated norms

$$\mu_{[\chi\to\chi']} := \Big(\sum_{a,b}\big(\mu_{[\chi\to\chi']}^{(a\to b)}\big)^2\Big)^{1/2}, \qquad \mu_{[\chi\to\chi']}^{(\mathrm{ns})} := \Big(\sum_{a\in\{\mathrm{vac},\mathrm{corr}\},\,b}\big(\mu_{[\chi\to\chi']}^{(a\to b)}\big)^2\Big)^{1/2}$$

for total and *non-spectral* (vac/corr-sourced) mixing, respectively.

Remark 10.129 (Well-posedness, safety, and trivial zeros)**.** All blocks in (10.66) are bounded on $\mathcal{I}^{[\mathscr{S}]}$ by Proposition 10.10; the definition is therefore well-posed. Typed/triad idempotents commute on the realized weave configuration (typed stability: Ch. 10 Definition 9.116, item (P7)). If a channel is symmetry-forbidden, the corresponding block vanishes (selection rules: Proposition 10.126). In particular, any block that would induce TT from a τ insertion is zero by TT–null preservation (Lemma 10.123), so $\mu_{[X\to\mathrm{TT}]}^{(a\to b)} = \mu_{[\mathrm{TT}\to X]}^{(a\to b)} = 0$ for $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$.

Proposition 10.130 (Stability bounds: visibilities vs. mixing norms)**.** *Let* $\mathbf{L}^{[\mathscr{S};\chi]}$ *and* $\mathbf{V}^{[\mathscr{S};\chi]}$ *be the calibrated law/state vectors and* $\Lambda_{\mathrm{law/state}}^{[\mathscr{S};\chi]}$ *the corresponding visibilities of Definition 10.82 and eq. (10.54). Consider a perturbation of the typed correlator by a single channel block* $\Delta\hat{\mathbf{G}} = \hat{\mathbf{G}}_\Lambda^{(a\to b)\,[\chi\to\chi']}$ *with norm* $\mu := \mu_{[\chi\to\chi']}^{(a\to b)}$*. Then there exist realized weave configuration-dependent constants* $K_{j,(a\to b)}^{\mathrm{law}}$, $K_{m,(a\to b)}^{\mathrm{state}}$ *(independent of* μ*) such that*

$$\left|\Delta R_j^{[\mathscr{S};\chi]}\right| \le K_{j,(a\to b)}^{\mathrm{law}}\,\mu, \qquad \left|\Delta S_m^{[\mathscr{S};\chi]}\right| \le K_{m,(a\to b)}^{\mathrm{state}}\,\mu,$$

and, using the calibrations $f_j(x) = e^{-\alpha_j x}$ *and* $g_m(x) = \frac{x}{1+\beta_m x}$ *(Definition 10.82),*

$$\left\|\Delta\mathbf{L}^{[\mathscr{S};\chi]}\right\| \le \left(\sum_j \alpha_j^2 \left(K^{\text{law}}_{j,(a\to b)}\right)^2\right)^{1/2} \mu,$$
$$\left\|\Delta\mathbf{V}^{[\mathscr{S};\chi]}\right\| \le \left(\sum_m \left(K^{\text{state}}_{m,(a\to b)}\right)^2\right)^{1/2} \mu,$$

and hence the visibility changes satisfy a Lipschitz bound

$$\left|\Delta\Lambda^{[\mathscr{S};\chi]}_{\text{law}}\right| \le C_{\text{law},(a\to b)}\,\mu, \qquad \left|\Delta\Lambda^{[\mathscr{S};\chi]}_{\text{state}}\right| \le C_{\text{state},(a\to b)}\,\mu, \tag{10.67}$$

with constants $C_{\text{law/state},(a\to b)}$ *determined by the above bounds and the cosine aggregation in* (10.54).

Proof. Each law residual R_j (Definition 10.80, (10.51)) and state feature S_m ((10.52)) is a realized weave configuration-norm of a *linear* map (commutator with BRST charge, divergences, traces, typed spectral densities, and triad projections) applied to the typed observable/correlator on $\mathcal{H}_{\text{phys}}$. By submultiplicativity of $\|\cdot\|_{\mathcal{I}}$ and boundedness of projectors/derivatives on $\mathcal{I}^{[\mathscr{S}]}$ (Proposition 10.10), perturbing by a single channel block of norm μ shifts each R_j, S_m by at most a constant times μ, yielding the stated K's. For the calibrated entries, $|f_j'(x)| = \alpha_j e^{-\alpha_j x} \le \alpha_j$ and $|g_m'(x)| = \frac{1}{(1+\beta_m x)^2} \le 1$, so $|f_j(x+\delta) - f_j(x)| \le \alpha_j|\delta|$, $|g_m(x+\delta) - g_m(x)| \le |\delta|$. Summing in quadrature gives the $\|\Delta\mathbf{L}\|$ and $\|\Delta\mathbf{V}\|$ bounds. Finally, Λ is a smooth function of its vector argument via the cosine with $\mathbf{1}$ (Definition 10.82, (10.54)), so perturbations are Lipschitz with constants depending on the baseline norms of $\mathbf{L}, \mathbf{V}$ and $\mathbf{1}$; composing the previous bounds yields (10.67). □

Corollary 10.131 (Monotone effects on mixing norms under audit moves)**.** *Under the audit moves of Definition 10.101:*

(i) IR tightening
IR tightening weakly decreases non-spectral mixing $\mu^{(\text{ns})}_{[\chi\to\chi']}$ *(coherence/vacuum suppression; Lemma 10.102, item (1)).*

(ii) Arena switch (boundary → bulk)
A boundary to bulk arena switch weakly decreases coherence-dominated mixing (Lemma 10.102, item (2)).

(iii) Spectral window refinement
Spectral window refinement weakly decreases off-band mixing while preserving certified features (Lemma 10.102, item (3), KL positivity eq. (7.12)).

Combining with (10.67)*, these moves weakly improve the visibilities whenever mixing is the sole cause of their degradation.*

Proof. Recall the typed, triad-resolved insertion (Def. Definition 10.113, (10.61))

$$\hat{\mathbf{G}}^{(a\to b)\,[\chi\to\chi']}_{\Lambda} = \mathsf{P}_{\text{phys}}\,\Pi^{(b)}\,\Pi^{[\chi']}\,\hat{\mathbf{G}}_{\Lambda}\,\Pi^{[\chi]}\,\Pi^{(a)}\,\mathsf{P}_{\text{phys}},$$

and the mixing norm (Def. Definition 10.128, (10.66)) $\mu^{(a\to b)}_{[\chi\to\chi']} = \big\|\hat{\mathbf{G}}^{(a\to b)\,[\chi\to\chi']}_{\Lambda}\big\|_{\mathcal{I}}$. All operators act on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ and enjoy BRST/band safety and boundedness (Proposition 10.10). We argue item-wise.

(i) IR tightening. Let $r \mapsto r'$ denote a tightening step (Ch. 8 IR window/band functor; Definitions 6.280 and 7.29). On the realized weave configuration there exist channelwise contractions (Schur multipliers/filters) $\mathcal{T}^{(a)}_{r\to r'}$ with

$$\|\mathcal{T}^{(\mathrm{vac})}_{r\to r'}\|_{\mathcal{I}} \le 1, \quad \|\mathcal{T}^{(\mathrm{corr})}_{r\to r'}\|_{\mathcal{I}} \le 1, \quad \|\mathcal{T}^{(\mathrm{spec})}_{r\to r'}\|_{\mathcal{I}} = 1,$$

and, functorially, the tightened correlator block factors as

$$\hat{\mathbf{G}}^{(a\to b)}_{\Lambda}(r') = \mathsf{P}_{\mathrm{phys}}\,\Pi^{(b)}\,\mathcal{T}^{(b)}_{r\to r'}\,\Pi^{[\chi']}\,\hat{\mathbf{G}}_{\Lambda}(r)\,\Pi^{[\chi]}\,\mathcal{T}^{(a)}_{r\to r'}\,\Pi^{(a)}\,\mathsf{P}_{\mathrm{phys}},$$

with commutation on the realized weave configuration (typed stability; Ch. 10 Definition 9.116, item (P7)). By submultiplicativity of $\|\cdot\|_{\mathcal{I}}$,

$$\mu^{(a\to b)}_{[\chi\to\chi']}(r') \;\le\; \|\mathcal{T}^{(b)}_{r\to r'}\|_{\mathcal{I}}\;\mu^{(a\to b)}_{[\chi\to\chi']}(r)\;\|\mathcal{T}^{(a)}_{r\to r'}\|_{\mathcal{I}}.$$

Hence $\mu^{(a\to b)}$ is nonincreasing whenever a or b is non-spectral (vac or corr), which yields the stated decrease for the aggregated non-spectral norm $\mu^{(\mathrm{ns})}$. If the tightened window removes positive spectral measure carrying the non-spectral part (KL positivity eq. (7.12)), at least one of the contractions is *strict* and the corresponding block strictly decreases (cf. Lemma 10.102, item (1)).

(ii) Arena switch (boundary→bulk). Let $\mathfrak{P}$: bdry $\to$ bulk be the arena move (Definition 10.101). By the bulk/boundary comparison (Lemma 10.102, item (2)), the bulk machine implements a coherence-suppressing contraction $\mathcal{B}^{(\mathrm{corr})}$ (with $\|\mathcal{B}^{(\mathrm{corr})}\|_{\mathcal{I}} \le 1$) and leaves spectral content unchanged (isometry on the certified band). Thus for any coherence-dominated block (i.e. with $a = \mathrm{corr}$ or $b = \mathrm{corr}$),

$$\mu^{(a\to b)}_{[\chi\to\chi']}(\mathrm{bulk}) \;\le\; \|\mathcal{B}^{(b)}\|_{\mathcal{I}}\;\mu^{(a\to b)}_{[\chi\to\chi']}(\mathrm{bdry})\;\|\mathcal{B}^{(a)}\|_{\mathcal{I}} \;\le\; \mu^{(a\to b)}_{[\chi\to\chi']}(\mathrm{bdry}).$$

If coherence has positive measure on the region affected by the switch, the inequality is strict (ibid.).

(iii) Spectral window refinement. Let $W_{\mathrm{spec}} \mapsto W'_{\mathrm{spec}} \subset W_{\mathrm{spec}}$ (Def. 10.101). The refinement acts by pre/post multiplication with the orthogonal spectral projector $\Pi_{W'_{\mathrm{spec}}}$ inside (10.61). Since $\|\Pi_{W'_{\mathrm{spec}}}\|_{\mathcal{I}} \le 1$ and $\Pi_{W'_{\mathrm{spec}}}\Pi_{W_{\mathrm{spec}}} = \Pi_{W'_{\mathrm{spec}}}$, we get

$$\mu^{(a\to b)}_{[\chi\to\chi']}(W'_{\mathrm{spec}}) \;\le\; \mu^{(a\to b)}_{[\chi\to\chi']}(W_{\mathrm{spec}}).$$

If off-band leakage with positive spectral measure is excised, the decrease is strict (KL positivity eq. (7.12); Lemma 10.102, item (iii)).

Visibilities. When mixing is the sole cause of visibility degradation, the Lipschitz bounds (10.67) (Prop. 10.130) together with the inequalities above imply that each move weakly *improves* (or leaves unchanged) $\Lambda^{[\mathcal{S};\chi]}_{\mathrm{law/state}}$, with strict improvement when a strict contraction occurs on a set of positive spectral measure.

All steps are within $\mathcal{I}^{[\mathcal{S}]}$ and preserve BRST/gauge hygiene by Proposition 10.10. □

Proposition 10.132 (Resolvent/Davis–Kahan type bound for visibilities)**.** *Let $\Lambda_\bullet^{[\mathscr{S};\chi]}$ be any visibility for type $[\chi]$ built as in Definition 10.82 and eq. (10.54) on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1). Assume the* unmixed *diagonal typed block $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]}$ (Def. Definition 10.113, (10.61)) admits a spectral gap $\Delta > 0$ around its certified feature (Riesz contour contained in the gap). Then for sufficiently small mixing norm μ (e.g. the aggregated channel norm from Definition 10.128),*

$$\left|\Lambda_\bullet^{[\mathscr{S};\chi]} - \Lambda_\bullet^{[\mathscr{S};\chi]}\big|_{\text{no-mix}}\right| \;\le\; C_\bullet\,\frac{\mu}{\Delta} \;+\; O\!\left(\frac{\mu^2}{\Delta^2}\right), \tag{10.68}$$

with a rig–dependent constant $C_\bullet > 0$. Here $|_{\text{no-mix}}$ denotes the visibility with the off–diagonal typed channels $[\chi] \leftrightarrow [\chi']$ suppressed.

Proof. Work on $\mathcal{H}_{[\chi]\oplus[\chi']} := \mathcal{H}_{[\chi]} \oplus \mathcal{H}_{[\chi']}$ equipped with the orthogonal sum inner product (see §10.11.1). Write the typed, block–decomposed correlator (Def. Definition 10.113)

$$\mathcal{G} = \begin{pmatrix} \hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]} & \hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']} \\ \hat{\mathbf{G}}_\Lambda^{[\chi'\to\chi]} & \hat{\mathbf{G}}_\Lambda^{[\chi'\to\chi']} \end{pmatrix} \;=:\; \mathcal{G}_0 + \mathcal{V},$$

with the *unmixed* part $\mathcal{G}_0 := \operatorname{diag}\!\big(\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]}, \hat{\mathbf{G}}_\Lambda^{[\chi'\to\chi']}\big)$ and the off–diagonal mixing $\mathcal{V} := \left[\begin{smallmatrix} 0 & \hat{\mathbf{G}}_\Lambda^{[\chi\to\chi']} \\ \hat{\mathbf{G}}_\Lambda^{[\chi'\to\chi]} & 0 \end{smallmatrix}\right]$. Let $\mu := \|\mathcal{V}\|_{\mathcal{I}}$; by Definition 10.128 one may take $\mu \le c\,\mu_{[\chi\to\chi']}$ for some realized weave configuration constant $c > 0$ that aggregates the $(a\to b)$ blocks.

By the gap hypothesis, there is a contour Γ enclosing the certified feature of $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]}$ and no other spectrum of $\mathcal{G}_0$, with $\operatorname{dist}(\Gamma, \sigma(\mathcal{G}_0 \setminus \text{feat})) = \Delta$. Let P_0 be the corresponding Riesz projector of $\mathcal{G}_0$ onto $\mathcal{H}_{[\chi]}$ (it equals the fixed typed/triad spectral idempotent used for the certified band; cf. Definition 10.2 and the Riesz usage in Lemma 10.103). Let P be the Riesz projector of $\mathcal{G}$ associated to the image of the same contour under the perturbed resolvent.

Kato's resolvent identity yields (on $\mathcal{I}^{[\mathscr{S}]}$, using Proposition 10.10 for boundedness/BRST safety)

$$P - P_0 = \frac{1}{2\pi i}\oint_\Gamma (\zeta - \mathcal{G})^{-1}\,\mathcal{V}\,(\zeta - \mathcal{G}_0)^{-1}\,d\zeta,$$

hence $\|P - P_0\|_{\mathcal{I}} \;\le\; \frac{1}{2\pi}\,|\Gamma|\,\sup_{\zeta\in\Gamma}\|(\zeta-\mathcal{G})^{-1}\|_{\mathcal{I}}\,\|\mathcal{V}\|_{\mathcal{I}}\,\|(\zeta-\mathcal{G}_0)^{-1}\|_{\mathcal{I}} = O\!\big(\mu/\Delta\big)$, since both resolvents are $O(1/\Delta)$ on Γ for μ small enough (standard Neumann–series control). Equivalently, by the Davis–Kahan $\sin\Theta$ theorem for invariant subspaces, $\|P - P_0\|_{\mathcal{I}} \;\le\; C\,\mu/\Delta$ for some numerical C depending only on the contour geometry.

The typed observables entering the meters are linear functionals of the projected correlator, built from P (or P_0) and the fixed typed/triad idempotents (Defs. Definitions 10.80 and 10.82); hence the underlying ledger entries (R_j, S_m) change by at most $K\,\|P - P_0\|_{\mathcal{I}}$ for rig–dependent $K > 0$ (bounded operator calculus on $\mathcal{I}^{[\mathscr{S}]}$, Proposition 10.10). Applying the calibrations $f_j(x) = e^{-\alpha_j x}$ and $g_m(x) = \frac{x}{1+\beta_m x}$ (Lipschitz on $\mathbb{R}_+$ with constants α_j and 1, respectively; Definition 10.82) and the cosine aggregation (Definition 10.82 and eq. (10.54)) gives—exactly as in Proposition 10.130—that the visibility perturbations are Lipschitz in the underlying projected objects. Composing these bounds yields

$$\left|\Lambda_\bullet^{[\mathscr{S};\chi]} - \Lambda_\bullet^{[\mathscr{S};\chi]}|_{\text{no-mix}}\right| \;\le\; C_\bullet\,\|P - P_0\|_{\mathcal{I}} \;\le\; C'_\bullet\,\frac{\mu}{\Delta},$$

for a rig–dependent $C'_\bullet > 0$. The $O(\mu^2/\Delta^2)$ remainder follows from the second–order term in the resolvent expansion (or from the refined Davis–Kahan estimates when the graph distance is small). All steps occur on $\mathcal{H}_{\text{phys}}$ and respect BRST/gauge and band safety by Proposition 10.10. □

Corollary 10.133 (Weak–mixing robustness of visibilities and onsets (gap–controlled))**.** *Fix a sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$, an admitted type $[\chi]$, and a triad $a \in \{\text{spec}, \text{vac}, \text{corr}\}$. Let $\Delta > 0$ be the certified spectral gap of the diagonal typed block for $[\chi]$ on the band (Prop. Proposition 10.132). Assume that, at some configuration (or along an admissible audit path), the* unmixed *visibilities exceed thresholds with margins*

$$\eta_L := \Lambda_{\text{law}}^{[\mathscr{S};\chi]} - \theta_{\text{law}} > 0, \qquad \eta_S := \Lambda_{\text{state}}^{[\mathscr{S};\chi]} - \theta_{\text{state}} > 0,$$

and let $\mu_*^{(a\to a)}$ be a mixing–norm bound for all off–diagonal channels into/out of $[\chi]$ on triad a:

$$\mu_*^{(a\to a)} \;\geq\; \Big\| \sum_{\chi' \neq \chi} \hat{\mathbf{G}}_\Lambda^{(a\to a)\,[\chi\to\chi']} \Big\|_{\mathcal{I}} \quad \textit{(e.g. the sum of norms; Def. Definition 10.128).}$$

If, uniformly after *each admissible move (or equivalently as a pathwise supremum),*

$$\frac{\mu_*^{(a\to a)}}{\Delta} \;<\; \min\Big\{ \frac{\eta_L}{C_{\text{law}}},\; \frac{\eta_S}{C_{\text{state}}} \Big\}, \tag{10.69}$$

where $C_{\text{law}}, C_{\text{state}}$ are the rig–dependent constants from (10.68) (Prop. Proposition 10.132), then:

(i) The visibilities remain above thresholds along the entire admissible path: $\Lambda_{\text{law}}^{[\mathscr{S};\chi]} \geq \theta_{\text{law}}$, $\Lambda_{\text{state}}^{[\mathscr{S};\chi]} \geq \theta_{\text{state}}$.

(ii) The certified onset $r^\star[\chi]$ (Def. Definition 10.85) is unchanged by the mixing, and, in particular, is stable *under IR tightening, spectral refinement, and arena switches (Defs. Definition 10.101, Lemmas 10.102 and 10.137 and Corollary 10.131).*

Proof. By the Davis–Kahan/Kato visibility bound (Prop. 10.132, (10.68)), for any single channel $[\chi] \leftrightarrow [\chi']$ one has

$$\big|\Delta\Lambda_\bullet^{[\mathscr{S};\chi]}\big| \;\leq\; C_\bullet \frac{\mu_{[\chi\to\chi']}^{(a\to a)}}{\Delta} \;+\; O\Big((\mu/\Delta)^2\Big), \qquad \bullet \in \{\text{law}, \text{state}\}.$$

Summing over $\chi' \neq \chi$ and using the triangle inequality (or the definition of $\mu_*^{(a\to a)}$), we get

$$\big|\Delta\Lambda_\bullet^{[\mathscr{S};\chi]}\big| \;\leq\; C_\bullet \frac{\mu_*^{(a\to a)}}{\Delta} \;+\; O\Big((\mu_*/\Delta)^2\Big).$$

Condition (10.69) ensures that the first–order term is strictly below the respective margin $\eta_\bullet$, so the post–move visibilities remain above their thresholds. This proves item (1).

For item (2), apply the same bound at $r^\star[\chi]$ and invoke the onset–stability radius from Proposition 10.88: the gap-controlled visibility variation is strictly smaller than the margin

to threshold, so the infimum defining $r^\star[\chi]$ does not change. Along admissible audit paths, Δ is arena–invariant (Lemma 10.137) and $\mu_*^{(a\to a)}$ weakly decreases under IR tightening and spectral refinement, and decreases under boundary→bulk when coherence dominates (Lemma 10.102, Cor. 10.131). Thus (10.69) remains valid along the path, yielding pathwise stability of the onset. All steps are on the realized weave configuration and respect BRST/band hygiene (Prop. 10.10); TT–null preservation of τ–types (Lemma 10.123 and Corollary 10.125) guarantees no spurious TT creation in $\Phi\Phi$ when τ mixing is present. □

Corollary 10.134 (Robustness of onsets under weak mixing)**.** *Let $r^\star[\chi]$ be the certified onset for type $[\chi]$ (Def. Definition 10.85), with stability radius $\rho[\chi]$ from Proposition 10.88. Write the* margins at onset

$$\eta_L := \Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r^\star[\chi]) - \theta_{\mathrm{law}}, \qquad \eta_S := \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r^\star[\chi]) - \theta_{\mathrm{state}},$$

both nonnegative, and let $\Delta > 0$ be the spectral gap for the certified feature of the diagonal typed block $\hat{\mathbf{G}}_\Lambda^{[\chi\to\chi]}$ (Riesz contour; Definition 10.113). If a mixing channel $[\chi] \leftrightarrow [\chi']$ has aggregated norm μ (Def. Definition 10.128) such that

$$\frac{\mu}{\Delta} \;<\; \min\Big\{\frac{\eta_L}{C_{\mathrm{law}}},\; \frac{\eta_S}{C_{\mathrm{state}}}\Big\}, \tag{10.70}$$

where $C_{\mathrm{law}}, C_{\mathrm{state}} > 0$ are the realized weave configuration-dependent constants from Proposition 10.132, then the certified onset is unchanged by the mixing: $r^\star[\chi]$ remains the onset after turning on $[\chi] \leftrightarrow [\chi']$. Equivalently, $\Lambda_{\mathrm{law/state}}^{[\mathscr{S};\chi]}(r^\star[\chi])$ stay above thresholds after mixing, and no earlier $r < r^\star[\chi]$ attains admission.

Proof. By the gap–perturbation bound (10.68) in Proposition 10.132,

$$\big|\Delta\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}\big| \le C_{\mathrm{law}}\frac{\mu}{\Delta} + O\big((\mu/\Delta)^2\big), \qquad \big|\Delta\Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}\big| \le C_{\mathrm{state}}\frac{\mu}{\Delta} + O\big((\mu/\Delta)^2\big).$$

For μ/Δ small, the quadratic remainder is dominated by halving the linear margin; the sufficient condition (10.70) guarantees

$$\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}(r^\star[\chi]) \ge \theta_{\mathrm{law}}, \quad \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}(r^\star[\chi]) \ge \theta_{\mathrm{state}}$$

after mixing. Thus $r^\star[\chi] \in \mathcal{A}_{[\chi]}$ (Def. Definition 10.85) still holds with mixing on.

It remains to rule out an earlier onset $\tilde{r} < r^\star[\chi]$. By Proposition 10.88, for $r < r^\star[\chi]$ the unmet threshold(s) have one–sided slope bounds $m_{\mathrm{law}}, m_{\mathrm{state}} > 0$; hence the deficit at r is at least $\min\{m_{\mathrm{law}}, m_{\mathrm{state}}\}\,(r^\star[\chi] - r)$. By (10.68), mixing lifts visibilities by at most $C_\bullet(\mu/\Delta)$, which cannot close this deficit for any $r \le r^\star[\chi] - \rho[\chi]$ if (10.70) holds (use the definition of $\rho[\chi]$ in Proposition 10.88 and that $C_\bullet(\mu/\Delta) < \eta_\bullet$). Therefore no $r < r^\star[\chi]$ reaches both thresholds under mixing, so the onset remains $r^\star[\chi]$ by uniqueness (part (1) of Proposition 10.88). All steps occur on $\mathcal{I}^{[\mathscr{S}]}$ and respect BRST/band safety (Proposition 10.10). □

Summary of the weave analysis. Typed insertions (10.61) give channel- and triad-resolved correlators on the realized weave configuration. The $\bar{\Sigma}$–weighted generalized eigen framework (§10.11.1, (10.63), (10.64)) quantifies mixing. TT–null is preserved for any τ–involving channel (Lemma 10.123), while symmetry selection rules (Proposition 10.126) kill forbidden typed pairs. Mixing impacts the calibrated visibilities *Lipschitzly* in the mixing norm (Prop. 10.130) and, with a band gap, admits the Davis–Kahan/Kato control (10.68) (Prop. 10.132). Consequently, Parasymmetric TLO decisions (type, location, onset) are robust: weak, gapped inter-modal mixing cannot shift the certified onset (Cor. 10.134) and audit moves monotonically suppress adverse mixing channels (Corollary 10.131), ensuring stable, falsifiable outcomes within SynTh/Audit.

10.12 Triad-Resolved Reporting with Boundary vs. Bulk Provenance

We finalize Step (7) by specifying a formal *reporting schema* for typed, triad-resolved outcomes with location provenance (bulk vs. boundary), and by preparing a *Boundary–vs–Bulk Invariance* statement: under admissible retunes, a bulk spectral claim cannot be created by boundary coherence alone (proved in §10.12.3). All objects live on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ (Def. Definition 10.1); triads and typed insertions are as in Definitions 10.2 and 10.113.

10.12.1 Schema and Macros for Weave Reports

Definition 10.135 (Weave report tuple)**.** Fix a sector $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$, an admitted type $[\chi]$ (e.g. TT, $S^{(b)}$, $S^{(L)}$, $\tilde{S}^{(p)}$, $A^{(\pm)}$, rad$\pm$; see Definitions 10.3 to 10.5), a triad $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Def. Definition 10.2), and a location $\mathrm{Loc} \in \{\mathrm{bulk}, \mathrm{boundary}\}$ (arena of Definition 10.101). The *report tuple* is

$$\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc})} := \Big(a,\ [\chi],\ \mathrm{Loc}\ ;\ \Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}},\ \Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}},\ r^{\star}[\chi]\Big),$$

where the calibrated visibilities $\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law/state}}$ are defined in Definition 10.82 and eq. (10.54) using the ledgers of Definition 10.80 and Remark 10.81, and the certified onset $r^{\star}[\chi]$ is from Definition 10.85 (uniqueness/stability in Proposition 10.88). The witnesses/meters this summarizes are those built in Section 10.9.

Definition 10.136 (Certified weave claim)**.** Fix thresholds $(\theta_{\mathrm{law}}, \theta_{\mathrm{state}}) \in (0,1)^2$. A tuple $\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc})}$ is a *certified claim* if

$$\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}} \geq \theta_{\mathrm{law}}, \qquad \Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}} \geq \theta_{\mathrm{state}},$$

and all applicable diagnostics are below their audit bounds:

$$\begin{aligned} \varepsilon &\leq \varepsilon_{\max} && \text{(graviton TT leak; Definition 10.32)},\\ |\Delta_P| &\leq \delta_P && \text{(CK parity; Definition 10.58)},\\ |\Delta^{(a)}_{\mathrm{CP}}| &\leq \delta_{\mathrm{CP}} && \text{(Higgs CP; Definition 10.51)}. \end{aligned}$$

with automatic trigger policy per Definition 10.108 and Corollary 10.91. When these hold, Law/State are co-tenable for $(\mathscr{S}, [\chi])$ at the reported triad/location (§10.10, Definition 10.99).

What the report tuple is summarizing. The tuple of Definition 10.135 is a compact, standardized payload that answers two questions at once: *where* in the weave a statement lives, and *how strong* that statement is. The "where'' fields $(a, [\chi], \mathrm{Loc})$ pin down the provenance triad $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2), the admitted type $[\chi]$ (e.g. TT, τ–scalar, Higgs–CP; Definitions 10.3 to 10.5), and the arena $\mathrm{Loc} \in \{\mathrm{bulk}, \mathrm{boundary}\}$ used in audit moves (Definition 10.101). The "how strong'' fields are the *calibrated visibilities* $\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law/state}}$ computed from the Law/State ledgers via the cosine meters (Definitions 10.80 and 10.82 and eq. (10.54)), and the unique onset $r^\star[\chi]$ that marks the minimal tightening at which law and state become co-tenable (Definition 10.85, Proposition 10.88, and Lemma 10.86). Because these objects are evaluated on the realized weave configuration and physical carrier, they inherit band/BRST hygiene and order-of-operations robustness (Definition 10.1 and Propositions 10.9 and 10.10); finiteness is guaranteed by Lemma 10.83. In practice, the tuple is the row you place in a table or the point you plot when comparing TT, τ–scalar, or Higgs–CP channels across sectors $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ (witness construction in Section 10.9).

When a tuple becomes a certified claim. Definition 10.136 turns a report into a *decision*. Given thresholds $(\theta_{\mathrm{law}}, \theta_{\mathrm{state}})$, a tuple is certified when both visibilities clear their bars and all applicable diagnostics are inside their audit bounds: TT-leak ε for the graviton TT sector (Definition 10.32), vector parity asymmetry Δ_P for CK vectors (Definition 10.58), and scalar CP asymmetry $\Delta^{(a)}_{\mathrm{CP}}$ in each provenance a for Higgs-like scalars (Definition 10.51). The bound values are governed by the automatic-trigger policy (Definition 10.95 and Corollary 10.91). When these conditions hold, Law/State are *co-tenable* for $(\mathscr{S}, [\chi])$ at the specified triad/location (§10.10, Definition 10.99); if not, the automatic triggers and audit path of Definition 10.95 prescribe a monotone, terminating retune to either reach the unique onset $r^\star[\chi]$ or to produce a certified failure certificate. In short, the schema provides a minimal, reproducible interface for reporting, comparing, and certifying results across the weave.

10.12.2 Arena-Invariant Spectral Set and Typed Stability

Lemma 10.137 (Arena-invariant certified spectral set)**.** *Let the certified band and contour families $\{\gamma_i\}_{(2)}, \{\Gamma_j\}_{(0)}, \{\zeta_m\}_{(1)}$ be fixed by the band tags P_x (Def. Definition 10.1; Riesz selectors Definition 10.7). Under an arena switch* bulk $\leftrightarrow$ boundary *(Def. Definition 10.101), these contour families—and hence the associated Riesz projectors—remain admissible and unchanged. Consequently, the presence/absence of spectral poles/bands on the certified set is* arena-invariant.

Proof. **Step 1: Fixed selectors and realized weave configuration.** The band tags P_x determine (i) the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ and (ii) the Riesz contours $\{\gamma_i\}_{(2)}, \{\Gamma_j\}_{(0)}, \{\zeta_m\}_{(1)}$ that enclose the certified spectral sets for spin $2, 0, 1$ respectively (Def. Definitions 10.1 and 10.7). All operators below are evaluated on $\mathcal{I}^{[\mathscr{S}]}$ and inherit BRST/gauge safety and band admissibility (bounded resolvents on the selected contours) by Proposition 10.10.

Step 2: Arena switch as an admissible homotopy. An arena switch bdry $\to$ bulk is an admissible audit move (Def. Definition 10.101). Hence there exists a norm–continuous path of certified operators $\{\hat{\mathbf{G}}_\Lambda(t)\}_{t\in[0,1]}$ on $\mathcal{I}^{[\mathscr{S}]}$ with $\hat{\mathbf{G}}_\Lambda(0) = \hat{\mathbf{G}}_\Lambda^{(\mathrm{bdry})}$, $\hat{\mathbf{G}}_\Lambda(1) = \hat{\mathbf{G}}_\Lambda^{(\mathrm{bulk})}$, such that for every fixed selector contour Γ from $\{\gamma_i, \Gamma_j, \zeta_m\}$, the resolvent set condition holds uniformly:

$$\Gamma \subset \rho\big(\hat{\mathbf{G}}_\Lambda(t)\big) \quad \text{and} \quad \sup_{\zeta\in\Gamma,\, t\in[0,1]} \big\|(\zeta - \hat{\mathbf{G}}_\Lambda(t))^{-1}\big\|_{\mathcal{I}} < \infty.$$

This is exactly the "admissibility" preservation guaranteed by realized weave configuration hygiene (Proposition 10.10) and the bulk/boundary comparison that leaves the certified *spectral* content unchanged while only affecting coherence (cf. Lemma 10.102, item (ii)).

Step 3: Riesz projectors are homotopy-invariant. For any such contour Γ, define the (typed/triad-suppressed) Riesz projector

$$\mathsf{P}_\Gamma(t) \;:=\; \frac{1}{2\pi i}\oint_\Gamma (\zeta - \hat{\mathbf{G}}_\Lambda(t))^{-1}\, d\zeta.$$

By the uniform resolvent bound along the path, $t \mapsto \mathsf{P}_\Gamma(t)$ is norm–continuous; moreover, the spectral mapping theorem for contour integrals implies $\mathsf{P}_\Gamma(t)$ is *constant in* t as long as Γ lies in the resolvent set for all t (standard homotopy invariance of the Riesz projection). Therefore $\mathsf{P}_\Gamma^{(\mathrm{bulk})} = \mathsf{P}_\Gamma^{(\mathrm{bdry})}$.

Step 4: Typed/triad refinement and conclusion. Typed and triad idempotents commute on the realized weave configuration and are stable under admissible retunings (Ch. 10: Definition 9.116, item (P7); triads Definition 10.2). Hence the typed/triad–refined spectral projectors (obtained by sandwiching P_Γ with the typed/triad idempotents; cf. Definition 10.113) are likewise invariant under the arena switch. Consequently, the presence/absence of spectral poles/bands *on the certified set*—equivalently, whether the corresponding Riesz projector is zero or nonzero—does not depend on the arena. (As used elsewhere, audit moves may suppress vac/corr features or off–band leakage, but they cannot create a new certified–band pole by admissibility and KL positivity; see Lemma 10.102 and eq. (7.12).) □

Lemma 10.138 (Typed spectral vacuum)**.** *Fix a type* $[\chi]$ *and a location*

$$\mathrm{Loc} \in \{\mathrm{bulk}, \mathrm{boundary}\}.$$

Assume that for every admissible spectral window W_{spec} *one has*

$$S_1^{[\chi]}(W_{\mathrm{spec}}) = 0, \tag{10.71}$$

where S_1 *is the spectral feature of* (10.52) *(see Definition 10.80) and admissibility of* W_{spec} *is as in Definition 7.665. Then the typed spectral projector onto the spin-s certified set annihilates the observable:*

$$\mathsf{P}_{\mathrm{spec}}^{(s)}\, \Pi^{[\chi]}\, \mathcal{O} = 0. \tag{10.72}$$

Here $\mathsf{P}_{\mathrm{spec}}^{(s)}$ *is the Riesz projector determined by the fixed contour family (Riesz selectors; Definition 10.7), and* $\Pi^{[\chi]}$ *is the typed projector (Ch. 10: Definition 9.116; see also Definitions 10.3 to 10.5).*

Proof. By (10.52), the spectral feature is

$$S_1^{[\chi]}(W_{\text{spec}}) \;=\; \int W_{\text{spec}}(\omega,\mathbf{k})\;\rho_{(s)}^{[\chi]}(\omega,\mathbf{k})\,d\mu(\omega,\mathbf{k}),$$

where $\rho_{(s)}^{[\chi]} \geq 0$ is the (KL-positive) typed spectral density on the certified band (KL positivity eq. (7.12)), and $s \in \{2,1,0\}$ matches the carrier (TT/vector/scalar). By Ch. 8, the admissible windows form a separating cone dense in the unit ball of L^∞ over the certified spectral set (cf. Definition 7.665); hence if $S_1^{[\chi]}(W_{\text{spec}}) = 0$ for *all* admissible W_{spec}, then by density and $\rho_{(s)}^{[\chi]} \geq 0$ we must have $\rho_{(s)}^{[\chi]} = 0$ almost everywhere on the certified spectral set (standard "testing by windows"/duality argument).

Let $\mathsf{P}_{\text{spec}}^{(s)}$ be the Riesz projector specified by the fixed contour family (Definition 10.7) that encloses precisely that certified spectral set. Since $\rho_{(s)}^{[\chi]}$ vanishes a.e. on that set, the spectral measure of $\Pi^{[\chi]}\mathcal{O}$ there is zero, whence the Riesz integral yields $\mathsf{P}_{\text{spec}}^{(s)}\,\Pi^{[\chi]}\mathcal{O} = 0$ on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$. Typed/triad idempotents and the unified correlator are band-admissible and BRST/gauge-safe on the realized weave configuration (Proposition 10.10), so the argument is valid in either arena. (If desired, arena invariance of the contour/projector itself follows from Lemma 10.137.) □

Remark 10.139 (Typed stability under arena switches)**.** Typed and triad idempotents commute on the realized weave configuration and are stable under admissible retuning (Ch. 10: Definition 9.116, item (P7); triads Definition 10.2). Together with Lemma 10.137, this implies that typed spectral claims (when present) are carried identically across bulk ↔ boundary; only the vacuum/coherence content changes (cf. Lemma 10.102, item (ii)).

10.12.3 Boundary–vs–Bulk Invariance

Proposition 10.140 (Boundary–vs–Bulk Invariance for spectral claims)**.** *Fix an admitted type* $[\chi]$ *and let* $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$. *Consider an arena switch* boundary → bulk *(or vice versa; Def. Definition 10.101). Suppose that in the* boundary *arena the spectral feature entry satisfies*

$$S_1^{[\chi]} \equiv 0 \quad \textit{for all admissible windows } W_{\text{spec}}$$

(as in Eq. (10.52), Def. Definition 10.80), and any conflict is attributed to vac/corr *features (no spectral support). Then, after any finite sequence of admissible audit moves (IR tightening, spectral refinement, arena switches; Def. Definition 10.101), one cannot obtain a* certified spectral claim in bulk, *i.e.*

$$\not\exists\; \mathfrak{R}_{(\text{spec,bulk})}^{[\mathscr{S};\chi]} \quad \textit{with} \quad \Lambda_{\text{state}}^{[\mathscr{S};\chi]} \geq \theta_{\text{state}}$$

(Def. Definitions 10.135 and 10.136), unless *a new spectral pole/band* outside *the certified set appears (disallowed by admissibility; Defs. Definitions 10.1 and 10.7).*

Proof. By Lemma 10.138, the hypothesis $S_1^{[\chi]} \equiv 0$ for all admissible W_{spec} implies that the typed spectral Riesz projector annihilates the observable on the certified band: $\mathsf{P}_{\text{spec}}^{(s)}\,\Pi^{[\chi]}\,\mathcal{O} = 0$. By Lemma 10.137, the certified contour families and their Riesz projectors are *arena-invariant*; hence the same spectral projector vanishes after switching to bulk.

IR tightening and spectral window refinement are admissible audit moves (Definition 10.101) that *cannot create* new spectral poles within the fixed certified set: they act as contractions that suppress vac/corr content and excise off-band leakage while preserving certified spectral locations (KL positivity eq. (7.12) and monotonicities Lemma 10.102). Therefore $S_1^{[\chi]}$ remains identically zero on the certified set throughout any finite audit sequence that respects admissibility.

From the meter construction (Definition 10.82 and eq. (10.54)) and the ledger definition (Definition 10.80), the spectral entry $S_1 = 0$ yields the calibrated component $g_1(S_1) = 0$, so the spec contribution to $\mathbf{V}^{[\mathscr{S};\chi]}$ vanishes. With thresholds $(\theta_{\text{law}}, \theta_{\text{state}}) \in (0,1)^2$ (Def. Definition 10.136), the state visibility for a *spectral* claim cannot cross θ_{state} when its spectral component is identically zero. Hence no tuple $\mathfrak{R}^{[\mathscr{S};\chi]}_{(\text{spec,bulk})}$ can be certified unless a new spectral pole/band appears *outside* the certified set (which is excluded by the admissibility of audit moves and the fixed selectors; Defs. Definitions 10.1 and 10.7).

All steps occur on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ and preserve BRST/gauge and band safety by Proposition 10.10. □

Corollary 10.141 (No creation of TT spectral claims from τ–coherence)**.** *Fix* $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$ *and consider an arena switch* boundary → bulk *(Def. Definition 10.101). Assume in the boundary arena that the TT spectral feature is absent on the certified set,*

$$S_1^{[\mathrm{TT}]} \equiv 0 \quad \textit{for all admissible } W_{\text{spec}} \qquad (\textit{Eq. (10.52) in Definition 10.80; Ch. 8 Definition 7.665}),$$

and that any nonzero content is vac/corr *coherence attributable to τ–typed channels $X \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ (typed only; Definition 10.4). Then, after any finite sequence of admissible audit moves (IR tightening, spectral refinement, and arena switches; Definition 10.101), there is no certified TT spectral claim in bulk:*

$$\nexists\ \mathfrak{R}^{[\mathscr{S};\mathrm{TT}]}_{(\text{spec,bulk})} \quad \textit{with} \quad \Lambda^{[\mathscr{S};\mathrm{TT}]}_{\text{state}} \geq \theta_{\text{state}} \quad (\textit{Defs. Definitions 10.135 and 10.136}),$$

unless a new spectral pole/band appears outside *the certified set (disallowed by admissibility; Definitions 10.1 and 10.7).*

Proof. (1) *Typed spectral vacuum at the boundary.* From $S_1^{[\mathrm{TT}]} \equiv 0$ for all admissible W_{spec} and KL positivity (eq. (7.12)), Lemma 10.138 gives

$$\mathsf{P}^{(2)}_{\text{spec}}\, \Pi^{[\mathrm{TT}]}\, \mathcal{O} \;=\; 0 \quad \text{on the certified band,}$$

where $\mathsf{P}^{(2)}_{\text{spec}}$ is the (spin–2) Riesz projector selected by the fixed contours (Riesz selectors; Definition 10.7).

(2) *Arena invariance of the spectral set.* By Lemma 10.137, the certified contour families and their Riesz projectors are invariant under boundary ↔ bulk. Therefore the same projector vanishes in bulk: $\mathsf{P}^{(2)}_{\text{spec}}\, \Pi^{[\mathrm{TT}]}\, \mathcal{O} = 0$.

(3) *τ–mixing cannot populate TT spectral content.* For any τ–typed channel X, TT–null preservation (Lemma 10.123) gives the typed, triad–resolved identities

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \hat{\mathbf{G}}^{(a\to b)\,[X\to\mathrm{TT}]}_{\Lambda} = 0, \qquad \hat{\mathbf{G}}^{(a\to b)\,[\mathrm{TT}\to X]}_{\Lambda}\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} = 0 \quad \text{for all } a, b \in \{\text{spec}, \text{vac}, \text{corr}\}$$

(typed insertion: Definition 10.113, (10.61)). Thus off–diagonal $\tau \leftrightarrow$ TT mixing cannot generate TT spectral weight; the only possible contributor to a TT spectral claim is the diagonal TT block, already annihilated by Step (2).

(4) *Audit moves cannot create certified–band poles.* IR tightening and spectral window refinement act as contractions that suppress vac/corr and remove off–band leakage but do not create poles inside the fixed certified set (monotonicities: Lemma 10.102; KL positivity: eq. (7.12); realized weave configuration hygiene: Proposition 10.10). Therefore $S_1^{[\mathrm{TT}]}$ remains 0 on the certified band along any admissible finite audit path.

Combining (2)–(4), the TT spectral component of the calibrated state vector stays null in bulk, preventing the spectral triad visibility from crossing θ_{state}; hence no certified tuple $\mathfrak{R}^{[\mathscr{S};\mathrm{TT}]}_{(\mathrm{spec,bulk})}$ exists. The only exception would be the appearance of a new TT spectral pole outside the certified set, which is excluded by admissibility of the selectors (Definitions 10.1 and 10.7). This also recovers Prop. 10.140 as the special case $[\chi] = \mathrm{TT}$. □

10.12.4 Stability of Reported Onsets under Arena Changes and Mixing

Proposition 10.142 (Report stability under admissible moves)**.** *Let* $\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc})}$ *be a* certified *report tuple (Defs. Definitions 10.135 and 10.136) with sector* $\mathscr{S} \in \{\Phi\Phi, \Theta\Theta, \Phi\Theta\}$*, triad* $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$*, and location* $\mathrm{Loc} \in \{\mathrm{bulk}, \mathrm{boundary}\}$*. Let the law/state margins be*

$$\eta_L := \Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}} - \theta_{\mathrm{law}}, \qquad \eta_S := \Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}} - \theta_{\mathrm{state}}, \quad \eta_{L,S} > 0,$$

and let $\Delta > 0$ *be the certified band gap for the diagonal typed block (Prop. Proposition 10.132). Assume a mixing channel* $[\chi] \leftrightarrow [\chi']$ *has aggregated triad-diagonal norm* $\mu^{(a\to a)}_{[\chi\to\chi']}$ *(Def. Definition 10.128). If*

$$\frac{\mu^{(a\to a)}_{[\chi\to\chi']}}{\Delta} \;<\; \min\Big\{\frac{\eta_L}{C_{\mathrm{law}}},\; \frac{\eta_S}{C_{\mathrm{state}}}\Big\}, \tag{10.73}$$

where $C_{\mathrm{law}}, C_{\mathrm{state}}$ *are the constants in the visibility bound (Prop. Proposition 10.132,* (10.68)*), then:*

IR tightening / spectral refinement
After any admissible IR tightening or spectral window refinement (Def. Definition 10.101), the updated report $\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc})}$ *remains certified.*

Arena switch
After an admissible arena switch $\mathrm{Loc} \to \mathrm{Loc}'$ *(Def. Definition 10.101), the updated report* $\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc}')}$ *remains certified.*

Proof. Let $\Delta\Lambda_{\mathrm{law/state}}$ denote the visibility change induced by a single admissible move together with the fixed mixing channel. By the gap–controlled Davis–Kahan/Kato bound (Prop. 10.132, (10.68)),

$$\big|\Delta\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}}\big| \;\le\; C_{\mathrm{law}}\frac{\mu^{(a\to a)}_{[\chi\to\chi']}}{\Delta} + O\big((\mu/\Delta)^2\big), \qquad \big|\Delta\Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}}\big| \;\le\; C_{\mathrm{state}}\frac{\mu^{(a\to a)}_{[\chi\to\chi']}}{\Delta} + O\big((\mu/\Delta)^2\big),$$

where Δ is the certified band gap for the diagonal typed block and $\mu^{(a\to a)}_{[\chi\to\chi']}$ is the *post-move* (or pathwise supremum) triad-diagonal mixing norm (Def. 10.128). Assume the smallness condition (10.73). Then, at the updated configuration,

$$\Lambda^{[\mathscr{S};\chi]}_{\mathrm{law}} \geq \theta_{\mathrm{law}} \quad \text{and} \quad \Lambda^{[\mathscr{S};\chi]}_{\mathrm{state}} \geq \theta_{\mathrm{state}},$$

so the law/state inequalities remain satisfied.

(1) IR tightening / spectral refinement. By Lemma 10.102, IR tightening weakly increases Λ_{law} and the spectral component of Λ_{state}, while decreasing non-spectral (vac/corr) contributions; spectral window refinement removes off-band leakage while preserving certified features. Moreover, non-spectral mixing norms weakly decrease under these moves (Cor. 10.131), so the right-hand side of the Davis–Kahan bound does not worsen. Diagnostics $(\varepsilon, \Delta_P, \Delta_{\mathrm{CP}})$ remain below bounds by the same monotonicities and trigger soundness (Lemma 10.96 and Corollary 10.110). Hence the tuple $\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc})}$ remains certified (Defs. 10.135, 10.136).
(2) Arena switch. The certified spectral set and the gap Δ are arena-invariant (Lemma 10.137). The arena switch weakly decreases coherence-dominated mixing (Lemma 10.102, item (2); Cor. 10.131), so if $a \in \{\mathrm{vac}, \mathrm{corr}\}$ the Davis–Kahan bound improves. If $a = \mathrm{spec}$, we apply the same bound directly with the post-move $\mu^{(\mathrm{spec}\to\mathrm{spec})}$ (the inequality (10.73) is stated in terms of the post-move ratio, or uniformly along the admissible path). Therefore the threshold inequalities hold at (a, Loc'), with diagnostics still below bounds as above, and $\mathfrak{R}^{[\mathscr{S};\chi]}_{(a,\mathrm{Loc}')}$ remains certified.

Finally, the onset $r^\star[\chi]$ is robust under weak, gapped mixing (Cor. 10.134), so the reported onset remains valid throughout. All steps occur on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ and preserve BRST/gauge and band safety (Prop. 10.10). □

10.13 Norms, Contours, and TT-Hyperbolicity

What these norms are doing. Definition 10.143 fixes a *house topology* on the physical carrier $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$ (Definition 10.1) for all operator estimates that appear later (ledgers, meters, mixing, and contour bounds). Every norm first *sandwiches* an operator X with the certified band tag $P_x(\lambda_{\mathrm{UV}})$ and IR window $K^{(\ell)}_{\mathrm{IR}}$—both commuting contractions by Proposition 10.10—and then measures its size either in the uniform (operator) sense, $\|\cdot\|_{\mathcal{B}}$, or in a Schatten sense, $\|\cdot\|_{\mathfrak{S}_p}$. The combined norm (10.76) balances *worst–case* control ($\|\cdot\|^{(\infty)}_{\mathcal{I}}$) with *bulk/average* control ($\|\cdot\|^{(2)}_{\mathcal{I}}$), tuned by $\kappa > 0$. Allowing $p \in [2, \infty]$ and varying the IR index ℓ within the certified class yields the admissible family $\mathfrak{N}$, which is stable under the windows/masks and spectral selectors used throughout Chs. 7–8 (Definitions 7.665 and 10.7). The hygiene statement in Remark 10.144 ensures that these sandwiches preserve BRST/Nielsen safety while remaining band–covariant, so that anything we measure lives where it should (on $\mathcal{H}_{\mathrm{phys}}$ and within the accepted band).

Why they matter (and where they are used). These norms are the ambient rulers for (i) forming Law/State ledgers and calibrated visibilities (Definitions 10.80 and 10.82), guaranteeing finiteness (Lemma 10.83); (ii) controlling typed mixing blocks (Definition 10.128); and (iii) bounding resolvents along Riesz contours used for spectral selection (Definition 10.7). Because

the sandwiches commute with the realized weave configuration/triad machinery (Proposition 10.10 and Definition 10.2), comparisons across types $[\chi]$ (e.g. TT, τ–scalar, Higgs–CP; Definitions 10.3 to 10.5) and across provenances (spec, vac, corr) are *order–independent* and robust. In the wider "Norms, Contours, and TT–Hyperbolicity" program of §10.13, this band–invariant topology is what lets us (a) keep contour integrals well posed as analysis settings are tightened, and (b) certify TT–sector propagation after projection with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ against the realized background (cf. Definition 10.3 and Σ–causal response in Remark 9.83). In short, the admissible norm family is the quiet infrastructure that makes meters stable, contours convergent, and TT statements meaningful under the certified band/BRST hygiene.

10.13.1 Admissible Norm Family

Definition 10.143 (Admissible band–invariant norm family $\|\cdot\|_{\mathcal{I}}$)**.** Work on $\mathcal{H}_{\mathrm{phys}} = \operatorname{Ran} \mathsf{P}_{\mathrm{phys}}$ (Def. Definition 10.1). For any certified band tags $P_x(\lambda_{\mathrm{UV}})$ and IR window $K_{\mathrm{IR}}^{(\ell)}$ (both contractions on $\mathcal{H}_{\mathrm{phys}}$, commuting with $\mathsf{P}_{\mathrm{phys}}$; cf. Proposition 10.10), define for an operator X on $\mathcal{H}_{\mathrm{phys}}$:

$$\|X\|_{\mathcal{I}}^{(\infty)} := \left\| K_{\mathrm{IR}}^{(\ell)} P_x X P_x K_{\mathrm{IR}}^{(\ell)} \right\|_{\mathcal{B}(\mathcal{H}_{\mathrm{phys}})}, \tag{10.74}$$

$$\|X\|_{\mathcal{I}}^{(2)} := \left\| K_{\mathrm{IR}}^{(\ell)} P_x X P_x K_{\mathrm{IR}}^{(\ell)} \right\|_{\mathfrak{S}_2(\mathcal{H}_{\mathrm{phys}})}. \tag{10.75}$$

Fix any $\kappa > 0$ and set

$$\|X\|_{\mathcal{I}} \;:=\; \|X\|_{\mathcal{I}}^{(\infty)} \;+\; \kappa\, \|X\|_{\mathcal{I}}^{(2)}. \tag{10.76}$$

The *admissible family* $\mathfrak{N}$ consists of all norms obtained from (10.76) by varying the IR index ℓ within the certified class and by replacing $\mathfrak{S}_2$ with any Schatten $\mathfrak{S}_p$ ($p \in [2, \infty]$) with uniform bounds along admissible retunes (Chs. 7–8; windows/masks Definition 7.665, selectors Definition 10.7).

Remark 10.144 (Realized weave configuration hygiene and band covariance)**.** By Proposition 10.10, P_x and $K_{\mathrm{IR}}^{(\ell)}$ are idempotent contractions on $\mathcal{H}_{\mathrm{phys}}$ and commute with the BRST projector $\mathsf{P}_{\mathrm{phys}}$, so the sandwiches $K_{\mathrm{IR}}^{(\ell)} P_x(\cdot) P_x K_{\mathrm{IR}}^{(\ell)}$ preserve BRST/Nielsen safety and band admissibility. These norms are the ones used for ledgers/meters (Definitions 10.80 and 10.82) and for mixing blocks (Definition 10.128).

Lemma 10.145 (Norm properties and admissible equivalence)**.** *For any fixed admissible $(P_x, K_{\mathrm{IR}}^{(\ell)})$ and $\kappa > 0$:*

1. *$\|\cdot\|_{\mathcal{I}}$ of (10.76) is a norm on $\mathcal{B}(\mathcal{H}_{\mathrm{phys}})$.*
2. *If $p \in [2, \infty]$, the replacement $\mathfrak{S}_2 \mapsto \mathfrak{S}_p$ defines an equivalent norm; likewise for any two admissible IR indices ℓ, ℓ' there exist $c_\pm \in (0, \infty)$ (independent of X) with*

$$c_-\, \|X\|_{\mathcal{I}}^{(\ell,p)} \;\le\; \|X\|_{\mathcal{I}}^{(\ell',p')} \;\le\; c_+\, \|X\|_{\mathcal{I}}^{(\ell,p)}.$$

3. *For any projector/idempotent Π that is band/BRST-admissible (typed or triad; Definitions 9.116 and 10.2), one has $\|\Pi X \Pi\|_{\mathcal{I}} \le \|X\|_{\mathcal{I}}$ (contraction under admissible sandwiches).*

Proof. (1) Positivity and homogeneity are immediate; the triangle inequality follows from the same property of $\|\cdot\|_{\mathcal{B}}$ and of Schatten norms after the fixed contraction sandwich by $K_{\mathrm{IR}}^{(\ell)} P_x$.

(2) For $p \geq 2$ one has $\|T\|_{\mathcal{B}} \leq \|T\|_{\mathfrak{S}_p}$ and $\|T\|_{\mathfrak{S}_{p'}} \leq C\,\|T\|_{\mathfrak{S}_p}$ on the band-limited range (finite or uniformly locally finite effective rank due to selectors/masks; Chs. 7–8, Definitions 7.665 and 10.7). The IR family $\{K_{\mathrm{IR}}^{(\ell)}\}$ is an admissible chain of contractions (monotone retunes, Definition 10.101 and Lemma 10.102); hence sandwiches with different ℓ's are uniformly comparable, giving the constants $c_{\pm}$.

(3) If Π is an admissible idempotent commuting with $P_x, K_{\mathrm{IR}}^{(\ell)}$ (typed/triad stability on the realized weave configuration; Ch. 10 Definition 9.116, item (P7)), then $KP\,\Pi X \Pi\,PK = (KP\Pi)\,X\,(\Pi PK)$, with $KP\Pi$ a contraction; submultiplicativity of $\|\cdot\|_{\mathcal{B}}$ and Schatten norms yields the claim. □

Remark 10.146 (Use downstream)**.** The equivalence in Lemma 10.145 ensures that (i) the meters/visibilities (Definition 10.82) and (ii) the mixing/perturbation bounds (Definition 10.128 and Propositions 10.130 and 10.132) are insensitive to the particular choice within $\mathfrak{N}$, up to fixed multiplicative constants absorbed into calibration weights.

Proposition 10.147 (Equivalence and stability in $\mathfrak{N}$)**.** *Let $\mathfrak{N}$ be the admissible family of band–invariant norms from Definition 10.143 on $\mathcal{H}_{\mathrm{phys}} = \mathrm{Ran}\,\mathsf{P}_{\mathrm{phys}}$ (Def. Definition 10.1). For any two choices $\|\cdot\|_{\mathcal{I}}, \|\cdot\|'_{\mathcal{I}} \in \mathfrak{N}$ there exist rig–dependent constants $0 < c_- \leq c_+ < \infty$ such that*

$$c_-\,\|X\|_{\mathcal{I}} \;\leq\; \|X\|'_{\mathcal{I}} \;\leq\; c_+\,\|X\|_{\mathcal{I}}$$

for all operators X formed by finite compositions of

$$\mathsf{P}_{\mathrm{phys}}, \quad \Pi^{(a)} \;\; (\textit{triads; } a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\},\ \textit{Definition 10.2}), \quad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \;\; (\textit{Definition 10.3}),$$

the typed projectors (Definitions 10.4 and 10.5), and the Riesz resolvents and projectors selected by the certified contour families (Definition 10.7). Moreover, if $K_{\mathrm{IR}}^{(\ell')} \leq K_{\mathrm{IR}}^{(\ell)}$ in the operator order (IR tightening within the certified class), then for the corresponding norms $\|\cdot\|_{\mathcal{I}'}$ (built with ℓ') and $\|\cdot\|_{\mathcal{I}}$ (built with ℓ) one has the monotonicity

$$\|X\|_{\mathcal{I}'} \;\leq\; \|X\|_{\mathcal{I}} \qquad \textit{for all such } X.$$

Proof. **Set-up and bounded sandwiches.** Each norm in $\mathfrak{N}$ has the form (cf. Definition 10.143)

$$\|X\|_{\mathcal{I}}^{(\infty)} = \|KP\,X\,PK\|_{\mathcal{B}}, \qquad \|X\|_{\mathcal{I}}^{(p)} = \|KP\,X\,PK\|_{\mathfrak{S}_p}, \qquad \|X\|_{\mathcal{I}} = \|X\|_{\mathcal{I}}^{(\infty)} + \kappa\|X\|_{\mathcal{I}}^{(p)},$$

with $P := P_x(\lambda_{\mathrm{UV}})$ and $K := K_{\mathrm{IR}}^{(\ell)}$ band/IR tags (Def. Definition 10.1). By realized weave configuration hygiene (Proposition 10.10), P, K are idempotent contractions on $\mathcal{H}_{\mathrm{phys}}$ commuting with $\mathsf{P}_{\mathrm{phys}}$, so $X \mapsto KPXPK$ is a bounded compression both in the operator norm and in Schatten $\mathfrak{S}_p$.

Class of operators. The generators listed in the statement are all bounded on $\mathcal{H}_{\mathrm{phys}}$: - $\mathsf{P}_{\mathrm{phys}}$, $\Pi^{(a)}$, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$, and the typed projectors are idempotent contractions stable on the realized weave configuration (triads Definition 10.2; TT and typed projectors Definitions 10.3 to 10.5; typed stability in Ch. 10 Definition 9.116, item (P7)). - Riesz resolvents/projectors along

the certified contours are uniformly bounded by construction (selectors; Definition 10.7) and remain admissible under retunes (Proposition 10.10).

Finite compositions of these remain bounded, and their band–sandwiched versions inherit Schatten class membership on account of the certified masks/windows (Chs. 7–8; Definitions 7.665 and 10.7).

Equivalence across $\mathfrak{N}$. Let $\|\cdot\|_{\mathcal{I}}$ and $\|\cdot\|'_{\mathcal{I}}$ be built from (P, K, p, κ) and (P', K', p', κ'), respectively. On the certified band, the effective ranks (or local spectral multiplicities) determined by the selectors are uniformly controlled (Chs. 7–8), and for $p, p' \in [2, \infty]$ one has the standard comparison of Schatten norms on a uniformly band-limited range:

$$\|Y\|_{\mathcal{B}} \;\le\; \|Y\|_{\mathfrak{S}_p} \;\le\; C_{p,p'}\,\|Y\|_{\mathfrak{S}_{p'}} \qquad \text{for all band-sandwiched } Y,$$

with $C_{p,p'} < \infty$ independent of Y. Since P, P', K, K' are contractions, there exist constants $c_1, c_2 \in (0, \infty)$ (depending only on the realized weave configuration choices) such that for all X in the stated class:

$$\|K'P'XP'K'\|_{\mathcal{B}} \;\le\; \|KPXPK\|_{\mathcal{B}}, \qquad \|K'P'XP'K'\|_{\mathfrak{S}_{p'}} \;\le\; c_1\,\|KPXPK\|_{\mathfrak{S}_p}.$$

Combining these and the linear combos that define $\|\cdot\|_{\mathcal{I}}, \|\cdot\|'_{\mathcal{I}}$ gives the two-sided inequality with constants $c_\pm$ depending only on (P, K, p, κ) and (P', K', p', κ'), not on X. This yields the claimed equivalence.

Monotonicity under IR tightening. If $K' \le K$ (operator order; admissible IR tightening, Definition 10.101 and Lemma 10.102), then $K' = K'K = KK'$, and with $C := K'P$ and $D := KP$ we have $C = K'D$ with $\|K'\| \le 1$. Thus, for every X,

$$\|K'PXPK'\|_{\mathcal{B}} = \|CXC\|_{\mathcal{B}} \le \|K'\|^2\,\|DXD\|_{\mathcal{B}} \le \|KPXPK\|_{\mathcal{B}}.$$

The same contraction argument applies to $\|\cdot\|_{\mathfrak{S}_p}$, since Schatten norms are two-sided ideal norms: $\|CXC\|_{\mathfrak{S}_p} \le \|C\|^2\,\|X\|_{\mathfrak{S}_p}$. Adding the components as in (10.76) (and its primed analogue) gives $\|X\|_{\mathcal{I}'} \le \|X\|_{\mathcal{I}}$.

Conclusion. We have established two-sided norm equivalence for all X in the stated operator class and the monotone stability under IR tightening. All steps are carried out on $\mathcal{I}^{[\mathscr{S}]}$ and preserve BRST/gauge and band admissibility by Proposition 10.10. □

Remark 10.148 (Downstream consequences)**.** By Proposition 10.147, the quantitative bounds for meters, mixing norms, and visibility stability are invariant up to fixed constants across $\mathfrak{N}$ (cf. Definitions 10.82 and 10.128 and Propositions 10.130 and 10.132). Moreover, IR tightening can only improve the non-spectral diagnostics and cannot worsen the norm-based estimates used in SynTh/Audit (Lemma 10.102 and Corollary 10.131).

10.13.2 Measurable Structure for Riesz Integrals

Bochner measurability and Riesz integrals. Bochner measurability is the standard notion of measurability for Banach–valued maps and underpins the construction of Bochner integrals, which generalize the Lebesgue integral to functions taking values in a Banach space rather than in $\mathbb{R}$ or $\mathbb{C}$ (see, e.g., [433, 253]). Let $(X, \|\cdot\|)$ be a Banach space (in our case $X = \mathcal{B}(\mathcal{H}_{\text{phys}})$ with the operator norm), and let $f : (\Omega, \mathcal{F}, \mu) \to X$ be a map from a measure space. The

map f is *Bochner–measurable* (or *strongly measurable*) if it is measurable with respect to the Borel σ–algebra on X induced by the norm topology; equivalently, by the Pettis theorem, f is almost everywhere the limit of X–valued simple functions [433]. Under mild integrability conditions, one then defines the *Bochner integral*

$$\int_\Omega f(\omega)\, d\mu(\omega) \ \in X,$$

which enjoys the usual linearity and dominated–convergence properties of the Lebesgue integral but now returns an element of X [433, 253, 55].

Within the measurable structure developed in Section 10.13.2, these general notions are applied to the resolvents of the band–limited, gauge–fixed kinetic operators $K \in \{K_{\Phi\Phi}, K^{(0)}_{\Theta\Theta}, K^{(1)}_{\tau}\}$. For fixed K and a Riesz contour γ enclosing a certified spectral island, the map

$$z \longmapsto (K - z)^{-1} \in \mathcal{B}(\mathcal{H}_{\text{phys}})$$

is norm–continuous on γ, thanks to the resolvent identity and the uniform spectral gap δ that separates the island from the rest of the spectrum [253, 487]. Norm–continuity implies Bochner measurability, so the operator–valued contour integral

$$P \ = \ \frac{1}{2\pi i} \oint_\gamma (K - z)^{-1}\, dz$$

is a well-defined Bochner integral in $\mathcal{B}(\mathcal{H}_{\text{phys}})$ [433, 253]. This is precisely the setting of Proposition 10.149: part (i) asserts that for every contour point z and every admissible IR retune r and arena $\text{Loc} \in \{\text{bulk}, \text{boundary}\}$, the mapping

$$(r, \text{Loc}) \ \longmapsto \ (K - z)^{-1} \ \in \ \mathcal{B}(\mathcal{H}_{\text{phys}})$$

is Bochner–measurable (indeed norm–continuous) along admissible paths on the realized weave configuration, and part (ii) then identifies the associated Riesz projectors as bounded operators obtained by such contour integrals, invariant under admissible contour deformations and commuting with the physical and typed projectors (Definitions 9.116 and 10.2).

A second, equally important role of Bochner measurability in Section 10.13.2 is to control how the Riesz projectors depend on the audit parameters. Along an admissible audit path $t \mapsto K(t)$ (retunings of r, arena switches, and related moves, as in Definitions 10.1 and 10.101), realized weave configuration hygiene guarantees norm–continuity of $K(t)$ on the certified class [487, 253]. The resolvent identity

$$(K(t) - z)^{-1} - (K(t_0) - z)^{-1} = (K(t) - z)^{-1}\Big(K(t_0) - K(t)\Big)(K(t_0) - z)^{-1},$$

together with a uniform bound on $\|(K(t) - z)^{-1}\|$ provided by the spectral gap, implies $\|(K(t) - z)^{-1} - (K(t_0) - z)^{-1}\| \to 0$ as $t \to t_0$. Thus $t \mapsto (K(t) - z)^{-1}$ is norm–continuous and therefore Bochner–measurable as a map into $\mathcal{B}(\mathcal{H}_{\text{phys}})$ [433]. By dominated convergence for Bochner integrals [433, 253], one may pass the limit under the Riesz integral and conclude that

$$P(t) \ := \ \frac{1}{2\pi i} \oint_\gamma (K(t) - z)^{-1}\, dz$$

varies continuously with t and is Bochner–measurable as a function of the realized weave configuration parameters. This provides the measurable/continuous structure on which Proposition 10.149 and the subsequent audit and onset analysis (Lemma 10.102, Proposition 10.87, and Theorem 10.107) are built, ensuring that SynTh/audit manipulations of the realized weave configuration do not introduce pathological jumps in the spectral decomposition of the kinetic operators and that the corresponding typed bands and visibilities evolve in a controlled, Lebesgue-style measurable framework [433, 253, 487].

Proposition 10.149 (Contour classes and Bochner measurability for Riesz projectors)**.** *Let $K_{\Phi\Phi}$ and $K^{(0)}_{\Theta\Theta}$ be the band–limited, gauge–fixed kinetic operators on the $\Phi\Phi$ (spin–2) and $\Theta\Theta$ (spin–0) blocks, and let $K^{(1)}_{\tau}$ denote the τ–*typed vector *(Chrono–Kymon) kinetic operator on the τ–vector typed subspace (cf. typed projectors in Definition 10.4 and instrumentation in Definition 10.1). Fix the certified band via P_x and choose piecewise C^1 Jordan contour families*

$$\{\gamma_i\}_{(2)} \ \text{ in } \ \rho(K_{\Phi\Phi}), \qquad \{\Gamma_j\}_{(0)} \ \text{ in } \ \rho(K^{(0)}_{\Theta\Theta}), \qquad \{\zeta_m\}_{(1)} \ \text{ in } \ \rho(K^{(1)}_{\tau}),$$

each enclosing disjoint spectral islands with a uniform gap $\delta > 0$ from the remainder of the spectrum across the certified class (Riesz selectors Definition 10.7; realized weave configuration hygiene Proposition 10.10). Then:

(i) Bochner measurability of resolvents

For every contour point z and every admissible IR retune r and arena $\mathrm{Loc} \in \{\mathrm{bulk}, \mathrm{boundary}\}$ *(audit moves Definition 10.101), the mappings*

$$(r, \mathrm{Loc}) \ \longmapsto \ (K - z)^{-1} \ \in \ \mathcal{B}(\mathcal{H}_{\mathrm{phys}})$$

are Bochner–measurable (indeed norm-continuous on admissible paths) for $K \in \{K_{\Phi\Phi}, K^{(0)}_{\Theta\Theta}, K^{(1)}_{\tau}\}$.

(ii) Riesz projectors: definition, boundedness, invariance, commutations

The Riesz projectors

$$\frac{1}{2\pi i}\oint_{\gamma_i} (K_{\Phi\Phi} - z)^{-1}\, dz, \quad \frac{1}{2\pi i}\oint_{\Gamma_j} (K^{(0)}_{\Theta\Theta} - z)^{-1}\, dz, \quad \frac{1}{2\pi i}\oint_{\zeta_m} (K^{(1)}_{\tau} - z)^{-1}\, dz$$

are well–defined bounded operators on $\mathcal{H}_{\mathrm{phys}}$, invariant under admissible contour deformations within the resolvent set, and they commute with $\mathsf{P}_{\mathrm{phys}}$, the triad maps $\Pi^{(a)}$ (Definition 10.2), and all typed projectors (Ch. 10: Definition 9.116, instantiated in Definitions 10.3 to 10.5).

Proof. **(1) Bochner measurability.** By admissibility of audit moves (Def. Definition 10.101) and realized weave configuration hygiene (Prop. Proposition 10.10), there is a norm–continuous path of band–limited, gauge–fixed kinetic operators $t \mapsto K(t)$ on the realized weave configuration $\mathcal{I}^{[\mathscr{J}]}$ interpolating any two admissible settings (r, Loc). Fix a contour point z; by the uniform gap δ one has $\|(K(t) - z)^{-1}\|_{\mathcal{B}} \le M$ for all t and some $M < \infty$ (selectors Definition 10.7). Using the resolvent identity,

$$(K(t) - z)^{-1} - (K(t_0) - z)^{-1} = (K(t) - z)^{-1}\Big(K(t_0) - K(t)\Big)\,(K(t_0) - z)^{-1},$$

so $\|(K(t)-z)^{-1}-(K(t_0)-z)^{-1}\| \le M^2\,\|K(t)-K(t_0)\| \to 0$ as $t \to t_0$. Thus $(r, \mathrm{Loc}) \mapsto (K-z)^{-1}$ is norm–continuous along admissible paths and therefore Bochner–measurable in $\mathcal{B}(\mathcal{H}_{\mathrm{phys}})$.

(2) Projector properties. Each Riesz projector is defined by the Cauchy integral over the corresponding contour; boundedness follows from the uniform resolvent bound and finite contour length (standard Riesz theory; the gap δ gives a uniform operator bound along the contour). Deformation invariance holds as long as the contour stays in the resolvent set, which is guaranteed by the selectors and realized weave configuration hygiene (Definition 10.7 and Proposition 10.10); the same argument shows arena invariance of the certified spectral set (cf. Lemma 10.137).

For commutations, note that on $\mathcal{I}^{[\mathscr{J}]}$ the projectors $\mathsf{P}_{\mathrm{phys}}$, $\Pi^{(a)}$, and all typed idempotents commute with the kinetic operators (typed stability and block structure; Definition 9.116, item (P7); see also Proposition 10.9). Hence they commute with every resolvent $(K-z)^{-1}$, and therefore with its contour integral. All statements are made on $\mathcal{H}_{\mathrm{phys}} = \operatorname{Ran}\mathsf{P}_{\mathrm{phys}}$ and preserve BRST/Nielsen safety and band admissibility (Prop. 10.10). □

Remark on the TT–Hyperbolic Indicator

The indicator $\mathbf{1}_{\{\sigma_{\mathrm{prin}}(K_{\Phi\Phi})\ \text{TT–hyperbolic}\}}$ used in Definition 10.27 is realized via the holomorphic functional calculus at the *symbol* level: restrict $K_{\Phi\Phi}$ to the TT typed subspace (projector $\Pi_{\Sigma}^{[\mathrm{TT}]}$, Definition 10.3), take the principal symbol σ_{prin} in the cotangent fiber ξ, choose a spectral cut that separates TT–hyperbolic eigenvalues from the rest, form the Riesz projector of the symbol–level resolvent over that cut, and quantize microlocally back to the operator on the certified band. This construction is compatible with band tags/selectors (Definition 10.7) and with realized weave configuration invariance (Prop. 10.10).

10.14 Findings and Quadrants: High-Level Synthesis

Instrumentation-first safety. All constructions are performed *on the realized weave configuration* $\mathcal{I}^{[\mathscr{J}]}$, so that every typed object (graviton, Higgs/radial kymon, τ-kairos scalars and Chrono–Kymon vectors) and every correlator inherits BRST/Nielsen flatness and band stability from the outset. Concretely, the BRST projector $\mathsf{P}_{\mathrm{phys}}$, the triad maps $\Pi^{(a)}$, and all typed idempotents commute and act on $\mathcal{H}_{\mathrm{phys}}$ without introducing gauge-parameter artifacts; see Propositions 10.9 and 10.10 and the standard BRST/Nielsen framework [445, 106, 120, 230]. This "instrumentation-first" posture ensures that subsequent claims are stated and tested under identical measurement conditions, avoiding spurious differences due to incompatible rigs.

τ-kairos purity and the Chrono–Kymon. The τ-kairos field decomposes into breathing and longitudinal scalars, a parity-odd pseudoscalar, and helicity-resolved vectors, and *each* typed component is TT-null by construction. As a result, projecting any τ-kairos content onto the background-covariant TT subspace annihilates it (Lemma 10.17), so there is no contamination of the graviton channel (Corollary 10.20). The vector content—the Chrono–Kymon—is extracted helicity by helicity, carries a parity audit Δ_P, and is selected spectrally by Riesz

projectors that automatically expand if new spin-1 features appear; cf. Definitions 10.57 and 10.58 and Lemma 10.62. The scalar/vector taxonomy follows the general GW-polarization classification beyond GR [477, 478, 479], while TT extraction is background-covariant in the York/Lichnerowicz sense [43].

Graviton (spin-2, TT). The graviton is obtained by a TT sandwich around the spin-2 Riesz selector, triad-resolved so that spectral, vacuum, and correlational TT pieces can be reported separately; see Definition 10.25. Independence from τ-mixing follows immediately from TT-nullity of the τ-types (Proposition 10.29 and Corollary 10.125). The TT-leak meter ε quantifies unexpected TT strength outside spectral support and is bounded by non-spectral TT components; it *decreases* under IR tightening (Lemma 10.103 and Corollary 10.104). If additional helicity-2 branches are realized physically, they are incorporated by adding contours to the spin-2 Riesz sum (Lemma 10.31), so the definition remains future-proof; the spectral selection and contour calculus follow standard holomorphic functional calculus [115, 253], and the radiative graviton degrees of freedom coincide with the usual massless spin-2 TT modes [7, 14, 43].

Higgs (radial kymon, CP-resolved). Within the tantrakyma scalar sector, the CP-refined radial projectors isolate amplitude (radial) directions in strict orthogonality to the NG/pNG manifold, ensuring no Goldstone leakage into the radial readout (Proposition 10.47). When CP is conserved the CP-even/odd channels decouple; otherwise their mixing is cleanly diagonalized by the spectral calculus (Proposition 10.49). Positivity of the spectral density on $\mathcal{H}_{\text{phys}}$ and the same contour-based future-proofing as above hold for the scalar case too (Propositions 10.48 and 10.50); compare with standard Higgs-sector CP diagnostics and positivity discussions [466, 467, 14, 255, 230].

Witnesses → visibilities → Parasymmetric TLO. Type-specific *law* residuals (Ward, trace, BRST/Nielsen) and *state* features (spectral weight, vacuum/coherence magnitudes, and diagnostics like $\varepsilon, \Delta_P, \Delta_{\text{CP}}$) are converted by calibrated meters into visibilities Λ_{law} and Λ_{state}. These meters are finite on the certified band (Lemma 10.83), monotone under IR retuning with the expected directions (Proposition 9.146), and yield unique onsets $r^\star[\chi]$ with explicit stability radii (Proposition 10.88). Consequently, the Parasymmetric TLO is well-posed, type by type, with controllable thresholds and robustness margins (Proposition 10.90); Ward/Slavnov–Taylor and BRST/Nielsen hygiene underpin the "law" side of these meters [483, 484, 445, 120].

Weaving (typed mixing) and robustness. Typed insertion into the Unified Inter-Modal Correlator furnishes a $\bar{\Sigma}$-weighted generalized eigenproblem that quantifies inter-type and inter-sector mixing on the certified band (Definitions 10.113 and 10.118). This problem is well-posed under our band assumptions (Lemma 10.122). Crucially, any channel touching the τ-block preserves TT-nullity (Lemma 10.123), so τ-mixing cannot generate spurious spin-2 TT content. Parity/helicity/CP symmetries gate which typed pairs can mix at all (Proposition 10.126). When mixing is permitted, visibility changes are perturbatively bounded in a Davis–Kahan sense and onsets remain stable under weak mixing (Proposition 10.132

and Corollary 10.134); spectral stability again relies on the standard holomorphic calculus [115, 253].

SynTh and finite audits. SynTh aggregates law/state shortfalls and diagnostic breaches into a single potential that *descends* under admissible moves (IR tightening, spectral refinement, arena switch). The No-Explosion/Audit Theorem guarantees that every conflict leads, in finitely many steps, either to co-tenability or to a stable certificate of non-co-tenability (Theorem 10.107). Automatic triggers for excessive TT-leak, parity, or CP asymmetry are sound and ensure that out-of-spec conditions are never silently accepted (Definition 10.95 and Corollary 10.110); see also the polarization/CP diagnostics context in [477, 478, 466, 467].

Reporting and provenance, boundary vs. bulk. We standardize reporting with a plain booktabs table listing sector, type, triad, location, visibilities, and onset. The certified spectral set and Riesz contours are arena-invariant, and tightening or switching arenas cannot *create* bulk spectral claims from boundary coherence alone (Proposition 10.140). In particular, τ-coherence at the boundary can never be promoted to a bulk TT graviton claim (Corollary 10.141). Admissible norm families and contour measurability are fixed once and for all (Definition 10.143 and Proposition 10.149), so that numerical meters and proofs share the same functional backbone [115, 253].

Quadrants: the SynTh Law $\oplus$ State map. Given thresholds $\theta_{\mathrm{law}}, \theta_{\mathrm{state}} \in (0,1)$, each typed, triad-resolved, and location-tagged outcome lands in one of four SynTh quadrants (Table 8.1). **QI** (both visibilities above threshold) is *co-tenable/certified* and should be reported with its onset $r^\star$ and diagnostics. **QII** (law OK, state weak) calls for IR tightening and spectral refinement; boundary coherence may be demoted and need not yield a spectral claim. **QIII** (state strong, law broken) mandates an immediate audit of gauges, meters, and off-band leakage before any claim is entertained. **QIV** (both weak) is the protected null zone: no claim is made, though exploratory retunes remain permissible. Across *all* quadrants, if any diagnostic exceeds its bound

$$\varepsilon > \varepsilon_{\max}, \qquad |\Delta_P| > \delta_P, \qquad |\Delta_{\mathrm{CP}}| > \delta_{\mathrm{CP}},$$

an audit is mandatory (Definition 10.95). Read in this way, the quadrants operationalize the theorems above: they translate instrumentation-first safety, typed mixing control, and audit guarantees into a clear decision map from raw meters to publishable, provenance-aware physics.

10.15 Permitted Spins, Polarizations, Helicities, and Tags: High-Level Overview

Scope of spins in this chapter. The realized weave configuration instantiated in this chapter admits spins $s \in \{2, 1, 0\}$. This is a *modeling choice*, not a prohibition: the operator-theoretic machinery (typed projectors, Riesz selectors, witnesses/TLO, SynTh) places no *a priori* ban on other spins (e.g. $s = \frac{3}{2}$ or higher); it simply was not activated here. Within the selected

scope, each spin is paired with its appropriate polarization/helicity structure, parity/CP tags when relevant, and the universal triad/location provenance.

Spins, helicities, and tags. This section declares, for the present realized weave configuration, which spins and polarization/helicity structures are *active* and how they are labeled for reporting and audit. Spin–2 lives in the $\Phi\Phi$ (geometry) block and is read exclusively through the background–covariant TT projector (Definition 10.3), so only the two massless helicities $\lambda = \pm 2$ appear, as required by the Poincaré/Wigner classification for a massless spin–2 representation (little group $E(2)$) [482, 14]; the operational extraction uses the York/Lichnerowicz TT machinery built into Definition 10.25 (cf. [43]). Non–TT content is *not* recorded here by design: if scalar or vector features are present, they are routed to the τ–kairos block and remain TT–null, so they cannot contaminate the graviton readout (Lemma 10.123 and Corollary 10.125). In parallel, the universal provenance tags—triad $a \in \{\text{spec}, \text{vac}, \text{corr}\}$ and location $\text{Loc} \in \{\text{bulk}, \text{boundary}\}$—travel with *every* type (Definitions 10.2 and 10.101), recording where the signal sits in the spectrum and arena without altering its spin/helicity meaning.

Where the other polarizations live (and why TT is safe). All non–TT gravitational content is organized in typed channels with symmetry tags that match standard GW–polarization taxonomies beyond GR [477, 478, 479]. The τ–kairos scalars comprise breathing and longitudinal even–parity types $S^{(b)}, S^{(L)}$ and an odd–parity pseudoscalar $\tilde{S}^{(p)}$; the matter vector (Chrono–Kymon) carries spin–1 with helicities $\lambda = \pm 1$ resolved by $A^{(\pm)}$ and a parity diagnostic Δ_P (Definitions 10.4, 10.57 and 10.58). Each of these is *TT–null* by construction (Lemma 10.123), so projecting onto the TT subspace annihilates them, preserving the purity of the spin–2 definition. In the $\Theta\Theta$ sector, the Higgs (radial kymon) is a spin–0 amplitude mode further refined by CP tags (rad$\pm$), with CP structure interpreted in the usual Higgs–sector sense [466, 467] and implemented here via Definition 10.5. Selection rules then gate mixing—parity–even does not mix with parity–odd, CP+ with CP−, and helicity sectors stay diagonal (Proposition 10.126)—and any sequence that touches the τ block still preserves TT–nullity (Lemma 10.123). Put together, the permitted spins/polarizations/helicities and their tags form a clean ledger: spin–2 TT for the graviton (Definitions 10.3 and 10.25), spin–1 vectors and spin–0 scalars in τ or Higgs channels, all triad/location–resolved and audited without ever blurring the TT graviton definition.

Graviton (geometry, $\Phi\Phi$). The graviton is pure spin-2 and *TT only*: the typed TT projector singles out helicities $\lambda = \pm 2$, with parity swapping $+2 \leftrightarrow -2$ (Definitions 10.25 and 10.26). No scalar or vector polarizations are admitted in this channel; any non-TT signatures that appear in practice are recorded in the τ-block (see below) and are identically TT-null, hence orthogonal to the graviton's TT readout (Proposition 10.29 and Corollary 10.125). Triad tags spec/vac/corr separate radiative spin-2 strength from vacuum structure and coherence, and bulk/boundary tags record provenance.

τ-kairos scalars and the Chrono–Kymon. The τ-kairos block captures non-TT structure in a typed, parity/helicity-aware way: two even-parity scalars—breathing $S^{(b)}$ and longitudinal

$S^{(L)}$—and one odd-parity pseudoscalar $\tilde{S}^{(p)}$ (Definition 10.4). All are *TT-null* by construction (Lemma 10.17). The matter vector channel—the Chrono–Kymon—carries spin-1 with helicities $\lambda = \pm 1$ resolved by $A^{(\pm)}$, parity swapping $+ \leftrightarrow -$ (Definitions 10.57 and 10.58 and Lemma 10.59). Each of these types is triad- and location-resolved just like the graviton, ensuring uniform reporting and audit.

Higgs (tantrakyma radial scalar). In the $\Theta\Theta$ sector, the Higgs (radial kymon) is a spin-0 amplitude mode equipped with CP tags rad± (even/odd), orthogonal to NG/pNG directions so that symmetry-breaking phases do not leak into the amplitude readout (Definitions 10.5 and 10.43 and Proposition 10.47). CP mixing—when present—is handled spectrally and reported without altering the typed structure (Proposition 10.49).

Triad and location are provenance, not polarizations. Every type, regardless of spin, carries the universal triad tag spec/vac/corr and the location tag bulk/boundary. These record *where* and *how* the signal arises (radiative vs. vacuum vs. coherence; bulk vs. boundary) and are orthogonal to spin/helicity or parity/CP. They are critical to SynTh's decision-making and to the *Boundary–vs–Bulk Invariance* guarantees established earlier.

Selection rules and TT safety under mixing. When the correlator respects a symmetry, selection rules block forbidden mixings: parity-even does not mix with parity-odd, helicity sectors are diagonal, and CP+ does not mix with CP− (Proposition 10.126). Moreover, any channel that involves the τ-block preserves TT-nullity, so no sequence of typed mixings can *create* TT graviton content from non-TT sources (Lemma 10.123). These two structural protections—selection rules and TT-null preservation—explain why "extra polarizations" observed operationally do not alter the spin-2 TT definition: they are registered and audited in the appropriate τ-types or scalar CP tags, not in the graviton projector.

Provenance of entries. The graviton's TT/helicity structure and its protection from τ-mixing come from Definitions 10.25, 10.26 and 10.32, Proposition 10.29, and Lemma 10.103. The τ-block's scalar/vector types, parity and helicity tags, and TT-nullity appear in Definitions 10.4, 10.57 and 10.58 and Lemmas 10.17 and 10.59. The Higgs CP split and NG/pNG orthogonality are in Definitions 10.5 and 10.43 and Propositions 10.47 and 10.49. Selection rules and TT-null preservation under mixing are gathered in Proposition 10.126 and Lemma 10.123, and universal triad/location tags are fixed by Definitions 10.1 and 10.2.

Scope and extensibility. The restriction to spins $s \in \{2, 1, 0\}$ in this chapter is a choice of scope, not a prohibition. Nothing in the typed–projector/Riesz–selector architecture, nor in the BRST/Nielsen safety layer of the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$, forbids $s = \frac{3}{2}$ or other spins. The framework is type–agnostic: once a carrier, its kinematic constraints, and the relevant symmetries are specified, the same three steps—(i) construct the typed projector(s), (ii) install the corresponding spectral selector(s) on the certified band, and (iii) insert them into witnesses, visibilities, TLO, SynTh, and reporting—apply unchanged.

Spin $3/2$ **(Rarita–Schwinger) channel.** For a spinor–vector carrier Ψ_μ, the pure-$3/2$ subspace is enforced by the divergence–free and γ-traceless constraints,

$$\Pi^{[\mathrm{RS}]} := \Pi^{[\nabla\Psi=0]}\,\Pi^{[\gamma\Psi=0]},$$

as in the Rarita–Schwinger (RS) framework [488, 14]. If the dynamics admits the RS gauge symmetry $\Psi_\mu \to \Psi_\mu + \nabla_\mu \epsilon$, the graded BRST structure of the realized weave configuration (same $\mathsf{P}_{\mathrm{phys}}$ with fermionic ghosts) applies verbatim [445, 106, 442, 489]. The spin-$3/2$ spectral selector is introduced exactly as for $s = 2, 1, 0$ using Riesz projectors on certified contours (Definition 10.7) [115, 253]):

$$\mathsf{P}^{(3/2)}_{\mathrm{spec}} = \sum_\ell \frac{1}{2\pi i} \oint_{\Upsilon_\ell} \left(K^{(3/2)} - z\right)^{-1} dz,$$

with certified contours $\{\Upsilon_\ell\}$. In the massless case one may helicity–resolve $\sum_{\lambda=\pm 3/2} \Pi^{(\lambda)} = \mathbf{1}_{\mathrm{RS}}$, with parity swapping $+ \leftrightarrow -$ [482, 14]. Triad and location tags (spec/vac/corr) $\times$ (bulk/boundary) attach verbatim (Definitions 10.2 and 10.101), maintaining uniform reporting and audits. The future–proof extractor mirrors the spin–2 graviton projector (Definition 10.25):

$$\mathcal{P}^{(3/2)}_{\mathrm{RS}} = \mathsf{P}_{\mathrm{phys}}\,\Pi^{[\mathrm{RS}]}\left(\mathsf{P}^{(3/2)}_{\mathrm{spec}} \oplus \Pi^{(\mathrm{vac})} \oplus \Pi^{(\mathrm{corr})}\right)\Pi^{[\mathrm{RS}]}\,\mathsf{P}_{\mathrm{phys}}.$$

Law–ledgers add RS–gauge closure and the γ-trace/divergence constraints; state–ledgers use the spin–$3/2$ spectral density $\rho_{(3/2)}$. Meter finiteness, monotonicity under IR tightening, onset uniqueness $r^\star[\frac{3}{2}]$, and stability–radius bounds carry over directly because they depend only on band–sandwiched norms and BRST covariance (Definition 10.143, Lemma 10.83, and Propositions 9.146, 10.10 and 10.88).[6]

Mixing and TT safety. Typed insertion into the unified correlator $\hat{\mathbf{G}}_\Lambda$ proceeds exactly as in the $s \in \{2, 1, 0\}$ cases (Definition 10.113); symmetry selection rules continue to determine admissible couplings (Proposition 10.126). The TT sandwich ensures that no spurious graviton is produced: the graviton extractor acts on symmetric 2–tensors within the TT subspace (Definitions 10.3 and 10.25), whereas Ψ_μ lives in a spinor–vector bundle. Any effect on the spin–2 channel must therefore appear as *genuine* $s = 2$ spectral support (i.e. new helicity–2 contours), which the Riesz–spectral formalism registers explicitly rather than via leakage (Definition 10.7 and Lemma 10.31).

Higher spins and anyonic sectors. The same template scales to higher integer spins and to fractional/anyonic content. For higher spins (e.g. symmetric Fronsdal fields with $s \geq 3$), impose the appropriate typed constraints (traceless/double–traceless, covariant transversality) and add $\mathsf{P}^{(s)}_{\mathrm{spec}}$ on certified contours; if massless, resolve helicities $\lambda = \pm s$; if massive, use polarization projectors indexed by $\pi \in \{1, \ldots, 2s+1\}$ [492, 493, 494, 495]. For anyons and fractional spin, work in 2+1 dimensions (or an effectively planar boundary arena) and replace helicity/parity tags by central idempotents $\Pi^{[a]}$ of a modular tensor category $\mathcal{C}$ (anyon charge

[6] Consistent interactions for spin–3/2 fields require the usual caveats (e.g. the Velo–Zwanziger problem and gauge-consistent couplings) [490, 491]; our use is kinematic/projector–level and agnostic to a specific interacting completion.

a, topological spin θ_a, braiding data); spectral selection can proceed via dispersive blocks $K^{[a]}$ or, when appropriate, via loop/line operators whose expectations enter the state–ledger—still band–sandwiched, so meters remain finite and monotone under IR tightening [496, 434, 497, 498, 499, 500]. Selection rules then follow braiding and charge–conjugation: mixing is allowed only when the fusion admits the vacuum (the tensor unit) [498, 499].

Conclusion. The weave is a reusable scaffold. To go beyond $\{2, 1, 0\}$—to $s = \frac{3}{2}$, to higher spins, or to anyonic sectors—no refactoring of prior constructions is required; one *extends the dictionary of types* by adding the relevant typed projectors and, where dispersive, the corresponding Riesz selectors on the same realized weave configuration. Core guarantees—BRST/Nielsen flatness, triad/location provenance, TT safety for the graviton, well–posed TLO with stable onsets, and finite, monotone meters—remain intact under these extensions (Definitions 10.1, 10.2, 10.82 and 10.95 and Lemma 10.86).

10.16 Fundamental Quanta and Their Excitations

Having distinguished the excitation channels of the τ–kairos (Section 10.17.3), the discussion turns to the quanta that populate those channels. The organization proceeds from the substrate fields to their typed, triad–resolved excitations: the *apeiron* of Gaiamiti (Φ) and the *kymon* of Tantrakyma (Θ), followed by the derived modes obtained through the constitutive split and the kinematic/typed projectors of the weave. In this ordering the higher excitations appear as structured outgrowths of the dual substrate (Φ, Θ) rather than as independent species fixed *a priori*.

Apeiron. The apeiron is the fundamental quantum register of the Gaiamiti field Φ (cf. Section 10.17.1). At the operator level it is the fluctuation $\delta\hat{\mathbf{\Phi}}$ on the Σ–realized carrier; at the spectral level relevant for the weave it materializes in the *scalar* typed family of the τ–kairos. When projected and certified within the typed, triad–resolved correlator, this scalar register yields the *Gaiaton* (Definitions 10.68 to 10.70). Through the constitutive dependence of the temporal tensor $t_{\mu\nu}[\Phi, \Theta]$ (eq. (10.101)), the apeiron also reappears in the temporal channel as the scalar contribution to $\hat{\tau}_{\mu\nu}$, consistently with TT–nullity and typed commutations (Definitions 10.2 and 10.4 and Lemma 10.71).

Kymon. The kymon is the generic quantum of the Tantrakyma field Θ (cf. Section 10.18.6). Its spectrum organizes matter, flavor, and internal–symmetry degrees of freedom in the weave's typed language. In the temporal channel, a dedicated vector register is singled out: the *Chrono–Kymon*, realized by the typed pair $A^{(\pm)}$ in the τ–kairos family (Definition 10.4) and mapped torsionally through the constitutive rules (cf. Section 10.7). This places the vector content of $\hat{\tau}_{\mu\nu}$ on the same realized weave configuration as the scalar content.

Graviton. From the Gaiamiti sector, the tangential (Goldstone) direction selected by the TT projector $\mathcal{P}^{(2)}$ defines the massless spin–2 graviton

$$\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}] \quad (Definition\ 10.167).$$

In the typed weave it saturates the TT content of the metric fluctuation and exhausts the radiative tensor degrees of freedom, consistent with the spin analysis (cf. Section 10.17.9) and with its identification as the spin–2 apeiron/Goldstone mode of Gaiamiti (eq. (10.28)). BRST/Nielsen safety and the triad commutations guarantee that no scalar or vector leakage contaminates the TT channel (Proposition 9.202 and Definition 10.2).

Gaiaton. When the apeiron is viewed in the metric sector through the τ–kairos *scalar* typed family $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$, it is termed the *Gaiaton*. Spectrally it is isolated by the spin–0 Riesz selector acting on the scalar kinetic generalized eigen-operator pair $K_\tau^{(0)}$ and realized by the CP– and triad–resolved projectors/fields of the weave (Definitions 10.68 to 10.70). TT orthogonality and typed safety ensure $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\mathcal{P}^{(0)}_{\mathrm{G},\eta} = 0$ for all admissible CP branches, so the tangent–radial decomposition of Gaiamiti fluctuations is cleanly implemented (Lemma 10.71).

Chrono–Kymon. Within the kymon family of Θ, the Chrono–Kymon provides the τ–kairos *vector* register via the typed pair $A^{(\pm)}$ (Definition 10.4). Its field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar\nabla_{[\mu}\hat K^{(\tau)}_{\nu]}$ maps into the antisymmetric component of the temporal tensor (cf. Section 10.7), and its dynamics are captured by the background–covariant Maxwell/Proca–type equations on $\bar\Sigma$ developed for the Tantrakyma sector (cf. Section 10.18.6). This supplies the vector ledger and visibilities that accompany the scalar ledger of the Gaiaton (Definitions 10.82 and 10.117).

Tau–kairos. The temporal tensor fluctuation $\hat\tau_{\mu\nu}$—defined from the constitutive temporal map $t_{\mu\nu}[\Phi,\Theta]$ on the certified rig—obeys the TT–null rule and decomposes as

$$\boxed{\hat\tau_{\mu\nu} = \underbrace{\Big(\bar\nabla_{(\mu}\bar\nabla_{\nu)} - \tfrac{1}{d}\,\bar\Sigma_{\mu\nu}\,\bar\Box\Big)\hat\varphi_A}_{S_{\mu\nu}[\hat\varphi_A]} + \underbrace{2\,\bar\nabla_{[\mu}\hat K^{(\tau)}_{\nu]}}_{A_{\mu\nu}[\hat K^{(\tau)}]} \quad \text{with} \quad \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\hat\tau_{\mu\nu} = 0 \;\; \text{(TT–null)}.}$$

where $\bar\Box := \bar\Sigma^{\rho\sigma}\bar\nabla_\rho\bar\nabla_\sigma$. This is equivalent to the τ-kairos typed split (10.10) once you resolve

$$S_{\mu\nu}[\hat\varphi_A] = S^{(b)}_{\mu\nu}[\hat\varphi_b] \oplus S^{(L)}_{\mu\nu}[\hat\varphi_L] \oplus \tilde S^{(p)}_{\mu\nu}[\tilde\varphi], \qquad A_{\mu\nu}[\hat K^{(\tau)}] = \sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}[\hat K^{(\tau)}_\lambda],$$

using the τ–kairos type projectors from Definition 10.4. Here $S_{\mu\nu}[\hat\varphi_A]$ is the scalar (symmetric, trace–adjusted) piece descending from the Gaiaton channel, selected in practice by the τ–scalar type projectors $\Pi^{[\chi]}$ and the Riesz selector on $K_\tau^{(0)}$ (cf. Definitions 10.4, 10.68 and 10.69); $A_{\mu\nu}[\hat K^{(\tau)}] = \hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ is the vector (antisymmetric) piece sourced by the Chrono–Kymon, with $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar\nabla_{[\mu}\hat K^{(\tau)}_{\nu]}$ (cf. Section 10.7). Typed/triad commutations ensure compatibility with the weave meters and visibilities, keeping all diagnostics BRST/Nielsen–safe on certified plateaus (cf. Definitions 10.2 and 10.82 and Proposition 9.97). In particular, τ–kairos enters the pipeline only via typed projectors (not as an independent sector), and TT–purity $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\hat\tau_{\mu\nu} = 0$ guarantees that graviton observables remain unaffected by $\hat\tau_{\mu\nu}$ insertions (cf. Definition 10.4 and Proposition 10.29).

Mition and Tantron (spin–1 internal connection quanta). The spin–1 quanta termed the *mition* (Gaiamiti) and the *tantron* (Tantrakyma) originate from the *relational bundle connection* that appears in the covariant derivatives of Chapter 7 (cf. eqs. (10.1) and (10.2)). Their masses are generated via internal gauge SSB (BEH) as developed in Chapter 10 (cf. Definitions 9.252, 9.258, 9.261 and 9.348), but the excitations themselves are connection modes rather than substrate (Φ, Θ) quanta. On the realized weave configuration (Definition 10.1), the spin–1 content is isolated by a transverse, typed vector block and a spin–1 Riesz selector, exactly paralleling the spin–2 and spin–0 cases. Let $\Pi^{[\mathrm{T}]}$ denote the typed transverse projector for the internal vector bundle (commuting with the triad and provenance projectors), and let K_{vec} be the linearized connection kinetic operator on the realized weave configuration. Define the transverse block

$$K^{(1)}_{\mathrm{vec}} := \left(\mathsf{P}_{\mathrm{phys}}\Pi^{(\mathrm{spec})}\Pi^{[\mathrm{T}]}\right) K_{\mathrm{vec}} \left(\Pi^{[\mathrm{T}]}\Pi^{(\mathrm{spec})}\mathsf{P}_{\mathrm{phys}}\right),$$

and let $\mathfrak{S}_1$ be the set of its band–limited *spectral islands* with contours $\{\Upsilon_k\}$ (cf. Definition 10.6). The spin–1 selector is

$$\boxed{\mathsf{P}^{(1)}_{\mathrm{spec}} := \sum_{k\in\mathfrak{S}_1} \frac{1}{2\pi i} \oint_{\Upsilon_k} \left(K^{(1)}_{\mathrm{vec}} - z\right)^{-1} dz} \qquad \text{(cf. Definition 10.7).}$$

Projector–fields for the mition/tantron are obtained by sandwiching the connection operators with $\mathsf{P}^{(1)}_{\mathrm{spec}}$ and the sector–typed projectors. Longitudinal components are BRST–exact and decouple on $\mathcal{H}_{\mathrm{phys}}$ (Nielsen/BRST hygiene), so poles/residues read off from the transverse block are *gauge–parameter independent* on certified plateaus and *stable under admissible retunings* (cf. Propositions 10.9 and 10.10 and Corollary 10.11). TT–isolation is automatic since $\Pi^{[\mathrm{TT}]}_{\Sigma}$ acts on symmetric 2–tensors: $\Pi^{[\mathrm{TT}]}_{\Sigma}\,\mathsf{P}^{(1)}_{\mathrm{spec}} = 0$ (cf. Definition 10.3). As in the spin–2 and spin–0 cases, vector–sector *meters* and *onsets* may be defined from $\mathsf{P}^{(1)}_{\mathrm{spec}}$, inheriting calibration and robustness (cf. Definition 10.82 and Corollary 10.11).

Synthesis. The certified spectrum is thus balanced across the dual substrate. From Φ (Gaiamiti) emerge the massless spin–2 graviton and the massive spin–0 Gaiaton; from Θ (Tantrakyma) emerges the kymon family with the Chrono–Kymon providing the τ–kairos vector register. The τ–kairos binds these contributions into a single constitutive response—scalar content from the Gaiaton and vector content from the Chrono–Kymon—subject to TT–nullity and the typed commutation rules of the weave (Definitions 10.2 and 10.4 and Lemma 10.71). In this way the graviton, Gaiaton, Chrono–Kymon, and τ–kairos appear as interlocking manifestations of the same (Φ, Θ) architecture, each carrying distinct spin and dynamical roles while remaining inseparable from the constitutive chronogeometry that unifies them.

Predicted Regimes of Operation for the τ–Kairos

Framework stance (precision). The temporal/coherence fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ is TT–null, $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ (eq. (10.90) and Sections 10.3 and 10.4), and decomposes constitutively as

$$\hat{\tau}_{\mu\nu} = S_{\mu\nu}[\hat{\varphi}_A] \;\oplus\; A_{\mu\nu}[\hat{K}^{(\tau)}],$$

with the Chrono–Kymon field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$ encoding antisymmetric temporal curvature (Definitions 10.4, 10.13 and 10.57 and Section 10.7). Parasymmetric execution $\mathscr{E}_\bullet$ stamps each admitted type $\chi \in \{\tau_S, \tau_A, K^{(\tau)}_{\mathrm{T}}, K^{(\tau)}_{\mathrm{L}}\}$ with a T–L–O triple $\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$ (Definitions 9.153 and 10.94 and Proposition 10.35); the onset $(r^\star, t^\star)$ is read from the meters $\upsilon^{(a)}_{\mathrm{Synthesis}}$, $\upsilon^{(LS)}_{\mathrm{Synthesis}}$, $\upsilon^{(LS)}_{\mathrm{Agreement}}$ (Definition 9.153). Crucially, *no additional spin–2 radiation* is predicted ($\mathcal{P}^{(2)}[\hat{\tau}] = 0$); the graviton remains the unique TT carrier (Section 10.17.8).

1. Microscopic Quantum Systems

Narrative. In laboratory settings that sustain quantum coherence, the τ–kairos operates as a phase–coherence modulator rather than as a classical force. Observable signatures include orientation– and history–dependent shifts in atom–interferometer phases (cf. Berry [24] and Pancharatnam [23]) and a geometry–tied dephasing channel for qubits, distinguishable from standard noise by its dependence on local temporal curvature.

T–L–O view (precision). *Type:* vector (τ_A, $K^{(\tau)}_{\mathrm{T}/L}$) for torsional/antisymmetric effects; scalar (τ_S) for trace/coarse–graining shifts (Definitions 10.4 and 10.13). *Location:* laboratory arena / instrument tags on the realized weave configuration. *Onset:* $(r^\star, t^\star)$ when the parasymmetric meters cross threshold (Definition 9.153). *Constraint:* TT purity remains intact ($\mathcal{W}_{\mathrm{TT\text{–}purity}} \approx 0$; Lemma 10.17); no extra GW polarizations (Section 10.17.8).

2. Early–Universe Cosmology

Narrative. In ultra–early (relational) epochs (table 9.3), temporal phase–flow can rival spatial curvature. The τ–kairos may seed *non–tensorial* imprints in primordial observables—e.g. scalar/vector contributions to CMB polarization anisotropies [439]—and feed characteristic structure into the stochastic GW background through non–TT couplings [501].

T–L–O view (precision). *Type:* τ_S (scalar) and $\tau_A/K^{(\tau)}$ (vector), admitted via Definition 10.94. *Location:* cosmological cone sheets determined by $\bar{\Sigma}$. *Onset:* early–epoch meter crossings yield wide coherence windows. *Constraint:* TT selection $\mathcal{P}^{(2)} \circ D_\Theta \Sigma = 0$ is preserved (eq. (10.101)); the graviton sector remains purely tensorial.

3. Near Black–Hole Horizons

Narrative. Near horizons, strong curvature and state–dependent coherence amplify τ–kairos sensitivity. Phase/entanglement structures of Hawking quanta can be modulated [87], informing information–paradox diagnostics [231, 138, 337]. Conversion proceeds through non–TT channels and through off–diagonal blocks of the weave's matrix propagator.

T–L–O view (precision). *Type:* primarily vector (τ_A, $K^{(\tau)}_{\mathrm{T}}$) via $\hat{\mathcal{F}}^{(\tau)}$; scalar τ_S if background profiles vary. *Location:* horizon–proximate sheets/tags on $\mathfrak{P}$ (and $\mathfrak{P}_\partial$ if used). *Onset:* meter–driven windows aligned with local redshift/time–dilation scales. *Mechanism:* mixing in off–diagonal correlators of the graviton–temporal matrix (Definition 10.182 and eq. (10.112)); TT purity guarded by $\mathcal{W}_{\mathrm{TT\text{–}purity}}$ (Lemma 10.17).

4. The Classical Macroscopic Limit

Narrative. Environmental decoherence averages temporal phase–flow to negligible levels [170, 282]. The effective radiative theory reduces to the purely tensorial TT sector carried by the graviton, reproducing GR phenomenology [7, 146].

T–L–O view (precision). *Type:* τ_S, τ_A fail admission (meters sub–threshold) or receive late/empty Onset windows. *Location:* macroscopic arenas with coarse tags. *Outcome:* $\mathrm{TLO}^{[\gamma]}$ is the sole radiative stamp; no reclassification errors (cf. Definition 10.26).

Synthesis. The domains above are precisely where the parasymmetric pipeline predicts enhanced τ–kairos visibility: where coherence persists and meters furnish early/strong onsets. These predictions respect TT isolation (eqs. (10.90) and (10.101)), typed admission (Definition 10.94), and the matrix–propagator architecture (Definition 10.182), *without* introducing extra GW polarizations and while remaining Nielsen/BRST–safe by design.

Proposition 10.150 (Predicted operational regimes of the τ–kairos)**.** *Let $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ denote the TT–null temporal/coherence fluctuation of the chronogeometric tensor (cf. eqs. (10.90), (10.100) and (10.101)), with scalar and vector components $S_{\mu\nu}[\hat{\varphi}_A]$ and $A_{\mu\nu}[\hat{K}^{(\tau)}]$ inherited respectively from the Gaiamiti and Tantrakyma substrates (see Section 10.16 and Definitions 10.4 and 10.13). Then:*

(i) Quantum–coherent dominance

τ–kairos couples constitutively to temporal phase flow rather than directly to classical stress–energy. Its effects therefore dominate only in regimes of sustained quantum coherence, where phase correlations cannot be coarse–grained away. T–L–O view: *$\chi \in \{\tau_S, \tau_A, K_{\mathrm{T}}^{(\tau)}, K_{\mathrm{L}}^{(\tau)}\}$ are admitted iff the hyperbolicity/cone and BRST conditions hold (Definition 10.94); onset $(r^\star, t^\star)$ is extracted from the parasymmetric meters $v^{(a)}_{\mathrm{Synthesis}}, v^{(LS)}_{\mathrm{Synthesis}}, v^{(LS)}_{\mathrm{Agreement}}$ (Definition 9.153), defining the coherence window in which $\hat{\tau}$ becomes operational.*

(ii) Microscopic quantum systems

In laboratory experiments sustaining coherence (e.g. atomic interferometry, entangled qubits), τ–kairos contributes orientation–dependent phase shifts and decoherence channels absent in the purely TT sector; these can appear as effective Berry/Pancharatnam–like phases of quantum–geometric origin [24, 23] (cf. Sections 10.3 and 10.4). T–L–O view: Type $=$ *τ_A (vector/antisymmetric) or τ_S (scalar/trace);* Location *from instrument/arena tags;* Onset *when meter thresholds are crossed (Definition 9.153).*

(iii) Early–universe cosmology

During ultra–early relational epochs (table 9.3), τ–kairos dynamics may rival curvature dynamics, leaving non–tensorial signatures in CMB polarization and contributing to the stochastic GW background [439, 501]. T–L–O view: Type $\in \{\tau_S, \tau_A\}$, Location *on cosmological cone sheets, with wide* Onset *windows when meters are large (parasymmetric synthesis).*

(iv) Near black–hole horizons

In the vicinity of event horizons, τ–kairos can modulate the coherence/entanglement structure of Hawking quanta, impacting information–paradox diagnostics [87, 231, 138, 337]. T–L–O view: *predominantly* Type $=$ *τ_A (via $K^{(\tau)}$ and its field strength),* Location

on horizon–proximate sheets/tags, with Onset *tied to local redshift/time–dilation scales (Definition 9.153).*

(v) Classical macroscopic limit

In decohered macroscopic regimes, environmental averaging suppresses τ–kairos contributions [170, 282], leaving the TT graviton sector $\hat{\gamma}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}]$ as the effective radiative carrier (cf. Section 10.17.8), consistent with GR phenomenology [7, 146]. T–L–O view: *τ-types fail admission or receive late/empty onset windows; only* $\mathrm{TLO}^{[\gamma]}$ *is radiative (Type from QI–QIV, Location from diagnostic realized reference configuration metadata, Onset from meters; cf. Definition 10.26).*

Proof sketch. (1) follows from TT isolation, $\mathcal{P}^{(2)}[\hat{\tau}] = 0$ and $\mathcal{P}^{(2)} \circ D_\Theta \Sigma = 0$ (eqs. (10.90) and (10.101)), which forbids direct spin–2/stress–energy coupling and confines $\hat{\tau}$ to scalar/vector coherence. (2)–(4) apply this structural constraint in regimes where the parasymmetric meters certify early/strong onset and the typed admission gate is passed (Definitions 9.153 and 10.94); signatures therefore appear as phase/entanglement modulations in the non–TT channel, not as extra GW polarizations. (5) uses standard decoherence: meter response drops below threshold, typed admission fails or yields trivial onset, and only the TT graviton sector remains dynamically radiative (Section 10.17.8). Law–side TT purity is monitored by $\mathcal{W}_{\text{TT–purity}}$ (Lemma 10.17), ensuring no hidden TT leakage. □

The Gaiamiti Field as the Architect of Spacetime

The *Gaiamiti field* $\hat{\mathbf{\Phi}}(x)$ is the exclusive source of purely geometric excitations in the IQR framework. Its potential $\mathcal{V}_\Phi$ and vacuum manifold $\mathcal{M}_{\text{vac}}$ determine the emergent chronogeometric background $\bar{\Sigma}_{\mu\nu}$ and the spectrum of geometric quanta (Definition 5.54 and Section 10.17.6). When the symmetries of $\mathcal{V}_\Phi$ are spontaneously broken, two canonical fluctuation types follow from the standard SSB logic on curved backgrounds [244, 7]:

Massless spin–2 graviton ($\hat{h}_{\mu\nu}$) Long–range geometry must be mediated by a massless spin–2 carrier sourced by a conserved rank–2 current; in our formalism this is the TT-projected metric fluctuation,

$$\hat{h}_{\mu\nu} \;:=\; \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\hat{g}_{\mu\nu},$$

with propagation captured by the TT graviton two–point function G^{TT} (eqs. (10.28) and (10.131) and Corollary 10.20). Within the Gaiamiti sector, the graviton's *masslessness* is not postulated but follows from the Goldstone mechanism for broken geometric vacuum symmetries (Section 10.17.9 and Proposition 11.29; see also [415, 502]).

Gaiaton (massive spin–0 apeiron) Fluctuations of the Gaiamiti field Φ orthogonal to the vacuum manifold $\mathcal{M}_{\text{vac}}$ of the potential $\mathcal{V}_\Phi$ (the trace/radial directions in field space) produce the scalar apeiron mode, canonically identified as the *Gaiaton* (Definitions 6.61 and 10.70). On the realized weave configuration it is realized in the τ–kairos *scalar* typed family $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ (Definition 10.4) and is isolated spectrally by the spin–0 Riesz selector acting on the τ–scalar kinetic generalized eigen-operator pair $K^{(0)}_\tau$, yielding the mass and projector of the channel (Definition 10.68). CP– and triad–resolved projectors/fields are provided by Definition 10.69, and TT–orthogonality is enforced by

Lemma 10.71, so no TT contamination occurs. The realized mass is governed by the curvature (Hessian) of $\mathcal{V}_\Phi$ at $\mathcal{M}_{\rm vac}$ in exact analogy with standard SSB ([244]), while any allowed scalar mixing proceeds only through typed, triad–compatible couplings in the weave (Section 10.19.6, Definition 10.2, and Proposition 9.202).

Absence of spin–1 Gaiamiti excitations The typed menu for the Gaiamiti ($\Phi\Phi$) sector admits the transverse–traceless (TT) graviton entry (spin–2) and the scalar/trace (apeiron) entry (spin–0), but *no* vector register (Definition 9.195). Consequently, physical Gaiamiti excitations reside only in the symmetric metric channel $\hat{g}_{\mu\nu}$ as either the TT Goldstone/tangential mode or the scalar (apeiron) mode; a spin–1 Gaiamiti register is not part of the admissible typed layer.

Vector/longitudinal coherence is carried instead by the τ–kairos family through the Chrono–Kymon typed pair $A^{(\pm)}$ (Definition 10.4). In the constitutive split of the temporal/coherence tensor,

$$\hat{\tau}_{\mu\nu} = S_{\mu\nu}[\hat{\varphi}_A] \;\oplus\; A_{\mu\nu}[\hat{K}^{(\tau)}],$$

the τ channel has spin content $0 \oplus 1$ and is TT–null by construction, i.e. $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ (Definitions 10.4 and 10.13, Sections 10.3 and 10.4, and eq. (10.90)). The antisymmetric piece is encoded by the Chrono–Kymon field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$ (cf. Section 10.7), providing the unique vector register of the weave while remaining orthogonal to the metric TT sector.

Any would–be spin–1 content tied to Gaiamiti metric fluctuations fails to survive in the physical cohomology $H^0(\hat{Q}_{\rm BRST})$ for two independent reasons. (i) Longitudinal vector pieces are gauge (BRST–exact) and therefore vanish in H^0. (ii) Antisymmetric/torsional pieces are, by the constitutive map, routed into the τ–kairos vector block $A_{\mu\nu}[\hat{K}^{(\tau)}]$, not into the symmetric metric channel (Definitions 10.4 and 10.13). Typed orthogonality and triad–compatibility ensure this routing is clean and gauge–parameter independent on certified plateaus (Proposition 9.202 and Definition 10.2).

TT purity further guarantees that no scalar or vector leakage contaminates the graviton readout. The typed $\Pi^{[\rm TT]}_{\bar{\Sigma}}$–null lemmas enforce $\Pi^{[\rm TT]}_{\bar{\Sigma}} S_{\mu\nu}[\cdot] = 0$ and $\Pi^{[\rm TT]}_{\bar{\Sigma}} A_{\mu\nu}[\cdot] = 0$ (Lemma 10.123), while orthogonality/completeness of the typed projectors prevents cross–mixing (Proposition 9.202). Hence the only radiative tensor degree of freedom in the metric channel is the massless spin–2 graviton, identified as the TT Goldstone/tangential mode of the Gaiamiti sector (eq. (10.28), Section 10.17.8, and Definition 10.167).

Consequence. Within the certified, typed weave, the Gaiamiti ($\Phi\Phi$) physical spectrum comprises the spin–2 TT graviton and the spin–0 apeiron (Gaiaton) channels (Definitions 9.195, 10.69 and 10.70), while all spin–1 content resides in the τ–kairos via $A^{(\pm)}$ (Definition 10.4). There is therefore *no spin–1 apeiron* in this framework.

$$\text{Gaiamiti } (\Phi\Phi) \text{ physical spectrum} = \{\text{spin-2 TT graviton}\} \cup \{\text{spin-0 apeiron (Gaiaton)}\},$$
$$\text{spin-1 lives in } \tau \text{ via } A^{(\pm)}.$$

The Gaiamiti field furnishes the full geometric stage: a symmetry–broken vacuum supporting (i) massless, channel–resolved spin–2 gravitons as geometric Goldstone modes (Sections 10.17.6 and 10.17.9) and (ii) a massive radial scalar; vector content is excluded by the canonical bimodal split and TT selection rules [502, 244, 7].

Related — Mition (spin–1 internal connection quantum). The **mition** is a spin–1 excitation of the **relational bundle connection** that enters the covariant derivative, not a substrate excitation of $(\hat{\mathbf{\Phi}})$ (cf. eq. (10.1)). Its mass is generated via internal gauge SSB (BEH) triggered by the Gaiamiti vacuum (cf. Definitions 9.252, 9.258 and 9.261). On the realized weave configuration $(\mathcal{R})$ (cf. Definition 10.1), the spin–1 content is isolated by a transverse, typed vector block and a spin–1 Riesz selector built from spectral islands (cf. Definitions 10.6 and 10.7); the resulting projector commutes with provenance/typed/triad projectors and is Nielsen-flat and retune-stable (cf. Propositions 10.9 and 10.10 and Corollary 10.11). TT isolation is automatic since $(\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}})$ acts on symmetric 2-tensors (cf. Definition 10.3), so the graviton channel is unaffected.

The Tantrakyma Field as the Source of Substance

The *Tantrakyma field* $\hat{\mathbf{\Theta}}(x)$ sources matter and temporal–coherence excitations in the typed weave. Its potential $\mathcal{V}_\Theta$ and the band–limited quadratic kernel determine the spectrum of its quanta (kymons) via the background–fluctuation split and second–variation dynamics (Definitions 9.310 and 10.204 and Section 10.18.6). Two–point functions in the typed (modal) basis and in projected "species" channels are encoded by the matrix propagator $\mathbf{\Delta}_\Theta$ and by the projected propagators Δ_p, respectively (Definitions 10.203 and 10.208; cf. [244, 7]).

Goldstone modes and the Higgs mechanism (matter sector). Spontaneous breaking of a continuous symmetry of the Tantrakyma potential $\mathcal{V}_\Theta$ produces massless Goldstone modes in the Tantrakyma sector, as read from the second–variation analysis on the Σ–realized background $\bar{\Sigma}$ (Definitions 9.310 and 10.204 and Section 10.18.6). For *global* breaking the modes appear as propagating, massless Goldstone kymons; for *local* (gauge) breaking the would–be Goldstones are removed from the asymptotic spectrum and reappear as the longitudinal polarizations of the corresponding gauge vectors (unitary–gauge Higgs mechanism). The construction is carried out within the typed projector framework of the weave (Definition 9.116) and is the standard SSB/Higgs paradigm adapted to the expectation–valued geometry $\bar{\Sigma}$ (see [244, 7, 415]).

Massive excitations. Following SSB (and, where applicable, Higgsing), the remaining Tantrakyma excitations become massive eigenmodes of the local mass operator $\mathcal{M}_\Theta(x)$ (eq. (10.157)). Their masses are read from the pole structure of the projected propagators Δ_p (Section 10.18.5).

1. **Massive spin–0 Higgs kymon (radial scalar).** The radial fluctuation in the Tantrakyma potential—an observable scalar remnant of SSB—acquires mass from the Hessian of $\mathcal{V}_\Theta$ at the vacuum (Section 10.18.6; [244]).

2. **Massive spin–1 Chrono–Kymon (vector).** The vector excitation of the Tantrakyma field furnishes the τ–kairos vector register via the typed family $A^{(\pm)}$ (Definition 10.4). Its field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$ sources the antisymmetric temporal sector and contributes to $\hat{t}_{[\mu\nu]}$ (anisotropic phase flow/"temporal torsion"), in agreement with the scalar–vector constitutive decomposition of the τ–kairos channel and with the operator definition of temporal curvature (Sections 10.3, 10.4 and 10.7 and Definitions 10.4, 10.13 and 10.57).

No spin–2 kymons. The Tantrakyma sector carries *no* irreducible spin–2 excitations: its contributions to the chronogeometric response are strictly non–TT, $\hat{\tau}_{\mu\nu} \in \mathbf{0} \oplus \mathbf{1}$ with $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ (Sections 10.3 and 10.4 and eq. (10.90)). Accordingly, $\mathcal{P}^{(2)}[\delta\hat{\boldsymbol{\Theta}}] = 0$ at the level of physical (typed, BRST–closed) observables, and the radiative spin–2 (TT) sector is exclusively geometric in the Gaiamiti channel—the graviton $\hat{\gamma}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}]$ (Definition 10.167 and Section 10.17.8).

Triadic organisation and state dependence. Propagation and mixing for Tantrakyma excitations are triad–resolved into spectral, vacuum, and correlational channels in the typed weave (Definitions 10.2 and 10.208). State dependence enters through the expectation–valued background $\bar{\Sigma}_{\mu\nu}$ and the local mass operator $\mathcal{M}_\Theta(x)$ (Section 10.18.6). Backreaction is mediated by the mixed (off–diagonal) blocks of the chronogeometric/graviton matrix propagator while preserving the TT selection rules (Section 10.17.5, Definition 10.182, and eqs. (10.90) and (10.112)); thus, TT purity of the graviton channel is maintained even in the presence of matter/coherence couplings.

Related — Tantron (spin–1 internal connection quantum). The *tantron* is a spin–1 excitation of the *relational bundle connection* that enters the Tantrakyma covariant derivative—*not* a substrate excitation of $(\hat{\boldsymbol{\Theta}})$ itself (cf. eq. (10.2) and Definition 9.348). Its mass is generated via internal gauge SSB (BEH) triggered by the Tantrakyma vacuum (cf. Definitions 9.252 and 9.261). On the realized weave configuration $(\mathcal{R})$, the tantron's *transverse* content is isolated by a spin–1 Riesz selector built from spectral islands of the connection's vector block, exactly paralleling the spin–2 and spin–0 cases (cf. Definitions 10.6 and 10.7). Longitudinal components are BRST–exact and decouple on $(\mathcal{H}_{\text{phys}})$, so pole locations/residues in the transverse block are *gauge–parameter independent* on certified plateaus and *stable under admissible retunings* (cf. Propositions 10.9 and 10.10 and Corollary 10.11). TT–isolation is automatic because $(\Pi^{[\text{TT}]}_{\bar{\Sigma}})$ acts on symmetric 2-tensors (cf. Definition 10.3), leaving the graviton channel unaffected.

The Deeper Principle at Play

Spin labels *alone* do not determine ontological identity in the typed weave. What matters is the *field of origin*—the geometric substrate $\hat{\boldsymbol{\Phi}}$ (Gaiamiti), the matter/coherence substrate $\hat{\boldsymbol{\Theta}}$ (Tantrakyma), or the *relational bundle connection* that enters the covariant derivatives (cf. eqs. (10.1) and (10.2))—together with the associated typed/constitutive selection rules. Thus two quanta may share the same spin and tensor type yet belong to distinct sectors

with different couplings, causal support, and propagation laws (Definitions 10.4, 10.13 and 10.182 and Sections 10.17.5 and 10.18.6; cf. [244, 7, 502]). Sectorial identity is fixed on the Σ–realized background $\bar{\Sigma}$ using the typed projectors and triad decomposition from Chs. 10–11 (Definitions 9.60, 9.116 and 10.2; see also the realized weave configuration Definition 10.1).

Concretely:

Geometric origin (Gaiamiti) The massless spin–2 graviton is the TT projection of the metric fluctuation, $\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}] = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$, the Goldstone/tangential mode of the Gaiamiti sector (Definition 10.167, eq. (10.28), and Section 10.17.8). The massive spin–0 *Gaiaton* is the apeiron (radial/trace) scalar realized in the τ–kairos scalar typed family and isolated by the spin–0 Riesz selector on $K^{(0)}_{\tau}$ (Definitions 10.68 to 10.70). Both are *geometric* (Gaiamiti) quanta, with TT–purity protecting the graviton from scalar/vector leakage (Lemma 10.123 and Proposition 9.202; cf. Definition 10.3).

Matter/coherence origin (Tantrakyma) The τ–kairos tensor carries exclusively spin $0 \oplus 1$ and is TT–null, $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ (Sections 10.3 and 10.4 and eq. (10.90)). Its *vector* register is the Chrono–Kymon typed family $A^{(\pm)}$ with field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$ (Definitions 10.4 and 10.57 and Section 10.7); its *scalar* register is a matter–induced phase fluctuation in the temporal channel, *not* the Gaiaton (despite sharing spin–0), and couples through the τ–channel blocks of the matrix propagator (Definitions 10.4, 10.13 and 10.182).

Higgs kymon (Tantrakyma scalar) Spontaneous symmetry breaking of the Tantrakyma potential $\mathcal{V}_{\Theta}$ produces Goldstone modes (global case) or longitudinal gauge polarizations (local case), with the *radial* scalar acquiring a mass from the Hessian of $\mathcal{V}_{\Theta}$ at the vacuum—the Higgs kymon of the matter sector (Section 10.18.6; see [244, 7, 415]).

Relational–connection origin (internal vectors) The *mition* (Gaiamiti–sourced) and *tantron* (Tantrakyma–sourced) are spin–1 excitations of the *relational bundle connection*—*not* substrate quanta of $\hat{\mathbf{\Phi}}$ or $\hat{\mathbf{\Theta}}$ (cf. eqs. (10.1) and (10.2) and Definitions 9.258 and 9.348). Their masses arise via internal gauge SSB (BEH) (Definitions 9.252 and 9.261). On the realized weave configuration (Definition 10.1) their *transverse* content is isolated by a spin–1 Riesz selector constructed from spectral islands of the vector connection block, exactly paralleling the spin–2 and spin–0 cases (Definitions 10.6 and 10.7). The resulting projectors commute with provenance/typed/triad projectors and are Nielsen–flat and retune–stable (Propositions 10.9 and 10.10 and Corollary 10.11); TT isolation holds because $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ acts on symmetric 2–tensors (Definition 10.3).

Hence, particle classification in the weave is *sectorial*: a quantum is indexed by $(\text{origin}, \text{channel}, \text{spin})$, not by spin alone. In the present context,
The TT selection rules ensure radiative spin–2 content remains purely geometric, while scalar/vector τ–kairos modes encode state–dependent coherence without adding GW polarizations (eqs. (10.90) and (10.101) and Section 10.17.8). Typed orthogonality and the triad commutations keep the channels separated and BRST/Nielsen–safe on certified plateaus (Propositions 9.97 and 9.202 and Definition 10.2); the internal–connection (mition/tantron)

Quantum	Origin	Channel (typed)	Spin
Graviton (TT)	Gaiamiti	metric/TT	2
Gaiaton (apeiron)	Gaiamiti	τ–scalar	0
Chrono–Kymon	Tantrakyma	τ–vector $A^{(\pm)}$	1
Higgs kymon	Tantrakyma	matter scalar	0
Mition	Gaiamiti-sourced (BEH)	internal conn., transverse vector	1
Tantron	Tantrakyma-sourced (BEH)	internal conn., transverse vector	1

projectors commute with the same provenance/typed/triad structure and remain TT–orthogonal by construction (Definitions 10.3 and 10.7 and Propositions 10.9 and 10.10).

Table 10.1: Typed classification of emergent quanta and their geometric/matter roles within the weave.

Excitation	Parent Field	Spin	Contributes to	Nature / Selector
Graviton	Gaiamiti ($\hat{\mathbf{\Phi}}$)	2	Metric TT sector: $\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}] = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$	Massless Goldstone/tangential mode of Gaiamiti (Definition 10.167 and eq. (10.28))
Gaiaton (apeiron scalar)	Gaiamiti ($\hat{\mathbf{\Phi}}$)	0	τ–kairos *scalar* typed block $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ (Definition 10.4)	Massive scalar; isolated by spin–0 Riesz selector on $K^{(0)}_{\tau}$ (Definitions 10.68 to 10.70)
Chrono–Kymon	Tantrakyma ($\hat{\mathbf{\Theta}}$)	1	τ–kairos *vector* block $A^{(\pm)}$; field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$	Vector (helicity $\pm$); Maxwell/Proca–type on $\bar{\Sigma}$; strictly non-TT (Definitions 10.4 and 10.57, Sections 10.7 and 10.18.6, and eq. (10.90))
Higgs kymon (radial scalar)	Tantrakyma ($\hat{\mathbf{\Theta}}$)	0	Matter scalar channel (radial mode of $\mathcal{V}_\Theta$)	Massive scalar; mass from Hessian of $\mathcal{V}_\Theta$ at the vacuum (Section 10.18.6)

How Kymons Make Matter and Write Time

Following the typed identification of the τ–vector register (Chrono–Kymon) and its field strength (Definitions 10.4 and 10.57 and Section 10.7), it is important to foreground the *dual role* of *kymons*—the excitations of the Tantrakyma field Θ. On one hand, they generate the spectrum of massive matter degrees of freedom; on the other, they inscribe themselves into the temporal/coherence channel through the τ–kairos tensor. These functions are *linked but not identical*, and their interplay is essential for understanding how matter and temporal coherence are co–woven within the dual substrate (Φ, Θ) (Section 10.18.6 and Definitions 10.4 and 10.13).

(A) Mass generation (matter side). Projected Tantrakyma modes $\delta\hat{\mathbf{\Theta}}^{(p)}$ acquire masses through the local mass operator $\mathcal{M}_\Theta(x)$, the Hessian of the potential $\mathcal{V}_\Theta$ around the vacuum background (eq. (10.157), Definition 10.204, and Section 10.18.6). The eigenvalue problem

$$\boxed{\mathcal{M}_\Theta(x)\,u_p(x) = m_p^2(x)\,u_p(x) \quad\Longrightarrow\quad \text{poles of } \Delta_p(k) \;\text{ at }\; k^2 = m_p^2(x),} \tag{10.77}$$

Table 10.2: Unified duality of emergent quanta and their properties. The Gaiamiti and Tantrakyma fields furnish complementary registers whose excitations interlock in the constitutive split.

Feature	**Geometric Sector (Gaiamiti field Φ)**	**Matter & Coherence Sector (Tantrakyma field Θ)**
Fundamental Role	Chronogeometry / metric sector ($\bar{\Sigma}$, TT channel) (Definition 9.60)	Substance & temporal coherence (kymons, τ–vector) (Section 10.18.6 and Definition 10.4)
Primary Quanta	**Apeiron** $\rightarrow$ **Gaiaton** (scalar)	**Kymon** (matter/coherence)
Emergent Spectrum	Massless **spin–2 graviton**; massive **spin–0 Gaiaton** (apeiron scalar) (Definitions 10.70 and 10.167 and eq. (10.28))	General **kymon** excitations; distinguished **spin–1 Chrono–Kymon**; **Higgs kymon** (spin–0) (Section 10.18.6 and Definitions 10.4 and 10.57)
Spin Domain	Extremes 0 and 2 (no vector register in $\Phi\Phi$) (Definition 9.195)	Intermediate 0 and 1 (strictly non-TT in τ) (eq. (10.90) and Sections 10.3 and 10.4)
Mechanism	SSB of $\mathcal{V}_\Phi$: TT Goldstone (graviton) + radial scalar (Gaiaton) (eq. (10.28) and Definition 10.70)	SSB of $\mathcal{V}_\Theta$: Goldstones / longitudinal gauge modes + Higgs kymon (Section 10.18.6)
Contribution to τ–kairos $\hat{\tau}_{\mu\nu}$	**Spin–0** scalar piece via $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ (Gaiaton channel) (Definitions 10.4 and 10.69)	**Spin–1** vector piece via $A^{(\pm)}$ (Chrono–Kymon) with $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ (Definitions 10.4 and 10.57 and Section 10.7)

determines the mass spectrum of emergent matter excitations, with u_p the species eigenvectors and Δ_p the projected propagators (Definitions 10.203 and 10.208). Thus the kymon family functions as the dynamical source of materiality in the Tantrakyma sector (for the SSB/Higgs narrative and the radial *Higgs kymon*, see Section 10.18.6).

(B) Temporal component (coherence side). Simultaneously, Tantrakyma fluctuations imprint upon the *temporal/coherence tensor* $\hat{\tau}_{\mu\nu}$. In the *vector channel* this imprint is carried by the *Chrono–Kymon*, extracted by the τ–vector typed projector from Tantrakyma fluctuations,

$$\hat{K}^{(\tau)}_{\mu} \;:=\; \left(\Pi^{[A]}_{\tau}\,\delta\hat{\mathbf{\Theta}}\right)_{\mu} \qquad \text{(helicity basis } A^{(\pm)} \text{ in } \textit{Definition } 10.4\text{)},$$

whose field strength yields antisymmetric temporal curvature,

$$\boxed{\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} \;=\; 2\,\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]},} \tag{10.78a}$$

$$\boxed{\hat{t}_{[\mu\nu]} \;=\; \chi_{\tau}\,\hat{\mathcal{F}}^{(\tau)}_{\mu\nu},} \tag{10.78b}$$

with χ_τ fixed by the constitutive map (Definitions 10.4 and 10.13 and Section 10.7). By contrast, the *scalar* temporal channel inherits its content from the Gaiamiti apeiron (the *Gaiaton*) realized in the τ–scalar typed family and isolated by the spin–0 selector (Definitions 10.68 and 10.70). Altogether, the constitutive decomposition

$$\hat{\tau}_{\mu\nu} \;=\; S_{\mu\nu}[\hat{\varphi}_A] \;\oplus\; A_{\mu\nu}[\hat{K}^{(\tau)}]$$

(Definitions 10.4 and 10.13 and eq. (10.90)) shows that τ–kairos is a mixed object: scalar feed from Gaiamiti (Gaiaton), vector feed from Tantrakyma (Chrono–Kymon).

(B') Clarification: Chrono–Kymon vs. internal connection vectors. The *Chrono–Kymon* is a τ–channel vector extracted from Tantrakyma fluctuations by typed projectors and governs *temporal/coherence* dynamics (Definitions 10.4 and 10.57). It is *distinct* from the spin–1 internal connection quanta—the *mition* and *tantron*—which originate from the *relational bundle connection* entering the covariant derivatives (not from $\hat{\mathbf{\Phi}}$ or $\hat{\mathbf{\Theta}}$) (eqs. (10.1) and (10.2) and Definitions 9.258 and 9.348). On the realized weave configuration (Definition 10.1) these internal vectors are isolated by a *spin–1* Riesz selector built from spectral islands of the connection's vector block (Definitions 10.6 and 10.7); their transverse projectors commute with provenance/typed/triad projectors and are Nielsen–flat and retune–stable (Propositions 10.9 and 10.10 and Corollary 10.11). TT isolation holds because $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ acts on symmetric 2–tensors (Definition 10.3). Thus, *Chrono–Kymon* (τ–vector) and *mition/tantron* (internal connection vectors) are separate origins, channels, and ledgers—no duplication occurs.

(C) Selection rule and non–duplication. Despite this dual role, a strict separation persists: kymons *do not* generate spin–2 radiation. The TT projector annihilates all τ–kairos contributions,

$$\boxed{\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0, \qquad \text{gravitational waves:}\;\; \hat{h}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}] = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu},} \tag{10.79}$$

so that GW radiation remains *purely geometric*, confined to the Gaiamiti/graviton TT sector (eqs. (10.90) and (10.101), Definition 10.167, and Sections 10.17.8 and 10.18.7). The kymon imprint is entirely scalar/vector and coherence–driven, never duplicating the spin–2 graviton channel.

Kymons are the fundamental quanta of the Tantrakyma field. They *make matter*, by acquiring masses through $\mathcal{M}_\Theta$ (with the radial *Higgs kymon* as the canonical scalar remnant of SSB), and they *write time*, by sourcing the τ–kairos tensor—most visibly through the spin–1 *Chrono–Kymon*, which imprints torsional/coherence structure on $\bar{\Sigma}$ via $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ (Definition 10.57 and Section 10.7). In this dual role, kymons bridge the material and temporal aspects of the dual substrate: they provide substance to matter while simultaneously modulating the relational timer that synchronizes geometry and quantum coherence (Section 10.16 and Proposition 10.150).

Reciprocity of the Sectors: From Pulse to Wave, From Wave to Form

A central feature of the dual–substrate construction is the *bidirectional traffic* between the geometric (Gaiamiti) and matter/coherence (Tantrakyma) registers. The constitutive split

$$\Sigma_{\mu\nu} = g_{\mu\nu}[\Phi] \;+\; t_{\mu\nu}[\Phi, \Theta]$$

(eq. (10.101) and Section 10.17.4) does not isolate geometry from matter but enables a disciplined reciprocity under strict typed and spin constraints: *no spin–1* in the Gaiamiti (metric) channel and *no spin–2* in the Tantrakyma (τ–kairos) channel (Definition 9.195, eq. (10.90), and Section 10.18.7).

Geometry → Matter (pulse release). On the geometric side, the spin–0 *apeiron* register of Φ—the **Gaiaton**—appears as a scalar pulse of geometric inertia. Certified insertions of the Gaiaton live in the τ–kairos *scalar* typed family $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ and are isolated by the spin–0 Riesz selector on $K^{(0)}_\tau$ (Definitions 10.4 and 10.68 to 10.70). Through the off–diagonal entries of the fourfold inter–modal structure, this scalar geometric energy can *discharge* into matter, feeding *kymons* of the Tantrakyma sector via the interaction action (Definition 10.223), in the same typed, triad–compatible sense used throughout Chs. 10–11.

Matter → Geometry (wave inscription). Conversely, on the matter/temporal side, the **Chrono–Kymon** (spin–1) inscribes back into geometry by writing phase and timing into the temporal block $t_{\mu\nu}[\Phi, \Theta]$. Concretely, the τ–kairos decomposes as

$$\hat{\tau}_{\mu\nu} = S_{\mu\nu}[\hat{\varphi}_A] \;\oplus\; A_{\mu\nu}[\hat{K}^{(\tau)}],$$

with the scalar piece inherited from the Gaiaton channel and the vector piece supplied by the Chrono–Kymon (Definitions 10.4 and 10.13). The latter carries field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$, sourcing the antisymmetric temporal curvature and entering the constitutive map as $\hat{t}_{[\mu\nu]} = \chi_\tau\, \hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ (Definition 10.57 and Section 10.7). This inscription *never* duplicates the graviton: $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ by construction, so GW radiation remains confined to the TT graviton sector (eq. (10.90), Definition 10.167, and Section 10.17.8).

Gatekeeping by τ–kairos. Across both directions, the τ–kairos acts as the gatekeeper of reciprocity. It prescribes *when* exchanges are admissible (coherence/plateau conditions) and *which* channels are open (scalar/vector only), enforcing the typed projector rules and triad commutations (Definitions 10.2 and 10.4 and Propositions 9.97 and 9.202). In this rigorously governed reciprocity—pulse becomes wave, wave becomes form—τ–kairos synchronizes the exchange without violating TT purity or sectorial identity.

Significance and Testable Consequences

The dual role of kymons is conceptually and empirically consequential: it unifies *mass generation* and *temporal coherence* within a single Tantrakyma sector while preserving the purely geometric nature of spin–2 radiation. This synthesis is realized with typed projectors, triad–resolved propagators, and background–field quantization on the expectation–valued geometry $\bar{\Sigma}$ (Definitions 9.60, 10.182 and 10.208; cf. [244, 7, 415, 502]).

Clean polarization prediction (consistency with GR) The TT selection rule

$$\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$$

forbids any additional tensor polarizations from the τ–channel; gravitational waves remain purely TT and geometric (eqs. (10.90) and (10.101) and Section 10.18.7). Thus the framework reproduces the standard two tensor polarizations of GR (Section 10.17.8; cf. [502, 415]). The τ–channel can modulate phases/amplitudes through matrix–propagator couplings without creating extra polarizations (Sections 10.17.5 and 10.17.6).

State–dependent masses and ranges (matter side) Kymon species masses arise as eigenvalues of the Tantrakyma mass operator $\mathcal{M}_\Theta(x)$ (eq. (10.157) and Sections 10.18.5 and 10.18.6), with propagator poles at $k^2 = m_p^2(x)$. In particular, the *Chrono–Kymon* admits a Proca mass $m_{(1)}$ and screening length $\ell_{(1)} \sim m_{(1)}^{-1}$ on $\bar{\Sigma}$ (Section 10.18.6); because $m_{(1)}$ is state–dependent, its effective range is environment–sensitive, making Yukawa–like laboratory/astrophysical probes natural tests.

Temporal torsion phenomenology (coherence side) Via the constitutive relation

$$\hat{t}_{[\mu\nu]} = \chi_\tau \, \hat{\mathcal{F}}^{(\tau)}_{\mu\nu},$$

the Chrono–Kymon sources antisymmetric temporal curvature (Section 10.7 and Definition 10.57). This leads to testable signatures: orientation/history– dependent phase shifts in interferometry, coherence transport in condensed–matter platforms, and phase–locking effects in quantum–optical arrays. In coherence–certified regimes the dynamics are Maxwell/Proca–type on $\bar{\Sigma}$ (Section 10.18.6), enabling quantitative modeling.

Triadic fingerprints Triad–resolved propagation produces distinctive imprints: matter propagators decompose as $\mathbf{\Delta}_\Theta = \sum_a \mathbf{\Delta}_\Theta^{(a)}$, and graviton propagators as $\mathbf{G}_\Sigma^{(2)} = \sum_a \mathbf{G}_\Sigma^{(2,a)}$ (Sections 10.17.6 and 10.18.7). This separation into correlational, vacuum, and spectral channels supports *source tomography*: diagnosing whether an effect is coherence–driven, vacuum–polarization–induced, or energy–momentum–driven.

Dark–sector avenue (conservative) A massive, electrically neutral, spin–1 Chrono–Kymon contributes to $\hat{t}_{\mu\nu}$ as a stress component while leaving the TT graviton sector unchanged. Relic Chrono–Kymons thus constitute a conservative dark–sector candidate—quantum–torsional and consistent with $\bar{\Sigma}$–causality and TT constraints (Section 5.4.5)—with potential imprints in cosmic stress–energy budgets and coherence observables.

In brief. The Tantrakyma sector furnishes *what* matter is (through mass spectra and mixings) and *how* time coheres (through temporal torsion and coherence dynamics). The Gaiamiti sector, by contrast, fixes *how* space curves (via the TT graviton) and supplies the scalar Gaiaton that populates the τ–scalar ledger. The separation is sharp in spin content yet intertwined operationally through channel–resolved propagators, exactly as laid out in Sections 10.17.5 and 10.18.7. This architecture grounds the theory in the standard QFT–in–curved–spacetime toolkit [244, 7, 415, 502], while pointing to testable phenomena in quantum–coherence laboratories, cosmology, and black–hole physics.

Typed portals between ledgers

Definition 10.151 (Typed portals between ledgers)**.** A *portal* is a typed/triad–compatible interaction (or mixing map) that connects two otherwise orthogonal ledgers (e.g. Gaiamiti scalar $\leftrightarrow$ τ–scalar; visible photon $\leftrightarrow$ τ–vector; visible currents $\leftrightarrow$ connection vectors), while preserving the weave's selection rules. Formally, a portal is specified by:

Target/source ledgers and channels
A pair $(\mathcal{L}_{\mathrm{src}}^{[\chi_{\mathrm{src}}]}, \mathcal{L}_{\mathrm{tgt}}^{[\chi_{\mathrm{tgt}}]})$ of typed subspaces selected by the commuting projectors (provenance/typed/triad) on the realized weave configuration (cf. Definitions 9.116, 10.1 and 10.2).

Small strength parameter(s)
Dimensionless couplings $\lambda \in \{\, g_{\mathrm{mix}},\ \epsilon,\ \chi_\tau \lambda', \dots \}$ that control the portal's observable imprint (cf. Section 10.16).

Structural constraints (typed safety)
The portal map P obeys

$$[\mathsf{P}, \Pi^{[\chi]}] = [\mathsf{P}, \Pi_\alpha] = 0, \qquad \mathsf{P} = \mathsf{P}_{\mathrm{phys}}\, \mathsf{P}\, \mathsf{P}_{\mathrm{phys}},$$

with $\Pi^{[\chi]}$ the typed projectors and Π_α the triad projectors (Definitions 9.116 and 10.2), and with $\mathsf{P}_{\mathrm{phys}}$ the BRST–physical projector. If spectral selectors are used (Riesz), P additionally commutes with the island projectors (Definitions 10.6 and 10.7 and Propositions 10.9 and 10.10).

TT–purity (no graviton contamination)
There is no leakage

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \mathsf{P} \;=\; \mathsf{P}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \;=\; 0,$$

so that the portal never feeds the radiative spin–2 channel (cf. Definition 10.3 and eq. (10.90)).

Realization

Either as an *off–diagonal block* in a typed/triad–resolved propagator (matrix Green's function) or as a *diagnostic realized reference configuration Lagrangian* cross–term, both read with the calibrated meters and $\bar{\Sigma}$–weighted inner products (Definitions 10.82, 10.117 and 10.182, Section 10.17.5, and eq. (10.112)).

Remark 10.152 (Canonical portal families with examples)**.** The following instances satisfy Definition 10.151; each is constrained by Section 10.16.

Scalar (Gaiaton–τ) portal

Allowed mixing in the *scalar* block between the Gaiamiti scalar (Gaiaton) and the τ–scalar:

$$\mathbf{G}^{(0)}(k) = \begin{pmatrix} G_{\text{Gaiaton}} & \boxed{g_{\text{mix}}\, G_{\text{cross}}} \\ g_{\text{mix}}\, G_{\text{cross}} & G_{\tau\text{-scalar}} \end{pmatrix},$$

read with the typed projectors (Definitions 10.68 to 10.70 and 10.182 and Section 10.17.5). Equivalently on the diagnostic realized reference configuration: $\delta\mathcal{L} \supset -\frac{1}{2}\, g_{\text{mix}}\, \varphi_{\text{G}} \varphi_{\tau}$.

Vector kinetic–mixing portal

A dark–photon–like, gauge–invariant mixing of field strengths for the τ–vector (Chrono–Kymon):

$$\delta\mathcal{L} \;\supset\; -\frac{\epsilon}{2}\, F^{\mu\nu}_{\text{vis}}\, \mathcal{F}^{(\tau)}_{\mu\nu}, \qquad \hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu} \hat{K}^{(\tau)}_{\nu]},$$

with $\epsilon \simeq g_{\text{mix}}$ (Definitions 10.4 and 10.57 and Section 10.7). An analogous kinetic–mixing portal can be written for the *connection* vectors (mition/tantron) using their field strengths and the spin–1 connection selector (cf. Definition 10.7).

Composition–dependent (fifth–force) portal

Couplings of a light vector to matter currents (e.g. B, L, $B-L$):

$$\delta\mathcal{L} \;\supset\; g_X\, V_\mu\, J^\mu_{B-L},$$

mapping to WEP tests; the effective strength scales as $\alpha_{\text{eff}} \propto g^2_{\text{mix}}$ (with constitutive weights where applicable) (cf. item B in Section 10.16).

Spin / torsion–like portal (antisymmetric temporal channel)

Using the constitutive law

$$\hat{t}_{[\mu\nu]} = \chi_\tau\, \hat{\mathcal{F}}^{(\tau)}_{\mu\nu},$$

one may couple to fermion axial currents (spin), producing torsion–like signatures; constraints effectively bound the *product* $\chi_\tau g_{\text{mix}}$ (cf. item C in Section 10.16).

Oscillatory (ultralight) portal

For a coherent background with frequency $\omega \simeq m_{(1)}$, portals induce phase/frequency modulation in clock and interferometric meters; sensitivities constrain $g_{\text{mix}}\chi_\tau$ across the Hz–mHz band (cf. item E in Section 10.16).

Parity–odd birefringent portal

If the portal plus constitutive transport violates parity, isotropic EB rotation in the CMB bounds $|g_{\text{mix}}\chi_\tau|$ (cf. item F in Section 10.16).

Connection–vector portals (mition/tantron)

The same structures apply to the internal connection vectors isolated by the spin–1 connection selector: kinetic mixing with the visible photon, composition–dependent couplings, and spin–coupled portals, all commuting with the typed/triad projectors and TT–null by construction (cf. Definitions 10.1, 10.3, 10.6 and 10.7).

What Present Data Allow (Mapping into $\{m_{(1)}, \chi_\tau, g_{\rm mix}\}$)

A. Absence of extra GW polarizations ⇒ limits on spin–1 leakage into the TT channel. Multi–event LVK tests (GWTC–3) report signals consistent with pure–tensor GR radiation and no statistically significant scalar/vector polarizations [122]. This supports the TT selection rule $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ and bounds any portal that would feed Chrono–Kymon power into the radiative channel through off–diagonal entries of the graviton/temporal matrix propagator (Definition 10.182, Section 10.17.5, and eq. (10.112)).

B. Weak Equivalence Principle (WEP) ⇒ bounds on long–range, composition–dependent portals. MICROSCOPE reports a null WEP–violation signal, $\eta = (-1 \pm 9) \times 10^{-15}$ at 1σ [503, 504], implying $|\eta| \lesssim 10^{-14}$ overall. Any Chrono–Kymon portal that couples nonuniversally to baryon number, $B-L$, or species number with range $\lambda \gtrsim 10^5\,\mathrm{m}$ must have a strongly suppressed effective Yukawa strength $\alpha_{\rm eff} \propto g_{\rm mix}^2$ (and, where applicable, proportional to the constitutive weight χ_τ). This constrains the ultralight regime $m_{(1)} \lesssim 10^{-12}\,\mathrm{eV}$.

C. Spin–dependent "torsion–like" couplings ⇒ bounds at the 10^{-31} GeV level. Chrono–Kymon exchange that mimics an axial torsion background via the constitutive map $\hat{t}_{[\mu\nu]} = \chi_\tau \hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ (coupled to fermion spin) is bounded by torsion–pendulum and maser experiments. SME analyses bound torsionlike components at $\lesssim 10^{-31}\,\mathrm{GeV}$, limiting $\chi_\tau g_{\rm mix}$ for long–range spin portals [56, 505, 506].

D. Kinetic–mixing / vector–portal limits ⇒ broad constraints on $g_{\rm mix}$. If the Chrono–Kymon kinetically mixes with the photon, $\epsilon \simeq g_{\rm mix}$, dark–photon bounds apply. Global reviews [430, 507] summarize constraints from $\epsilon \sim 10^{-12}$ (radio/cosmology) to $\epsilon \sim 10^{-3}$ (MeV–GeV). Parker Solar Probe measurements constrain 70 kHz–20 MHz particularly strongly, cutting into the ultralight vector sector [508, 430].

E. Clock networks and ultralight coherent backgrounds ⇒ constraints on oscillatory portals. Optical–clock networks bound periodic modulations of fundamental constants sourced by ultralight bosons. Modeling a coherent Chrono–Kymon background $\hat{K}^{(\tau)}_\mu$ with $\omega \simeq m_{(1)}$, non–observation constrains $g_{\rm mix}\chi_\tau$ responsible for phase/frequency shifts. Sensitivity peaks for $m_{(1)} \sim 10^{-22}$–$10^{-15}\,\mathrm{eV}$ (Hz–mHz), complementing plasma/radio probes [509].

F. Cosmic birefringence (isotropic EB rotation) ⇒ bounds on parity–odd transport. CMB polarization analyses suggest a marginal isotropic EB rotation at the few–tenths–degree level [429]. If $\hat{t}_{[\mu\nu]} = \chi_\tau \hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ combined with a portal induces parity–violating temporal transport,

these observations bound $|g_{\rm mix}\chi_\tau|$. Because EB vanishes in parity–conserving ΛCDM, any confirmed nonzero rotation would directly trace τ–kairos–mediated birefringence.

G. Near–future reach (atom–interferometry mid–band). Large–baseline atom–interferometer programs (**MAGIS–100**, **AION**) will probe the GW mid–band (10^{-2}–10 Hz) and ultralight dark–sector fields. Projected reach for vector portals with $m_{(1)} \sim 10^{-15}$–10^{-12} eV can strengthen limits on $g_{\rm mix}$, targeting coherence–preserving regimes where Chrono–Kymon dynamics are most active [510, 511].

Synthesis of constraints. Current data allow a massive spin–1 Chrono–Kymon that modulates temporal phase torsion (χ_τ) and participates in the Tantrakyma spectrum ($\mathcal{M}_\Theta$), subject to: (i) TT silence in the radiative channel (LVK polarization tests) consistent with $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ (eqs. (10.90) and (10.101)); (ii) sufficient universality or short range to evade WEP bounds (MICROSCOPE); and (iii) consistency with kinetic–mixing limits (especially tight in the kHz–MHz window). Spin–pendulum/SME constraints cap long–range spin portals near 10^{-31} GeV. The most promising discovery windows are ultralight coherent backgrounds accessible to clock networks and the GW mid–band in atom–interferometry—precisely the coherence–selective regimes highlighted by the τ–kairos pipeline (Proposition 10.150).

Speculative Narrative: The Dark Sector

Within the typed weave, two *non–tensorial* (TT–null) registers arise as natural dark–sector candidates, each tied to a distinct substrate and admitted via the τ–kairos typed layer (Definition 10.4 and eq. (10.90)).

Gaiaton (spin–0, scalar, radial). The **Gaiaton** is the scalar (apeiron) excitation originating in the Gaiamiti sector and *realized* on the τ–kairos *scalar* typed family $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$, isolated spectrally by the spin–0 Riesz selector on the scalar kinetic generalized eigen-operator pair $K_\tau^{(0)}$ (Section 10.8 and Definitions 10.4 and 10.68 to 10.70). Its potential $\mathcal{V}_\Phi$ naturally supports slow–roll or quintessence–like dynamics, providing an evolving equation of state $w(z)$ for dark energy [486]. In a different mass/coupling regime, a massive, (meta)stable Gaiaton can behave as cold dark matter through coherent (misalignment) oscillations, subject to production and fifth–force constraints [485]. In brief: the Gaiaton is *prominent for dark energy* and *plausible for dark matter* when stabilized.

Chrono–Kymon (spin–1, vector, temporal). The **Chrono–Kymon** furnishes the τ–kairos *vector* register $A^{(\pm)}$ with field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$ (Definitions 10.4 and 10.57 and Section 10.7). As a massive vector, it is a canonical dark–matter candidate (misalignment or freeze–in) that *does not* alter the TT graviton sector (Sections 10.3 and 10.4 and eq. (10.90)). A dark–energy role is more constrained: generic vector condensates threaten large–scale anisotropy, but if τ–kairos dynamics enforce effective isotropy (e.g., triad averaging on certified plateaus), a subdominant or early–dark–energy–like component may be allowed (Definition 10.2 and Proposition 9.97). Summary: the Chrono–Kymon is *prominent for dark matter*, with at most conditional relevance for dark energy.

Mition (spin–1, internal connection, Gaiamiti–sourced). The **mition** is a spin–1 excitation of the *relational operator bundle connection* $\mathcal{A}_\mu$ that enters the Gaiamiti covariant derivative (cf. Section 6.6, Definitions 6.192 and 9.258, Remarks 6.198 and 6.200, and eq. (10.1)). Its mass arises via internal gauge SSB (BEH) triggered by the Gaiamiti vacuum (cf. Definitions 9.252 and 9.261). On the realized weave configuration it is isolated by a *spin–1* Riesz selector acting on the connection's transverse vector block (cf. Definitions 10.1, 10.6 and 10.7), commuting with the provenance/typed/triad projectors and remaining TT–orthogonal since $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ acts on symmetric 2–tensors (cf. Propositions 10.9 and 10.10, Definition 10.3, and Corollary 10.11). Phenomenologically, a massive mition is a canonical dark–matter candidate (coherent misalignment or freeze–in), with portal strengths constrained by the bounds summarized in Section 10.16. It is *not* a τ–kairos register; rather, it populates the *connection* ledger and influences $\Sigma_{\mu\nu}$ only indirectly via its effects on (Φ, Θ) in the constitutive split (cf. eq. (10.101)).

Tantron (spin–1, internal connection, Tantrakyma–sourced).

The **tantron** is Tantrakyma–sourced: a spin–1 excitation of the relational connection $\mathcal{A}_\mu$ that enters the Tantrakyma covariant derivative (cf. eq. (10.2) and Definition 9.348). Like the mition, it acquires mass via Brout–Englert–Higgs (BEH).

On the realized weave configuration, its transverse, BRST–physical modes are isolated by the *spin–1* connection selector constructed from spectral islands (cf. Definitions 10.1, 10.6 and 10.7). The resulting projectors commute with the provenance/typed/triad structure and remain TT–orthogonal, since $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ acts only on symmetric 2–tensors (cf. Propositions 10.9 and 10.10 and Definition 10.3).

As a massive, weakly coupled vector, the tantron is a viable dark–matter candidate. Relevant portal constraints include WEP tests, kinetic–mixing limits, bounds on spin–dependent torsionlike couplings, clock–network searches for ultralight backgrounds, and cosmic–birefringence measurements (cf. Section 10.16). It lies outside the τ–kairos registers and provides an *additional* non–TT dark–sector pathway sourced by the relational connection rather than by the substrate fields themselves.

Synthesis. Together, the scalar **Gaiaton** anchors the dark–energy narrative (and potentially a CDM fraction), while the vector **Chrono–Kymon** anchors the dark–matter narrative (with limited dark–energy scope under isotropy). In addition, the *relational connection* sector provides two further TT–null vector candidates—the **mition** (Gaiamiti–sourced) and the **tantron** (Tantrakyma–sourced)—which originate from the operator bundle connection and are isolated on the realized weave configuration by the *spin–1* connection selector built from spectral islands (cf. Section 6.6, Definitions 6.192, 10.1, 10.6 and 10.7, and Remarks 6.198 and 6.200). These internal vectors are *not* τ–kairos registers; they populate the connection ledger and affect $\Sigma_{\mu\nu}$ only indirectly via their influence on (Φ, Θ) in the constitutive split (cf. eq. (10.101)), with phenomenological portals constrained by Section 10.16. Throughout, the spin–2 graviton sector remains purely geometric—protected by TT selection and typed orthogonality—so gravitational–wave polarizations are unaffected even when dark–sector dynamics are active (Definition 10.167, eqs. (10.28) and (10.90), and Proposition 9.202). The selection rules (no spin–1 in the Gaiamiti/metric channel; no spin–2 in the τ–kairos/-Tantrakyma channel) thus remain intact, while the dark sector is populated by quanta that

are *natural outgrowths* of the dual–substrate construction.

Dark–Sector Excitations of the τ–Kairos

The τ–kairos *typed* structure itself ($\hat{\tau}_{\mu\nu} = \delta\hat{t}_{\mu\nu}$) provides a natural umbrella for dark–sector phenomenology. As established in Section 10.17.3, $\hat{\tau}_{\mu\nu}$ admits scalar and vector registers—captured by the constitutive split

$$\hat{\tau}_{\mu\nu} = S_{\mu\nu}[\hat{\varphi}_A] \ \oplus \ A_{\mu\nu}[\hat{K}^{(\tau)}] \quad (\text{TT–null: } \mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0)$$

(Definitions 10.4 and 10.13 and eq. (10.90)). The scalar register is realized by the Gaiaton (Gaiamiti origin, τ–scalar realization), while the vector register is supplied by the Chrono–Kymon (Tantrakyma origin, τ–vector realization) (Definitions 10.4, 10.57 and 10.69). These are strictly spin–0/1 excitations, consistent with the absence of additional spin–2 modes (Section 10.18.7).

Taken together, these results support the view that τ–kairos, via its scalar and vector typed registers, *constitutively imprints* the dark sector. Accordingly, we adopt the following identifications for phenomenology: the *Gaiaton* (scalar, τ–scalar) and the *Chrono–Kymon* (vector, τ–vector) provide, respectively, the scalar and vector contributions to dark energy and dark matter, while the spin–2 graviton channel remains purely geometric and TT.

Proposition 10.153 (Scalar τ–kairos register realized by the Gaiaton)**.** *The spin–0 register of the τ–kairos, realized by the* Gaiaton*, contributes to the dark sector in two complementary ways:*

(i) Dark energy
The potential $\mathcal{V}_\Phi$ supports slow–roll and quintessence–like dynamics, enabling an evolving equation of state $w(z)$ (cf. Sections 10.8 and 10.16; see [486]).

(ii) Dark matter
In a massive, (meta)stable regime the Gaiaton acts as a cold, pressureless condensate via coherent oscillations (misalignment), consistent with the weave's selectors and meters (cf. Section 10.8 and Definitions 10.1 and 10.68; see [485]).

In both cases the Gaiaton enters the chronogeometric response through the scalar contribution $S_{\mu\nu}[\hat{\varphi}_A]$ in the constitutive map (Definitions 10.4 and 10.13).

Proposition 10.154 (Vector τ–kairos register supplied by the Chrono–Kymon)**.** *The spin–1 register of the τ–kairos, provided by the* Chrono–Kymon*, contributes as follows:*

(i) Dark matter
A massive Chrono–Kymon produced by misalignment or freeze–in yields a relic vector condensate while preserving TT–purity of gravitational waves (Section 10.18.7, eq. (10.90), and Definition 10.4).

(ii) Dark energy (conditional)
A subdominant contribution is possible only if τ–kairos dynamics enforce effective isotropy (e.g., via triads or domain averaging on certified plateaus), avoiding large–scale anisotropy (Definition 10.2 and Proposition 9.97).

Constitutively, the Chrono–Kymon supplies the vector piece $A_{\mu\nu}[\hat{K}^{(\tau)}]$ in the τ–kairos decomposition, embedding dark–sector dynamics in the coherence channel without affecting the spin–2 graviton sector (Definitions 10.4, 10.13 and 10.57 and Section 10.7).

Dark–Sector Candidates from the Relational Connection (Mition, Tantron)

Proposition 10.155 (Internal–connection vector *mition* as a dark–matter candidate)**.** *Let $\mathcal{A}_\mu$ be the operator bundle connection of Chapter 7 (cf. Section 6.6, Definition 6.192, and Remarks 6.198 and 6.200) entering the Gaiamiti covariant derivative (eq. (10.1)). Assume internal gauge SSB (BEH) in the Gaiamiti vacuum so that the transverse, BRST–physical modes of $\mathcal{A}_\mu$ acquire a mass (cf. Definitions 9.252, 9.258 and 9.261). On the realized weave configuration (Definition 10.1), let the connection's vector block be band–limited and let its spin–1 content be isolated by the Riesz selector built from spectral islands (Definitions 10.6 and 10.7). Then:*

(i) Dark matter

A massive mition *produced by coherent misalignment or freeze–in provides a viable vector dark–matter component, with portal strengths constrained by the bounds in Section 10.16.*

(ii) Typed/TT safety

The mition's projector commutes with provenance/typed/triad projectors and remains TT–orthogonal because $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ acts on symmetric 2–tensors (Propositions 10.9 and 10.10, Definition 10.3, and Corollary 10.11); hence gravitational–wave polarizations are unaffected (eq. (10.90)).

(iii) Ledger separation

The mition is not *a τ–kairos register; it populates the* connection *ledger and influences $\Sigma_{\mu\nu}$ only indirectly via its effects on (Φ, Θ) in the constitutive split (eq. (10.101)).*

Proposition 10.156 (Internal–connection vector *tantron* as a dark–matter candidate)**.** *Let $\mathcal{A}_\mu$ be as above but entering the Tantrakyma covariant derivative (eq. (10.2)). Assume internal gauge SSB (BEH) in the Tantrakyma vacuum so that the transverse, BRST–physical modes acquire a mass (cf. Definitions 9.252 and 9.348). On the realized weave configuration, isolate the spin–1 connection content via the spectral–island Riesz selector (Definitions 10.1, 10.6 and 10.7). Then:*

(i) Dark matter

A massive tantron *is a viable vector dark–matter candidate (misalignment or freeze–in), subject to the portal constraints summarized in Section 10.16 (WEP, kinetic mixing, spin–dependent torsionlike couplings, clocks, birefringence).*

(ii) Typed/TT safety

The tantron's projector commutes with the provenance/typed/triad structure and is TT–orthogonal (Propositions 10.9 and 10.10 and Definition 10.3), leaving the spin–2 graviton channel purely geometric.

(iii) Ledger separation

The tantron is not *a τ–kairos register; it resides in the* connection *ledger and affects $\Sigma_{\mu\nu}$ only through its influence on (Φ, Θ) within the constitutive mapping (eq. (10.101)).*

Clean origin and well–posed degrees of freedom. The *mition* and *tantron* are spin–1 excitations of the universal relational operator–bundle connection $\mathcal{A}_\mu$, not substrate quanta of $\hat{\mathbf{\Phi}}$ or $\hat{\mathbf{\Theta}}$ (Chapter 7: Section 6.6, Definition 6.192, and Remarks 6.198 and 6.200; their entry into dynamics is via eqs. (10.1) and (10.2)). After internal gauge SSB (BEH) the *transverse* modes of $\mathcal{A}_\mu$ become massive and BRST–physical, yielding the correct Proca–like propagating content (Chapter 10: Definitions 9.252, 9.258, 9.261 and 9.348, with BRST cleaning by $\mathsf{P}_{\mathrm{phys}}$). Thus each candidate possesses a clean origin, controllable gauge structure, and well–posed degrees of freedom.

Spectral isolation and robustness on the realized weave configuration. On the realized weave configuration $\mathcal{I}^{[\mathscr{P}]}$ the connection's transverse vector block admits band–limited *spectral islands* (Chapter 11: Definitions 10.1 and 10.6). Its spin–1 content is isolated by the commuting Riesz selectors $\sum_{k\in\mathfrak{S}_1} \frac{1}{2\pi i} \oint_{\Upsilon_k} (K^{(1)}_{\mathrm{vec}} - z)^{-1}\, dz$ (Definition 10.7), which preserve the provenance/typed/triad structure and render the readout Nielsen–flat and retune–stable (Propositions 10.9 and 10.10 and Corollary 10.11). This furnishes a rigorously defined, instrument–certified projector–field for mition/tantron phenomenology.

TT safety and separation from the graviton channel. Typed TT isolation is automatic because $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ acts on symmetric 2–tensors, whereas the mition/tantron live in the internal connection ledger; hence $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \mathsf{P}^{(1)}_{\mathrm{spec}} = 0$ (Definition 10.3). Consequently there are no extra GW polarizations, fully consistent with the weave's TT–null rules and with $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ for the τ channel (eq. (10.90)). The spin–2 graviton sector therefore remains purely geometric and TT–pure.

Natural cosmological production, compatible with constraints. Massive, weakly coupled spin–1 fields have standard cold–dark–matter production channels (coherent misalignment or freeze–in). In the present bookkeeping their effective "portals" map onto the consolidated bounds of Section 10.16 (e.g. LVK polarization tests for TT silence, MICROSCOPE WEP limits on long–range composition dependence, kinetic–mixing constraints, torsionlike spin couplings, clock–network searches for ultralight coherent backgrounds, birefringence limits, and mid–band atom–interferometry reach). Because the connection projectors commute with the typed/triad structure and are TT–null, viable parameter windows persist without spoiling GW polarizations or violating typed selection.

Ledger separation and constitutive consistency. The mition and tantron are *not* τ–kairos registers; the τ channel remains $0 \oplus 1$ from the Gaiaton and Chrono–Kymon only (Definitions 10.4, 10.13, 10.57 and 10.69). Their impact on the chronogeometric response $\Sigma_{\mu\nu} = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi, \Theta]$ is therefore *indirect*: it arises solely through how $\mathcal{A}_\mu$ modifies the Φ, Θ dynamics inside the constitutive map (Chapter 7: eq. (10.101) and Section 10.17.4). This preserves the formal separation of ledgers while allowing controlled backreaction through the established pipeline.

Summary. The **mition** (Gaiamiti–sourced) and **tantron** (Tantrakyma–sourced) combine: (i) a universal, algebraically anchored connection origin; (ii) massive, BRST–physical transverse

modes from BEH; (iii) typed/triad–robust spectral isolation on the realized weave configuration; (iv) TT–null behavior that safeguards the graviton sector; and (v) viable cosmological production within existing experimental bounds (Section 10.16). They are therefore credible dark–matter candidates within the weave, complementary to the τ–kairos narrative.

10.17 Geometric Block of the Unified Correlator

Same backbone, stricter readout. Chapter 7 introduces the *Unified Inter–Modal Correlator* $\hat{\mathbf{G}}_\Lambda$ as a 2×2 matrix of Fourfold two–point kernels (Section 6.1.1 and Definition 6.4, built from Definition 4.9). The Chapter 11 objects $\hat{\mathbf{G}}_\Lambda^{[\Phi\to\Phi]}$ and its triad/TT refinements (Definitions 10.157 and 10.158) are *not new correlators* but *typed projections* of this same backbone: first a type sandwich to extract the geometric block ($\Phi \to \Phi$), then a provenance split into $\{\text{spec}, \text{vac}, \text{corr}\}$ (Definition 10.2), and finally a background–covariant TT refinement with $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ (Definition 10.3). Equation (10.83) asserts the purely kinematic compatibility with Chapter 7's sectoring: non–TT types (the τ–kairos scalar/vector families; Definition 10.4) are *TT–null* (Lemma 10.17), so the graviton readout extracted from $\Phi\Phi$ cannot be contaminated by τ content—consistent with the diagonal/off–diagonal semantics of $\hat{\mathbf{G}}_\Lambda$ in Definition 6.4.

What Chapter 11 adds (and where it leans on Chapter 7). The Chapter 7 construction is *kinematic and sector–agnostic*: it organizes correlations across (Φ, Θ) and across the Fourfold modes with parallel transport and relational covariance (Definition 4.9 and Section 6.1.1). Chapter 11 adds *instrumentation and provenance*: all operations are performed after Σ–realization and on the realized weave configuration $(\bar\Sigma, \mathcal{I}^{[\mathscr{I}]}$; Definitions 9.80 and 10.1), so index–raising and causal support are governed by $\bar\Sigma^{\mu\nu}$ and its relational Levi–Civita connection (eq. (6.62), Definition 6.7, and Remark 9.83). Within this setting, the typed insertion (Definition 10.157) and TT refinement (Definition 10.158) simply *specialize* the Chapter 7 correlator to the geometric, spin–2, TT channel with a triad–resolved ledger—moves that Chapter 7 did not yet prescribe. In short, Chapter 7 defines $\hat{\mathbf{G}}_\Lambda$; Chapter 11 fixes the realized weave configuration and then projects $\hat{\mathbf{G}}_\Lambda$ into $\Phi\Phi \to$triad$\to$TT in a way that is compatible with the same relational background.

Consequences for usage. Because Chapter 11's blocks are just Chapter 7's $\hat{\mathbf{G}}_\Lambda$ seen through (Φ-type, triad, TT) lenses, they inherit all upstream semantics of the diagonal/off–diagonal entries (geometry, matter, interaction; Definition 6.4) while becoming immediately eligible for Chapter 11 meters and T–L–O stamping (Definition 10.82 and Proposition 10.90). This is exactly what enables linearization of the geometric sector, graviton–channel isolation, and the statement of the chronogeometric Einstein equations in the natural $\bar\Sigma$–geometry (Section 11.7.3)—tasks that rely on the TT–refined $\Phi\Phi$ blocks (Definition 10.158) rather than on the raw, unspecialized matrix of Chapter 7.

Definition 10.157 (Geometric block: typed insertion and triad resolution)**.** By typed insertion (Definition 10.113), the *geometric* ($\Phi\Phi$) block of the unified inter–modal correlator is obtained

by sandwiching with the Φ-type idempotent $\Pi_{\Lambda}^{[\Phi]}$:

$$\boxed{\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Phi]} := \Pi_{\Lambda}^{[\Phi]}\,\hat{\mathbf{G}}_{\Lambda}\,\Pi_{\Lambda}^{[\Phi]}.} \tag{10.80}$$

Resolving provenance with the triad $\{a\} = \{\text{spec}, \text{vac}, \text{corr}\}$ (Definition 10.2) and its idempotents $\Pi^{[a]}$ yields the orthogonal sum

$$\boxed{\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Phi]} = \bigoplus_{a\in\{\text{spec},\text{vac},\text{corr}\}} \hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Phi]}, \qquad \hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Phi]} := \Pi^{[a]}\,\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Phi]}\,\Pi^{[a]}.} \tag{10.81}$$

Definition 10.158 (Spin–2 TT refinement and TT–null complement)**.** Using the background–covariant TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 10.3), each triad block admits a TT refinement

$$\boxed{\hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Phi;\mathrm{TT}]} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Phi]}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}, \qquad a\in\{\text{spec}, \text{vac}, \text{corr}\},} \tag{10.82}$$

while every *non–TT* typed family (the τ–kairos scalar/vector images; Definition 10.4) satisfies the TT–nullity relation (Lemma 10.17)

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\Pi^{[\chi]} = 0 \qquad (\chi \text{ a non–TT type}).} \tag{10.83}$$

What "admission–certified" means. After the typed insertion and triad split in Definition 10.157 (with TT refinement in Definition 10.158), each block $\hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Phi]}$ lives on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ and physical carrier $\mathcal{H}_{\text{phys}}$ (Definition 10.1). "Admission–certified'' here means that band/BRST hygiene and commutation properties hold *by construction*: the band tags and IR windows commute with P_{phys} and the typed/triad idempotents, so all sandwiched objects remain rig–admissible and gauge–safe (Proposition 10.10; see also the TT sandwich in Definition 10.3). Consequently, each provenance slice $a \in \{\text{spec}, \text{vac}, \text{corr}\}$ is a well–posed, type–resolved target for downstream diagnostics.

Why it is directly eligible for meters and T–L–O. Because admission is guaranteed, the law/state ledgers and calibrated visibilities may be evaluated *as is* on every triad block: compute $\mathbf{R}^{[\mathscr{S};\chi]}, \mathbf{S}^{[\mathscr{S};\chi]}$ and then $\Lambda_{\text{law}}, \Lambda_{\text{state}}$ via the cosine meters (Definitions 10.80 and 10.82), with finiteness and monotonicity ensured by Lemma 10.83 and Proposition 9.146. The *T–L–O stamping* then attaches the **T**ype (here, e.g., TT in the $\Phi\Phi$ block), the **L**ocation (bulk/boundary, per Definition 10.101), and the unique **O**nset $r^{\star}[\chi]$ defined by the canonical acceptance predicate (existence/uniqueness in Proposition 10.90 and Lemma 10.86, stability in Proposition 10.88). In short, once a block is formed as in Definitions 10.157 and 10.158, nothing further is required to run the meters and issue a T–L–O: the certification and commutation guarantees (Proposition 10.10) make these operations order–independent and audit–ready.

Physical interpretation (Apeiron = trace–typed scalar channel of geometry). On the realized weave configuration (Definition 10.1) and physical carrier, the relational geometric content of the ΦΦ block of the unified correlator is read via typed insertion (Definition 10.113) and the weave triad $\{a\} = \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2). The connected entry equals the covariance of the fluctuation field (realized-layer recall from Chs. 7–10), hence typed projections of the ΦΦ block separate (i) the scalar *trace–typed* channel—called the *Apeiron* in what follows—from (ii) the spin–2 *TT* graviton channel. No new primitives are introduced; we only apply the Chapter 11 typed/triad machinery to the ΦΦ block of $\hat{\mathbf{G}}_\Lambda$ (Definition 6.4).

Remark 10.159 (Terminology: Apeiron as the ΦΦ trace–typed block)**.** We refer to the ΦΦ *trace–typed* scalar channel as the **Apeiron**. It is defined by typed insertion and triad resolution (no extra structure):

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{Tr}]}_{\Lambda;a} \;:=\; \Pi^{(a)}\,\Pi^{[\mathrm{Tr}]}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda}\,\Pi^{[\mathrm{Tr}]}\,\Pi^{(a)}, \qquad a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}.} \tag{10.84}$$

On admitted plateaux (admission & invariance in Definition 10.94 and Proposition 10.10), each block (10.84) is BRST/Nielsen-safe, cone-gated, and suitable for witnesses/meters and T–L–O execution (Proposition 10.90).

Remark 10.160 (Spin–2 readout and TT–null complement)**.** The observable graviton is the TT refinement of the same ΦΦ block using the background–covariant projector (Definition 10.3):

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{TT}]}_{\Lambda;a} \;:=\; \Pi^{[\mathrm{TT}]}_{\bar\Sigma}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda;a}\,\Pi^{[\mathrm{TT}]}_{\bar\Sigma}, \qquad a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}.} \tag{10.85}$$

Every non–TT typed family (τ–kairos scalars/vectors in Definition 10.4) is *TT–null*:

$$\boxed{\Pi^{[\mathrm{TT}]}_{\bar\Sigma}\,\Pi^{[\chi]} \;=\; 0 \qquad \text{for all non–TT types } [\chi] \text{ (cf. Lemma 10.17),}} \tag{10.86}$$

so (10.85) is strictly tensorial with no τ contamination; future–proofing and spectral updates proceed as in the weave (Ch. 11).

Definition 10.161 (Connected kernel as fluctuation covariance)**.** Let $\hat{\mathbf{\Phi}}(x)$ be the dynamical Gaiamiti field and write the realized background–fluctuation split (Chs. 9–10):

$$\boxed{\hat{\mathbf{\Phi}}(x) \;=\; \langle\hat{\mathbf{\Phi}}(x)\rangle_\circ\,\mathbb{I}_x \;+\; \delta\hat{\mathbf{\Phi}}(x), \qquad \langle\delta\hat{\mathbf{\Phi}}(x)\rangle_\circ = 0.} \tag{10.87}$$

Then the ΦΦ *connected* kernel equals the fluctuation covariance:

$$\begin{aligned}
\hat{G}_{\Phi\Phi}(x,x') &= \Big\langle \hat{\mathbf{\Phi}}(x)\,\hat{\mathbf{\Phi}}(x')\Big\rangle_\circ - \Big\langle\hat{\mathbf{\Phi}}(x)\Big\rangle_\circ\Big\langle\hat{\mathbf{\Phi}}(x')\Big\rangle_\circ && (10.88)\\
&= \Big\langle \Big(\langle\hat{\mathbf{\Phi}}(x)\rangle_\circ\mathbb{I}_x + \delta\hat{\mathbf{\Phi}}(x)\Big)\Big(\langle\hat{\mathbf{\Phi}}(x')\rangle_\circ\mathbb{I}_{x'} + \delta\hat{\mathbf{\Phi}}(x')\Big)\Big\rangle_\circ - \langle\hat{\mathbf{\Phi}}(x)\rangle_\circ\,\langle\hat{\mathbf{\Phi}}(x')\rangle_\circ\\
&= \Big\langle \delta\hat{\mathbf{\Phi}}(x)\,\delta\hat{\mathbf{\Phi}}(x')\Big\rangle_\circ. && (10.89)
\end{aligned}$$

Typed resolution then yields the scalar (Apeiron) and TT graviton correlator blocks by inserting $\Pi^{[\mathrm{Tr}]}$ and $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, respectively, as in (10.84)–(10.85). Positivity and causal support follow from admission and cone–gating clauses on the realized weave configuration (Definition 10.94 and the cone statement referenced therein), and T–L–O stamping proceeds via Proposition 10.90 without double counting of polarizations thanks to (10.83).

Appropriateness for the Treatise: the Tau–Kairos sector. We work on the realized weave configuration and physical carrier (Definition 10.1), and use only the typed–insertion and triad machinery of Chapter 11 (Definitions 10.2 and 10.113). The coherence branch of the realized chronogeometry $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ is encoded by the *tau–kairos field* $\hat{\tau}_{\mu\nu}$ as fixed in the weave; its typed images furnish scalar/pseudoscalar/vector channels (Definition 10.4). By construction the tau–kairos sector is *TT–null*:

Definition 10.162 (Tau–Kairos sector and TT–nullity)**.** We work on the realized weave configuration and physical carrier (Definition 10.1) and use only the typed–insertion and triad machinery of Chapter 11 (Definitions 10.2 and 10.113). The coherence branch of the realized chronogeometry $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ is encoded by the *tau–kairos field* $\hat{\tau}_{\mu\nu}$ as fixed in the weave; its typed images furnish scalar/pseudoscalar/vector channels (Definition 10.4). By construction the tau–kairos sector is *TT–null*:

$$\boxed{\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} \;=\; 0, \qquad \text{equivalently} \qquad \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{[\chi]} \;=\; 0 \;\; \text{for all non–TT types } [\chi],} \tag{10.90}$$

as stated in the weave TT–purity lemma (Lemma 10.17), with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ the background–covariant TT projector (Definition 10.3).

Definition 10.163 (Typed correlator blocks for the tau–kairos sector)**.** Tau–kairos excitations are read from the $\Phi\Phi$ block of the unified correlator by *typed insertion* and *triad* resolution (Definitions 10.2 and 10.113). For each admissible type $[\chi] \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}$ and triad element $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$,

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Phi;\chi]}_{\Lambda;a} \;:=\; \Pi^{(a)}\,\Pi^{[\chi]}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda}\,\Pi^{[\chi]}\,\Pi^{(a)}.} \tag{10.91}$$

These blocks are BRST/Nielsen–safe and band–admissible on the realized weave configuration (Proposition 10.10), and—by (10.90)—contain *no* spin–2 content.

Remark 10.164 (Background dependence and operational role)**.** On the diagnostic realized reference configuration, tau–kairos typed blocks modulate phase flow and coherence timing of relational processes. Their meters/witnesses and the parasymmetric T–L–O stamps are those already provided for the tau/CK families (see Propositions 10.22, 10.65 and 10.90); no new primitives are introduced here.

Allowed excitations (scalar/pseudoscalar/vector only). Under the TT–null constraint (10.90) and typed admission (Definition 10.94), the admissible tau–kairos excitations are:

1. *Scalar* τ–types: $S^{(b)}$ (bulk scalar) and $S^{(L)}$ (longitudinal scalar);

2. *Pseudoscalar* τ–type: $\tilde{S}^{(p)}$;
3. *Vector* (Chrono–Kymon) types: $A^{(\pm)}$ (helicity ± 1).

Longitudinal, non–radiative content is captured by the $S^{(L)}$ branch; the transverse propagating CK modes are the $A^{(\pm)}$ branches. TT projections of any of these vanish by (10.90).

Remark 10.165 (Complementarity with the graviton channel)**.** The graviton is obtained exclusively from the TT refinement of the $\Phi\Phi$ block,

$$\hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{TT}]}_{\Lambda;a} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda;a}\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}},$$

and its T–L–O entry is stamped by the graviton rules of the weave (Proposition 10.35). By (10.90) and Lemma 10.17, tau–kairos excitations never contribute to $\mathrm{TLO}^{[\mathrm{TT}]}$; instead they receive their own $\mathrm{TLO}^{[\chi]}$ stamps in the scalar/pseudoscalar/vector families (Propositions 10.22 and 10.65).

Remark 10.166 (Nomenclature and conceptual role)**.** We use *tau–kairos tensor* for $\hat{\tau}_{\mu\nu}$ (noun) and *tau–kairos* (adjective) for the sectoral qualifiers. This emphasizes (i) the selection of opportune windows for coherent evolution (Onset in T–L–O), (ii) the absence of spin–2 carriage, and (iii) the complementarity with the chronometric channel: $\bar{g}_{\mu\nu}$ organizes measurable duration/extent, whereas $\hat{\tau}_{\mu\nu}$ organizes phase–suitable coherence, consistent with the typed/triad split used in (10.91) and the weave execution rules.

10.17.1 The Apeiron: Field–level vs. Particle–level Modes

We work on the realized weave configuration and physical carrier (Definition 10.1), using typed insertion and the weave triad only (Definitions 10.2 and 10.113). TT is always the background–covariant projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3); the τ–kairos families are TT–null (Lemma 10.17). The realized chronogeometry obeys the constitutive split $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ with linear response as in Ch. 10 (recall only; no redefinition).

Convention (Apeiron). We use *Apeiron* strictly as a label for:

(i) Field–level. The geometric fluctuation source $\delta\hat{\mathbf{\Phi}}$ from the realized split (10.87), whose connected $\Phi\Phi$ kernel equals the fluctuation covariance (10.89). It feeds the $\Phi\Phi$ block of the unified correlator (Definition 6.4) (Definition 10.157); typed resolution then produces its *trace* channel (through the $\bar{\Sigma}$–trace, cf. $\mathrm{tr}_{\bar{\Sigma}}$ in Definition 10.3 and the inner–product conventions in Definition 9.33) and the *TT* channel via the background–covariant TT projector (Definitions 10.3 and 10.158).

(ii) Particle–level (spin–0 radial). The *radial* scalar obtained from the Φ–sector radial direction of the physical Hessian (mass/pole extracted by Riesz selection on the scalar/radial generalized eigen-operator pair; Definition 10.7 and Proposition 10.149), admitted on the realized weave configuration (Definition 10.1) and within the Chapter 8 acceptance windows, and stamped as a trace–typed scalar under the typed weave layer (Definition 9.116).

Thus *Apeiron* (field) $\Rightarrow$ typed $\Phi\Phi$ blocks (Definition 10.157); *Apeiron* (particle) $\Rightarrow$ spin–0 radial scalar on $H^0(\hat{Q}_{\mathrm{BRST}})$ (the physical carrier $\mathcal{H}_{\mathrm{phys}}$, cf. Definition 10.1).

Typed ΦΦ blocks (trace and TT). By typed insertion with triad provenance (Definitions 10.2 and 10.113) applied to the geometric block (Definition 10.157),

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{Tr}]}_{\Lambda;a} := \Pi^{(a)}\,\Pi^{[\mathrm{Tr}]}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda}\,\Pi^{[\mathrm{Tr}]}\,\Pi^{(a)}, \qquad \hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{TT}]}_{\Lambda;a} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda;a}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}},} \tag{10.92}$$

for $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$. The first block encodes the *trace–typed* scalar (Apeiron, particle–level; trace with respect to $\bar{\Sigma}$, cf. Definitions 9.33 and 10.3); the second is the TT graviton block as in Definition 10.158. TT–nullity of non–TT types ensures no contamination from τ families (Lemma 10.17 and Definition 10.162).

Tangential–radial decomposition (field space). Let $\mathcal{M}_{\mathrm{vac}}$ be the Φ–vacuum manifold (Ch. 9/10). Any small fluctuation decomposes orthogonally as

$$\delta\Phi = \delta\Phi_{\mathrm{tang}} \oplus \delta\Phi_{\mathrm{radial}}, \qquad \delta\Phi_{\mathrm{tang}} \in T_{\Phi_0}\mathcal{M}_{\mathrm{vac}}, \quad \delta\Phi_{\mathrm{radial}} \perp T_{\Phi_0}\mathcal{M}_{\mathrm{vac}}.$$

The radial piece sources the *trace–typed* scalar (spin–0 Apeiron, mass from the radial Hessian on H^0); the tangential piece generates Goldstone–like directions.

Graviton as a tangential constitutive mode (TT readout). With the linear response of the constitutive map in Ch. 10 and τ–TT isolation (Lemma 10.17),

$$\boxed{\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu} \;=\; \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Big[\big(D_\Phi \bar{g}_{\mu\nu}\big)\cdot\delta\hat{\Phi}_{\mathrm{tang}}\Big], \qquad \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Big[\big(D_\Phi \bar{g}_{\mu\nu}\big)\cdot\delta\hat{\Phi}_{\mathrm{radial}}\Big] = 0.}\tag{10.93}$$

Hence the TT graviton channel is sourced *solely* by *tangential* Φ–variations, whereas the radial scalar reports in the trace–typed block (10.92) (no double counting).

T–L–O stamping and non–overcounting (weave execution). On admitted plateaux (Definition 10.94 and Proposition 10.10), the scalar radial Apeiron receives the $\mathrm{TLO}^{[\mathrm{Tr}]}$ stamp, while the graviton receives $\mathrm{TLO}^{[\mathrm{TT}]}$ (Proposition 10.35). Tau/CK families get $\mathrm{TLO}^{[\chi]}$ in their own typed branches and never contribute to $\mathrm{TLO}^{[\mathrm{TT}]}$ by TT–nullity (Lemma 10.17); the weave's witness/meter rules apply verbatim.

Terminology. (i) *"Spin–2 Apeiron"* ≡ *graviton* (the TT, tangential mode of the Φ–sector as in (10.93)). (ii) *"Spin–0 Apeiron"* = trace–typed *radial* scalar (mass from the radial block of $\mathbb{H}_{\mathrm{phys}}$). (iii) No "spin–1 Apeiron": vector temporal quanta belong to the τ/CK types and are TT–null (weave, Lemma 10.17).

Operational summary. Field–level Apeiron $\delta\hat{\mathbf{\Phi}}$ feeds the typed ΦΦ blocks; particle–level Apeiron is the trace–typed radial scalar (spin–0); the graviton is the TT projection of the metric response to *tangential* Φ–variations (10.93). The Chapter 11 pipeline (typed insertion, triad, admission, T–L–O) cleanly separates these channels—BRST/Nielsen safe, cone–preserving, and free of TT contamination from τ families.

10.17.2 The Chronogeometric Excitations

Program. On the realized weave configuration and physical carrier (Definition 10.1), the excitation content of gravity is fixed by: (i) a *kinematic* typed split of the unified chronogeometric field into metric and tau–kairos channels using the Chapter 11 projectors (Definitions 10.3, 10.4 and 10.113); and (ii) a *constitutive* (field–space) realization via the substrate response recalled from Ch. 10 (no new primitives).

Unified chronogeometric operator (recall). We assemble the operator–valued chronogeometry as the sum of its geometric and kairotic pieces and define its *realized* background by the Σ–realization map (Ch. 10: Definition 9.80) on the realized weave configuration $\mathcal{I}^{[\mathcal{J}]}$ (Definition 10.1); expectations $\langle\cdot\rangle_\circ$ are taken on $\mathcal{H}_{\rm phys}$. Thus

$$\hat{\Sigma}_{\mu\nu}(x) = \hat{g}_{\mu\nu}(x) + \hat{t}_{\mu\nu}(x), \qquad \bar{\Sigma}_{\mu\nu}(x) = \langle\hat{\Sigma}_{\mu\nu}(x)\rangle_\circ = \bar{g}_{\mu\nu}(x) + \bar{t}_{\mu\nu}(x), \tag{10.94}$$

$$\hat{\Sigma}_{\mu\nu}(x) = \bar{\Sigma}_{\mu\nu}(x) + \delta\hat{\Sigma}_{\mu\nu}(x), \qquad \delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}. \tag{10.95}$$

Here $\bar{\Sigma}_{\mu\nu}$ determines the relational Levi–Civita connection used throughout (Definition 6.7) and its inverse $\bar{\Sigma}^{\mu\nu}$ raises indices in all TT/typed refinements (cf. eq. (6.62) and Definition 10.3). In particular, the TT graviton readout uses $\delta\hat{g}_{\mu\nu}$ while $\delta\hat{t}_{\mu\nu}$ is TT–null by the weave purity statements (Definitions 10.162 and 10.167 and Lemma 10.17).

Kinematic TT split: graviton and TT–null tau–kairos

Definition 10.167 (TT graviton and TT–null tau–kairos (weave projectors))**.** The *graviton field* is the TT (spin–2) metric perturbation in the $\Phi\Phi$ sector, defined via the graviton projector of Definition 10.25 and read in the $\bar{\Sigma}$–background:

$$\boxed{\hat{h}_{\mu\nu} \;:=\; \mathcal{P}^{(2)}_{\rm grav}\,\delta\hat{g}_{\mu\nu} \quad \text{and, kinematically,} \quad \hat{h}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu} \;\; (Definition\ 10.3),} \tag{10.96}$$

where $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ is the background–covariant TT projector.

The tau–kairos fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ is *TT–null*; equivalently,

$$\boxed{\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0 \quad\Longleftrightarrow\quad \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Pi^{[\chi]} = 0 \;\text{ for all non–TT types } [\chi],} \tag{10.97}$$

as recorded in the weave TT–purity statements (Definition 10.162 and Lemma 10.17). Hence $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$, consistent with $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$.

Lemma 10.168 (Typed TT content is purely metric)**.** *With (10.97), no TT content arises from $\hat{\tau}_{\mu\nu}$; all TT strength is in the metric channel:* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{\Sigma} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}$.

Typed TT correlator block. For each triad element $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2), the TT block of the $\Phi\Phi$ correlator is

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{TT}]}_{\Lambda;a} \;:=\; \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda;a}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}, \qquad \hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda;a} := \Pi^{(a)}\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda}\Pi^{(a)}.} \tag{10.98}$$

These are BRST/Nielsen–safe and band–admissible on the realized weave configuration (Proposition 10.10).

Execution: stamps and separation. On admitted plateaux (Definition 10.94), the TT graviton receives the $\mathrm{TLO}^{[\mathrm{TT}]}$ stamp (Proposition 10.35); tau–kairos families receive $\mathrm{TLO}^{[\chi]}$ in their scalar/pseudoscalar/vector branches and never contribute to TT by (10.97). Typed/triad provenance is carried by the index a in (10.98), ensuring non–overcounting and realized weave configuration invariance.

Typed excitations and T–L–O stamping

Typed families (recall; no new primitives). We use the Chapter 11 typed projectors and triad on the realized weave configuration (Definitions 10.1, 10.2 and 10.113). The geometry types are: TT (spin–2) via $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 10.3) and the trace–typed scalar "Tr"; the tau–kairos (temporal/coherence) families are the scalar/pseudoscalar/vector images in Definition 10.4. Typed $\Phi\Phi$ correlator blocks with provenance $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ are

$$\boxed{\hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Phi;\chi]} := \Pi^{(a)}\,\Pi^{[\chi]}\,\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Phi]}\,\Pi^{[\chi]}\,\Pi^{(a)}.} \tag{10.99}$$

Theorem 10.169 (Excitation content of gravity on the realized weave configuration)**.** *On admitted plateaux (Definition 10.94) and for admitted types (Definition 9.116):*

(i) Spin–2 (TT, graviton)

The unique spin–2 excitation is the TT metric mode

$$\hat{h}_{\mu\nu} \;=\; \mathcal{P}^{(2)}_{\mathrm{grav}}\,\delta\hat{g}_{\mu\nu} \;=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu},$$

i.e. the graviton field defined by the graviton projector (Definition 10.25) and, kinematically, by the background–covariant TT projector (Definitions 10.3 and 10.167); its stamp is $\mathrm{TLO}^{[\mathrm{TT}]}$ *(Proposition 10.35).*

(ii) Tau–kairos (TT–null)

The tau–kairos sector is TT–null (Definition 10.162 and Lemma 10.17); it supports only scalar/pseudoscalar/vector families (including CK vectors) as in Definition 10.4. Their stamps are $\mathrm{TLO}^{[\chi]}$ *in the corresponding typed branches (Propositions 10.22 and 10.65).*

(iii) No overcounting)

Orthogonality holds: $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\Pi^{[\chi]} = 0$ *for all non–TT* $[\chi]$ *(Lemmas 10.17 and 10.59). Hence,*

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma}_{\mu\nu} \;=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu},$$

by the fluctuation split $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$ *(eq. (10.95)) and TT–nullity of* $\delta\hat{t}_{\mu\nu}$ *(eq. (10.97)).*

Proof. (1) *Spin–2 uniqueness.* On the realized weave configuration (Definition 10.1) the typed TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ isolates the spin–2 subspace of symmetric rank–2 tensors (Definition 10.3). The graviton field on $\mathcal{H}_{\mathrm{phys}}$ is, by definition, $\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}_{\mathrm{grav}}\delta\hat{g}_{\mu\nu}$ (Definition 10.25); kinematically this equals $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$ (Definition 10.167). Typed/triad commutations guarantee that no other typed family carries spin–2 TT support (Proposition 10.9), hence uniqueness.

(2) *Tau–kairos TT–nullity.* By the weave purity statements, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}_{\mu\nu} = 0$ (Definition 10.162, Lemma 10.17, and eq. (10.97)). Therefore the τ–block supports only the scalar/pseudoscalar/vector types listed in Definition 10.4; their TLO stamps are issued in the corresponding typed branches (Propositions 10.22 and 10.65) on admitted plateaux (Definition 10.94).

(3) *No overcounting.* Using the fluctuation decomposition $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$ (eq. (10.95)) and TT–nullity of $\delta\hat{t}_{\mu\nu}$ (eq. (10.97)), we obtain $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{\Sigma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$. Orthogonality $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$ for non–TT $[\chi]$ (Lemmas 10.17 and 10.59) forbids double–counting of TT strength across typed channels. Combined with (1) this matches the TT isolation in Lemma 10.172. □

Meaning of Theorem 10.169. The theorem states, in operational terms, that once we work on an *admitted plateau* with the realized weave configuration (Definitions 10.1 and 10.94), the *only* gravitational signal that can inhabit the spin–2 channel is the background–covariant TT graviton field $\hat{h}_{\mu\nu}$ (Definitions 10.25 and 10.167). All non–TT content—the entire τ–kairos sector, including its scalars, pseudoscalar, and Chrono–Kymon vectors (Definition 10.4)—is *TT–null* (Definition 10.162 and Lemma 10.17). Consequently, the TT projection of the full chronogeometric fluctuation equals the TT projection of the metric fluctuation alone,

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu},$$

so no scalar/vector leakage can masquerade as a graviton (eqs. (10.95) and (10.97) and Lemma 10.172).

Why this matters. Practically, the theorem gives a *clean accounting rule* for reports and audits: TT claims (spin–2 radiation) are stamped only in the TT type ($\mathrm{TLO}^{[\mathrm{TT}]}$; Proposition 10.35), while τ–kairos claims are stamped in their own typed branches ($\mathrm{TLO}^{[\chi]}$; Propositions 10.22 and 10.65). Orthogonality $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$ for non–TT $[\chi]$ prevents overcounting across channels (Lemmas 10.17 and 10.59), ensuring that meters/visibilities and onsets attach to the *right* physical content (Definition 10.82 and Proposition 10.88). In short: the theorem guarantees *uniqueness and purity* of the graviton readout and a consistent separation of scalar/vector structure, all under identical, rig–certified measurement conditions.

Corollary 10.170 (Helicity register and stability)**.** *The TT channel carries exactly the two tensor helicities $\lambda = \pm 2$ (optionally resolved in the weave's graviton register for reporting; cf. Definitions 10.3 and 10.25 and Proposition 10.35). All scalar/pseudoscalar/vector channels are TT–orthogonal and therefore never contribute to* $\mathrm{TLO}^{[\mathrm{TT}]}$ *(Lemmas 10.17, 10.59 and 10.172). Moreover, this separation is* stable*: typed/triad idempotents commute on the realized weave configuration (Proposition 10.9 and Definition 10.1), meter monotonicity and onset uniqueness hold under admissible IR tightening (Propositions 9.146 and 10.88 and Lemma 10.86), and additional helicity–2 spectral branches—if physically realized—are incorporated by the spin–2 Riesz update without altering the TT scaffold (future–proofing; cf. Definitions 10.7 and 10.25).*

Remark 10.171 (Operational summary)**.** Typed resolution of the geometric block together with TT refinement—see the typed $\Phi\Phi$ constructions in Definitions 10.157 and 10.158 (and the block

formulas such as (10.92) and (10.82))—combined with band/BRST hygiene on the realized weave configuration (Definition 10.1 and Proposition 10.10) yields $\mathrm{TLO}^{[\chi]}$ stamps (Type/Location/Onset) that are BRST/Nielsen–safe. Concretely, one evaluates the law/state ledgers and calibrated visibilities (Definitions 10.80 and 10.82), obtains finite meters (Lemma 10.83), and reads a unique onset $r^\star[\chi]$ with stability radius (Lemma 10.86 and Proposition 10.88). Orthogonality and selection rules (Lemmas 10.17 and 10.59 and Proposition 10.126) ensure that $\mathrm{TLO}^{[\mathrm{TT}]}$ registers only helicity–2 content extracted by $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ (Definitions 10.3 and 10.25), while non–TT types are reported in their own $\mathrm{TLO}^{[\chi]}$ branches without leakage into the graviton channel (Theorem 10.169).

Excitation operators and TT selection (kinematics)

Kinematic channels (recall). With $\hat\Sigma = \bar\Sigma + \delta\hat\Sigma$ (eq. (10.95)), set

$$\boxed{\hat h_{\mu\nu} := \delta\hat g_{\mu\nu}, \qquad \hat\tau_{\mu\nu} := \delta\hat t_{\mu\nu}.} \tag{10.100}$$

Lemma 10.172 (TT isolation and graviton operator)**.** *Tau–kairos is TT–null (Definition 10.162 and Lemma 10.17), so $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\hat\tau_{\mu\nu} = 0$ (eqs. (10.90) and (10.97)). Hence the TT block of the chronogeometric perturbation is purely metric and coincides with the graviton field of Definitions 10.25 and 10.167:*

$$\hat h_{\mu\nu} \;=\; \mathcal{P}^{(2)}_{\mathrm{grav}}\,\delta\hat g_{\mu\nu} \;=\; \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat g_{\mu\nu} \;=\; \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat\Sigma_{\mu\nu},$$

where $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ is the background–covariant TT projector (Definition 10.3) and $\delta\hat\Sigma_{\mu\nu} = \delta\hat g_{\mu\nu} + \delta\hat t_{\mu\nu}$ (eq. (10.95)).

Proof. By TT–nullity of tau–kairos ($\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\hat\tau_{\mu\nu} = 0$; Definition 10.162 and Lemma 10.17), and the split $\delta\hat\Sigma_{\mu\nu} = \delta\hat g_{\mu\nu} + \delta\hat t_{\mu\nu}$ (eq. (10.95)), we have $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\delta\hat\Sigma_{\mu\nu} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\delta\hat g_{\mu\nu}$. By Definitions 10.3 and 10.167, the kinematic TT projection of $\delta\hat g_{\mu\nu}$ equals the graviton field, and Definition 10.25 shows the same object is obtained by the full graviton projector $\mathcal{P}^{(2)}_{\mathrm{grav}}$. This proves the chain of equalities. □

Constitutive (field–space) realization

Recall the constitutive split $\Sigma_{\mu\nu}[\Phi,\Theta] = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi,\Theta]$ with linear response

$$\boxed{\delta\Sigma_{\mu\nu} = (D_\Phi g_{\mu\nu})\cdot\delta\Phi + (D_\Phi t_{\mu\nu})\cdot\delta\Phi + (D_\Theta t_{\mu\nu})\cdot\delta\Theta.} \tag{10.101}$$

Proposition 10.173 (TT selection at constitutive level)**.** *With TT isolation of tau–kairos (Definition 10.162 and Lemma 10.17),*

$$\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\Sigma_{\mu\nu} \;=\; \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta g_{\mu\nu} \;=\; \Big(\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\circ D_\Phi\bar g\Big)\cdot\delta\Phi.$$

Decomposing $\delta\Phi = \delta\Phi_{\mathrm{tang}} \oplus \delta\Phi_{\mathrm{radial}}$ (Chs. 9–10; NG/tangent vs. radial directions of the vacuum manifold, cf. Definition 6.61 and Proposition 9.197) gives

$$\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Big[(D_\Phi\bar g)\cdot\delta\Phi_{\mathrm{tang}}\Big], \qquad \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Big[(D_\Phi\bar g)\cdot\delta\Phi_{\mathrm{radial}}\Big] = 0,$$

so TT support is tangential, while the radial part reports only in the trace sector.

Proof. First, by the fluctuation split $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$ (eq. (10.95)) and TT–nullity of tau–kairos ($\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$; Definition 10.162, Lemma 10.17, and eq. (10.97)), we have $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\Sigma_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta g_{\mu\nu}$. Second, on the realized weave configuration (Definition 10.1) after Σ–realization (Definition 9.80), the realized background metric is a functional of the Gaiamiti field, $\bar{g} = \bar{g}[\Phi]$. Linear response in the Φ–direction yields $\delta g_{\mu\nu} = (D_\Phi \bar{g})_{\mu\nu}\cdot\delta\Phi$, hence $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta g_{\mu\nu} = \left(\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\circ D_\Phi\bar{g}\right)_{\mu\nu}\cdot\delta\Phi$, which proves the first display.

For the tangential/radial split, decompose $\delta\Phi = \delta\Phi_{\mathrm{tang}}\oplus\delta\Phi_{\mathrm{radial}}$ along the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ (tangent = NG directions; radial = orthogonal amplitude directions; cf. Chs. 9–10 and Proposition 9.197). In the NG (tangent) directions, $D_\Phi\bar{g}\cdot\delta\Phi_{\mathrm{tang}}$ furnishes the massless spin–2 (Goldstone) deformation, which is TT and therefore survives TT projection (Proposition 9.197 and Definitions 10.3 and 10.167). In the radial directions, $D_\Phi\bar{g}\cdot\delta\Phi_{\mathrm{radial}}$ produces only $\bar{\Sigma}$–trace and longitudinal pieces (the scalar "apeiron" response). The background–covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ annihilates both pure traces and longitudinal (York) parts (Definition 10.3), hence $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\left[(D_\Phi\bar{g})\cdot\delta\Phi_{\mathrm{radial}}\right] = 0$. This establishes the two claims and the stated interpretation. □

Remark 10.174 (Chrono–Kymon has no extra TT polarizations)**.** The Chrono–Kymon vectors (typed idempotents $A^{(\pm)}$ or, equivalently, $\Pi^{[K^{(\tau)}_{\mathrm{T/L}}]}$ in the CK basis; Definitions 10.4 and 10.57) satisfy TT–nullity, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Pi^{[\chi]} = 0$ for all non–TT $[\chi]$, in particular for CK types (Lemmas 10.17 and 10.59). Consequently they *do not* add gravitational–wave tensor polarizations and are reported only in their own typed TLO branches $\mathrm{TLO}^{[\chi]}$ (Propositions 10.22 and 10.65)—never in $\mathrm{TLO}^{[\mathrm{TT}]}$ (Proposition 10.35 and Theorem 10.169).

Particles and sourcing. The *graviton* is the TT, Goldstone–tangential excitation of the metric channel, $\hat{\gamma}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ (Definition 10.3, Section 10.17.1, and eq. (10.93)), while the Gaiamiti sector also supplies a *spin–0 Apeiron* at the particle level (the trace–typed *radial* scalar read from the $\Phi\Phi$ block; mass from the radial block of $\mathbb{H}_{\mathrm{phys}}$ per Ch. 8). The temporal/coherence (tau–kairos) tensor carries only scalar/pseudoscalar/vector structure (no TT): its vector quanta are the Tantrakyma $U(1)_C$ *Chrono–Kymons* (CK) (Definition 10.4 and Propositions 10.22 and 10.65). We record this via the *typed sourcing* furnished by the weave, without introducing new maps.

Remark 10.175 (Typed τ–kairos sourcing (weave form; no new primitives))**.** By the τ–decomposition (Definition 10.4),

$$\boxed{\hat{\tau}_{\mu\nu} \;=\; S^{(b)}_{\mu\nu}[\hat{\varphi}_b] \;\oplus\; S^{(L)}_{\mu\nu}[\hat{\varphi}_L] \;\oplus\; \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}] \;\oplus\; \sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}\left[\hat{K}^{(\tau)}_{\lambda}\right], \qquad \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0,} \tag{10.102}$$

where $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ are the scalar/pseudoscalar typed images and $A^{(\pm)}$ the CK helicity vectors. Equation (10.102) *is* the scalar/vector sourcing of $\hat{\tau}_{\mu\nu}$ in Chapter 11 notation and already encodes TT–nullity (Lemmas 10.17 and 10.59).

Remark 10.176 (Typed reading and T–L–O stamps)**.** Using typed insertion with triad provenance (Definitions 10.2 and 10.113), the $\Phi\Phi$ blocks

$$\hat{\mathbf{G}}^{[\Phi\to\Phi;\chi]}_{\Lambda;a} := \Pi^{(a)}\Pi^{[\chi]}\,\hat{\mathbf{G}}^{[\Phi\to\Phi]}_{\Lambda}\,\Pi^{[\chi]}\Pi^{(a)}, \qquad a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\},$$

are BRST/Nielsen–safe and band–admissible (Proposition 10.10). For $\chi = \mathrm{Tr}$ (Apeiron scalar) and $\chi \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ (tau/CK families), the weave stamps $\mathrm{TLO}^{[\chi]}$ via Propositions 10.22 and 10.65; for $\chi = \mathrm{TT}$, the graviton uses Proposition 10.35. TT–orthogonality is automatic: $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$ for all non–TT $[\chi]$ (Lemmas 10.17 and 10.59).

Corollary 10.177 (No gravitational–wave polarizations from tau–kairos)**.** *From* (10.102) *and TT–nullity, the tau–kairos sector contributes* no *TT (GW) polarizations. All spin–2 radiative content resides in the metric TT channel* [TT] *with two tensor helicities (see Definition 10.3 and Proposition 10.35).*

10.17.3 Excitation Channels and the Role of the Tau–Kairos

Program (typed split + constitutive recall). On the realized weave configuration (Definition 10.1) we resolve observable fluctuations of $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ by the Chapter 11 typed projectors and triad (Definitions 10.2 to 10.4 and 10.113). The constitutive identity $\Sigma_{\mu\nu}[\Phi, \Theta] = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi, \Theta]$ and its linear response are recalled from Ch. 10 (no new primitives).

Metric (Gaiamiti) channel — TT (spin–2) only. The unique radiative tensor excitation is the *graviton*, the TT projection of metric fluctuations:

$$\boxed{\hat{h}_{\mu\nu} \;:=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \text{ as in } \textit{Definition } 10.3.} \tag{10.103}$$

TT exhausts the tensor content of $\delta\hat{\Sigma}$: $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}$ (cf. TT–nullity of τ below). Field–space wise, the TT mode is sourced by *tangential* (Goldstone-like) Φ–variations, whereas the orthogonal radial direction reports in the trace–typed scalar (Apeiron) (Section 10.17.1 and eq. (10.93)).

Temporal/coherence (tau–kairos) channel — non–TT (spin–0/1 only). By construction the tau–kairos tensor is TT–null (Lemma 10.17):

$$\boxed{\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\tau}_{\mu\nu} = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\Pi^{[\chi]} = 0 \;\text{ for all non–TT } [\chi].} \tag{10.104}$$

Its typed decomposition (τ-kairos) is

$$\hat{\tau}_{\mu\nu} = S^{(b)}_{\mu\nu}[\hat{\varphi}_b] \;\oplus\; S^{(L)}_{\mu\nu}[\hat{\varphi}_L] \;\oplus\; \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}] \;\oplus\; \sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}\big[\hat{K}^{(\tau)}_{\lambda}\big],$$

with $A^{(\pm)}$ the CK vector helicities. The CK field strength $\hat{\mathcal{F}}^{(\tau)}_{\mu\nu} := 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}$ is the natural constitutive input for antisymmetric/phase–transport features of $t_{\mu\nu}$ (weave usage).

Scalar sector of Gaiamiti ("Apeiron"). As in Section 10.17.1, "Apeiron'' has (i) a *field–level* sense: the source $\delta\hat{\mathbf{\Phi}}$ feeding typed $\Phi\Phi$ blocks; and (ii) a *particle–level* sense: the trace–typed *radial* scalar (spin–0) with mass from the radial block of $\mathbb{H}_{\mathrm{phys}}$. Nomenclature policy: the spin–2 collective is the TT graviton; no spin–1 register exists in the Φ–sector— spin–1 belongs to CK in the τ channel (Definition 10.4).

Putting it together (no extra TT modes). Typed separation and TT–nullity imply: (i) all propagating *tensor* radiation sits in the TT graviton ($\lambda = \pm 2$); (ii) the tau–kairos supports only scalar/pseudoscalar/vector responses. Non–overlap is guaranteed by $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\Pi^{[\chi]} = 0$ for all non–TT $[\chi]$ (Lemmas 10.17 and 10.59) and by realized weave configuration admissibility/invariance (Definition 10.94 and Proposition 10.10).

On the scalar contribution to $\hat{\tau}_{\mu\nu}$. Although the Apeiron originates in Φ, the temporal tensor $t_{\mu\nu}[\Phi, \Theta]$ is a *constitutive* object depending on (Φ, Θ). Thus the scalar piece of $\hat{\tau}_{\mu\nu}$ is simply the Apeiron as seen through the temporal channel, preserving TT–nullity and adding no TT content (compatible with (10.25)–(10.104)).

Remarks on dynamics (i) The TT (spin–2) sector governed by $\hat{h}_{\mu\nu}$ is dynamically closed: off–diagonal metric–temporal mixing is non–TT, and the TT block obeys a hyperbolic wave equation obtained by TT–projecting the linearized field equations (Definition 10.3 and TT–purity).
(ii) The temporal/coherence sector influences observations *indirectly* via $\bar{t}_{\mu\nu}$ (background transport, dissipation, KMS/thermodynamic data) and through scalar/vector perturbations in cosmological or condensed regimes, but never by introducing additional GW polarizations (Propositions 10.22 and 10.65).

Summary. The unified fluctuation $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$ separates cleanly into (a) a TT, spin–2 *graviton* sector $\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ (eq. (10.103); equivalently $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma} = \hat{h}$), sourced by tangential Φ–variations, and (b) a non–TT *tau–kairos* sector $\hat{\tau}_{\mu\nu}$ populated by scalar/pseudoscalar/vector (CK) channels (eq. (10.25)). This realizes, in a single operator framework, the coexistence of geometric radiation (two tensor polarizations) with temporal/coherence dynamics, while preserving TT purity and typed/triad provenance throughout the weave pipeline (Propositions 10.10, 10.22, 10.35 and 10.65).

10.17.4 Observable (Kinematic) vs. Constitutive (Microscopic) Descriptions

On the realized weave configuration (Definition 10.1) there are two mutually consistent descriptions of chronogeometry: (i) a *formal/observable* (kinematic) split that reads metric and tau–kairos channels by the Chapter 11 typed projectors; and (ii) a *constitutive/microscopic* realization through the substrate fields (Φ, Θ). Using the *same* typed projectors and admission gate in both views yields identical Type–Location–Onset outcomes (Definitions 10.3, 10.4, 10.94 and 10.113 and Propositions 10.22 and 10.35).

Formal/observable split (recall; no new projectors). Write the operator–valued chronogeometry and its background/fluctuation split as in (10.94)–(10.95):

$$\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}, \qquad \delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}.$$

The TT (spin–2) content is isolated by the background–covariant projector $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ (Definition 10.3), and tau–kairos is TT–null (Lemma 10.17):

$$\boxed{\hat h_{\mu\nu} := \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat g_{\mu\nu}, \qquad \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\hat\tau_{\mu\nu} = 0, \qquad \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat\Sigma_{\mu\nu} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat g_{\mu\nu}.} \tag{10.105}$$

Constitutive map (recall from Ch. 10). Chronogeometry is realized by the constitutive identity

$$\Sigma_{\mu\nu}[\Phi,\Theta] = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi,\Theta],$$

with linear response about $(\bar\Phi,\bar\Theta)$ given by (10.101):

$$\delta\Sigma_{\mu\nu} = (D_\Phi g_{\mu\nu})\cdot\delta\Phi + (D_\Phi t_{\mu\nu})\cdot\delta\Phi + (D_\Theta t_{\mu\nu})\cdot\delta\Theta.$$

Tau–kairos TT–isolation implies $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\circ D_\Theta\Sigma = 0$ (weave usage of Lemma 10.17).

Theorem 10.178 (Equivalence after TT projection and graviton sourcing)**.** *With* (10.105) *and* (10.101)*,*

$$\boxed{\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\Sigma_{\mu\nu} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta g_{\mu\nu} = \left(\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\circ D_\Phi\bar g\right)\cdot\delta\Phi, \qquad \hat h_{\mu\nu} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat g_{\mu\nu} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\delta\hat\Sigma_{\mu\nu}.} \tag{10.106}$$

Thus the TT sector depends only on Gaiamiti variations; at the operator level the graviton is the TT metric fluctuation.

Proposition 10.179 (Parasymmetric alignment and T–L–O invariance)**.** *Run the sector execution functor with the* same *typed projectors and admission (Definitions 9.153 and 10.94) on either description:*

TT sector (geometry)
$\mathrm{TLO}^{[\mathrm{TT}]}_{\mathrm{formal}} = \mathrm{TLO}^{[\mathrm{TT}]}_{\mathrm{constitutive}}$ *with identical Type/Location/Onset, as per Proposition 10.35.*

Tau–kairos sector (non–TT)
For each admitted $\chi \in \{S^{(b)}, S^{(L)}, \tilde S^{(p)}, A^{(\pm)}\}$, $\mathrm{TLO}^{[\chi]}_{\mathrm{formal}} = \mathrm{TLO}^{[\chi]}_{\mathrm{constitutive}}$, *and* $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$ *prevents bleed into TT (Lemmas 10.17 and 10.59 and Propositions 10.22 and 10.65).*

Helicity register and purity guards
Optional TT–helicity refinement and the stability witness follow the same meters in both views (weave graviton register; TT–purity from Lemma 10.17).

Corollary 10.180 (Uniqueness of the split (up to benign field redefinitions))**.** *If (i)* $g_{\mu\nu}$ *is Lorentzian, (ii)* $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\hat\tau = 0$*, and (iii)* $t_{\mu\nu}\to 0$ *when temporal/KMS data are trivial, then any explicit* Θ*–dependence in* $g_{\mu\nu}$ *would produce TT strength via* $D_\Theta g$ *and violate* $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\circ D_\Theta\Sigma = 0$*. Hence, modulo benign field redefinitions,*

$$g_{\mu\nu} = g_{\mu\nu}[\Phi], \qquad t_{\mu\nu} = t_{\mu\nu}[\Phi,\Theta].$$

Proof. Work on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ after Σ–realization (Definitions 9.80 and 10.1). By the fluctuation split $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$ (eq. (10.95)) and TT–nullity of tau–kairos ($\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$; Definition 10.162, Lemma 10.17, and eq. (10.97)),

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\Sigma_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta g_{\mu\nu}.$$

Assume, for contradiction, that $g_{\mu\nu}$ depends explicitly on Θ, so that $\delta g_{\mu\nu} = (D_\Phi g)_{\mu\nu}\cdot\,\delta\Phi + (D_\Theta g)_{\mu\nu}\cdot\,\delta\Theta$. Choose variations with $\delta\Phi = 0$. Then

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\Sigma_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Big[(D_\Theta g)_{\mu\nu}\cdot\,\delta\Theta\Big].$$

However, by TT selection at the constitutive level (Proposition 10.173), the only source of TT support in the geometric channel is $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Big[(D_\Phi g)\cdot\,\delta\Phi\Big]$; that is, TT arises from *tangential* Φ–directions and not from Θ–directions. Therefore we must have

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\circ D_\Theta g \;=\; 0,$$

i.e. any Θ–dependence of g is annihilated by the York TT projector (pure trace/longitudinal content; Definition 10.3).

Let Θ_0 denote trivial temporal/KMS data (assumption (iii) gives $t_{\mu\nu}[\Phi,\Theta_0] = 0$). Define the benign field redefinitions

$$g'_{\mu\nu}[\Phi] := g_{\mu\nu}[\Phi,\Theta_0], \qquad t'_{\mu\nu}[\Phi,\Theta] := t_{\mu\nu}[\Phi,\Theta] + \Big(g_{\mu\nu}[\Phi,\Theta] - g_{\mu\nu}[\Phi,\Theta_0]\Big).$$

Since $g_{\mu\nu}[\Phi,\Theta] - g_{\mu\nu}[\Phi,\Theta_0]$ is TT–killed for all Θ (previous line), this addition is a pure trace/-longitudinal transfer that does not alter the TT channel, meters, or TLO stamps (band/BRST hygiene and commutations: Propositions 10.9 and 10.10; TT isolation: Lemma 10.172 and Theorem 10.169). Consequently the geometry can be represented as $g'_{\mu\nu}[\Phi]$ with all Θ–dependence absorbed into $t'_{\mu\nu}[\Phi,\Theta]$, proving the claim "modulo benign field redefinitions." Lorentzian character (assumption (i)) ensures the background–covariant TT projector is well–defined (ellipticity/York decomposition; Definition 10.3). □

Meaning. The corollary formalizes an identifiability statement: on the realized weave configuration, the *tensor* (TT, spin–2) content of the chronogeometry comes *only* from the Gaiamiti sector Φ (tangential directions), while all Θ (temporal/kairotic) effects can be placed—without loss of physics—into the non–TT piece $t_{\mu\nu}$. If one tried to let $g_{\mu\nu}$ depend on Θ, any nontrivial $D_\Theta g$ would otherwise feed TT power and contradict the TT–selection/uniqueness results (Proposition 10.173 and Theorem 10.169). Thus, after harmless field redefinitions that shuffle pure trace/longitudinal parts (Definition 10.3 and Proposition 10.9), the split is unique in the sense stated:

$$g_{\mu\nu} = g_{\mu\nu}[\Phi] \quad \text{(TT source)}, \qquad t_{\mu\nu} = t_{\mu\nu}[\Phi,\Theta] \quad \text{(trace/longitudinal, TT–null)}.$$

Operationally, this guarantees that TT graviton claims ($\mathrm{TLO}^{[\mathrm{TT}]}$) are insensitive to temporal/KMS choices, while Θ–driven structure is recorded only in the appropriate non–TT typed ledgers (Definition 10.4 and Proposition 10.22).

Remark 10.181 (Coordinate choice and parasymmetric invariants)**.** The formal view uses $(\Sigma;$ typed projectors); the constitutive view uses (Φ, Θ) and then the *same* typed projectors. Because the sector execution depends only on typed insertion, admission, and meters (Definitions 9.153, 10.94 and 10.113), the realized T–L–O stamps on $\mathfrak{P}$ are *coordinate–invariant*:

$$\textbf{Formal:}\quad \delta\hat{\Sigma} = \delta\hat{g} + \delta\hat{\tau}, \qquad \textbf{Constitutive:}\quad \delta\Sigma = (D_\Phi g)\cdot\delta\Phi + (D_\Phi t)\cdot\delta\Phi + (D_\Theta t)\cdot\delta\Theta,$$

with TT selection and non–overlap guaranteed by (10.105) and the weave TT–null rules.

10.17.5 Relational Graviton Propagator Matrix

To characterize the dynamical behavior of quantum gravitational excitations in the IQR, we introduce the two–point correlation structure of the unified chronogeometric fluctuations organized by the Chapter 11 typed/triad machinery (Sections 10.17.3 and 10.17.4 and Definitions 10.2 to 10.4 and 10.113). In the background/fluctuation split,

$$\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}, \qquad \delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}, \tag{10.107}$$

(cf. eq. (10.95)) we define the channel operators in the Chapter 11 convention

$$\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}, \qquad \hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}, \tag{10.108}$$

so that TT–selection yields $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0$ by Lemma 10.17, and the TT projector acts on the unified fluctuation as

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu} = \hat{h}_{\mu\nu} \quad \text{(cf. eqs. (10.103), (10.105) and (10.106)).}$$

Thus all radiative spin–2 content resides in the metric channel and is represented by the TT graviton $\hat{h}_{\mu\nu}$.

Definition 10.182 (Geometric propagator matrix)**.** The complete two–point function of the geometric excitation sector is the matrix–valued propagator

$$\boxed{\mathbf{G}^{(2)}_{\Sigma}(x,x') := \begin{pmatrix} \langle\Omega|T\{\hat{h}_{\mu\nu}(x)\,\hat{h}_{\rho\sigma}(x')\}|\Omega\rangle & \langle\Omega|T\{\hat{h}_{\mu\nu}(x)\,\hat{\tau}_{\rho\sigma}(x')\}|\Omega\rangle \\ \langle\Omega|T\{\hat{\tau}_{\mu\nu}(x)\,\hat{h}_{\rho\sigma}(x')\}|\Omega\rangle & \langle\Omega|T\{\hat{\tau}_{\mu\nu}(x)\,\hat{\tau}_{\rho\sigma}(x')\}|\Omega\rangle \end{pmatrix}}, \tag{10.109}$$

where correlators are taken in the interacting vacuum $|\Omega\rangle$ (Section 6.1.20) and $T\{\cdot\}$ denotes the time–ordering operator (Definition 11.53). The TT definition of $\hat{h}_{\mu\nu}$ and the TT–nullity of $\hat{\tau}_{\mu\nu}$ ensure consistency with the typed projector algebra (Definition 10.3 and Lemma 10.17); typed/triad insertions and provenance constraints may be applied to each block via Definition 10.113, Proposition 10.10, and Section 10.15.

Tensorial structure. Each entry of $\mathbf{G}^{(2)}_{\Sigma}$ is a rank–4 bitensor over $\mathcal{X}_q \times \mathcal{X}_q$ with typed/triad provenance (Definitions 10.2 and 10.113 and Proposition 10.10), symmetric in each index pair and obeying reciprocity for real neutral fields:

$$G_{\mu\nu\rho\sigma}(x,x') = G_{\rho\sigma\mu\nu}(x',x). \tag{10.110}$$

When needed, one may resolve $\mathbf{G}^{(2)}_{\Sigma}$ by relational channel $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ consistent with the SynTh/typed ledger (Section 10.15 and Definition 10.94) and write

$$\mathbf{G}^{(2)}_{\Sigma}(x,x') = \sum_{a} \mathbf{G}^{(2,a)}_{\Sigma}(x,x')\,. \tag{10.111}$$

For the block entries, the operators are the Chapter 11 graviton $\hat{h}_{\mu\nu}$ and tau–kairos $\hat{\tau}_{\mu\nu}$ of Definition 10.182, with $\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ and $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$ (Definition 10.3, Lemma 10.17, and eqs. (10.105) and (10.106)).

Matrix Green's equation (block form and causality). By the split eq. (10.95) and identifications eq. (10.100), the second variation of the action around $\bar{\Sigma}_{\mu\nu}$ defines a background–covariant block operator that acts on the $(\hat{h},\hat{\tau})$ sector:

$$\mathcal{D}(x) = \begin{pmatrix} \mathcal{D}_{hh} & \mathcal{C}_{h\tau} \\ \mathcal{C}_{\tau h} & \mathcal{D}_{\tau\tau} \end{pmatrix}_{(x)}, \qquad \mathcal{D}(x)\,\mathbf{G}^{(2)}_{\Sigma}(x,x') = \mathbf{I}\,\delta^{(d)}(x-x')\,. \tag{10.112}$$

Here $\mathcal{D}_{hh}$ is the (gauge–fixed) Lichnerowicz–type metric operator acting on the TT graviton sector $(\hat{h}_{\mu\nu})$, $\mathcal{D}_{\tau\tau}$ acts on tau–kairos fluctuations, and the off–diagonal couplings $\mathcal{C}_{h\tau}, \mathcal{C}_{\tau h}$ encode state–dependent conversion between metric and temporal/coherence channels (cf. Definition 10.182). TT–purity implies that, after projection with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, cross–blocks do not generate additional TT content (Lemma 10.17 and eqs. (10.105) and (10.106)); causality choices (retarded/advanced/Feynman) are selected consistently with the time–ordering operator and typed admission gate (Definitions 10.94 and 11.53). Fundamental solutions exist for (10.112) within the second–variation framework [156] and, for matrix–valued normally hyperbolic operators on curved backgrounds, under the standard hypotheses [244, 245].

Causal support from the unified architecture. Causality is governed by the two–layer light–cone structure determined by $\bar{\Sigma}_{\mu\nu}$ (see Chapter 5 and Section 5.4.5 and the Chapter 11 kinematic/constitutive setup Section 10.17.4). Denoting $J^{\pm}_{\bar{\Sigma}}(x')$ the future/past domains defined by the $\bar{\Sigma}$ cone, the retarded/advanced matrix propagators satisfy

$$\operatorname{supp}\mathbf{G}^{R}_{\Sigma}(\cdot,x') \subseteq J^{+}_{\bar{\Sigma}}(x'), \qquad \operatorname{supp}\mathbf{G}^{A}_{\Sigma}(\cdot,x') \subseteq J^{-}_{\bar{\Sigma}}(x'), \tag{10.113}$$

and the time–ordered (Feynman) propagator in Definition 10.182 is recovered by the usual combination with the time–ordering operator (Definition 11.53). Microcausality holds in the sense that equal–time commutators vanish at $\bar{\Sigma}$–spacelike separation [245]. Typed/triad provenance for all blocks follows the admission/ledger rules of Chapter 11 (Definitions 10.2 and 10.113 and Proposition 10.10).

TT sector consistency. Applying the Chapter 11 TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3) to eq. (10.112) and using $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0$ (Lemma 10.17 and eq. (10.105)) isolates the graviton equation in the spin–2 sector, reproducing the GW operator and TT wave dynamics (eqs. (10.96) and (10.131)). Equivalently, with eq. (10.106) one has that off–diagonal blocks do not generate extra TT polarizations after projection.

Definition 10.183 (TT–projected and typed propagators)**.** Define the TT–projected metric–metric propagator

$$G^{\mathrm{TT}}_{\mu\nu\rho\sigma}(x,x') := \Big\langle \Omega \Big| \, T\{\hat{h}_{\mu\nu}(x)\hat{h}_{\rho\sigma}(x')\} \, \Big| \Omega \Big\rangle = \Pi^{[\mathrm{TT}]\,\alpha\beta}_{\bar{\Sigma}\,\mu\nu}\, \Pi^{[\mathrm{TT}]\,\gamma\delta}_{\bar{\Sigma}\,\rho\sigma}\, G^{hh}_{\alpha\beta\gamma\delta}(x,x'), \tag{10.114}$$

where $\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\hat{g}_{\mu\nu}$ is the Chapter 11 graviton (eqs. (10.103) and (10.105) and Definition 10.3). Typed correlators are obtained by inserting the admissible typed projectors $\Pi^{[\chi]}$ on the operator legs,

$$G^{[\chi\chi']}(x,x') := \Big\langle \Omega \Big| \, T\{\Pi^{[\chi]}\cdot \delta\hat{\Sigma}(x)\ \Pi^{[\chi']}\cdot \delta\hat{\Sigma}(x')\} \, \Big| \Omega \Big\rangle,$$

with the typed/triad conventions of Chapter 11 (Definitions 10.2, 10.25 and 10.113). For $\chi \in \{\gamma, 0_\Phi, \tau_S, \tau_A, K^{(\tau)}_{\mathrm{T}}, K^{(\tau)}_{\mathrm{L}}\}$ (cf. Definition 10.13, Lemma 10.59, and Section 10.15), these correlators resolve $\mathbf{G}^{(2)}_{\Sigma}$ into the physically meaningful spin/helicity/polarization blocks while preserving TT purity (Lemma 10.17).

Proposition 10.184 (TT closure and null cross–blocks)**.** *With the Chapter 11 identities* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \circ \Pi_t = 0$ *and* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \circ D_\Theta \Sigma = 0$ *(cf. eqs. (10.8) and (10.101) and Lemma 10.17), one has*

$$\Big\langle \Omega \Big| \, T\{\hat{h}_{\mu\nu}(x)\, \hat{\tau}_{\rho\sigma}(x')\} \, \Big| \Omega \Big\rangle = 0, \tag{10.115}$$

and, more generally, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ *annihilates any typed leg in the temporal class* $\chi \in \{\tau_S, \tau_A, K^{(\tau)}_{\mathrm{T}}, K^{(\tau)}_{\mathrm{L}}\}$ *(Definition 10.4). Hence the TT propagator eq. (10.114) is dynamically closed (eqs. (10.105) and (10.106)).*

Proposition 10.185 (Parasymmetric T–L–O augmentation of propagators)**.** *On a certified plateau* $\mathfrak{P}$ *(Definition 10.1), the sector execution functor* $\mathcal{E}_\bullet$ *(Definition 9.153) acts on* $\mathbf{G}^{(2)}_{\Sigma}$ *as follows:*

(i) Permit ledger and typed admission
Build the ledger of admissible types $\Pi^{[\chi]}$ *and enforce the admission gate (Definition 10.94) and cone–gating (eq. (10.65)); non–admitted types receive no T–L–O. Typed/triad consistency follows Definitions 10.2 and 10.113 and Proposition 10.10.*

(ii) Typed visibilities from correlators
Extract law/state visibilities $\vec{\Lambda}^{[\chi]}$ *by reading spectral weight (poles/residues) and integrated strengths from the typed correlators* $G^{[\chi\chi]}$*; assign the quadrant* $\mathrm{Quad}^{[\chi]}$ *(QI–QIV) using the Chapter 9 decision rule, while respecting Chapter 11's spin/polarization scope (Section 10.15).*

(iii) Parasymmetric meters and Onset
Evaluate $v^{(a)}_{\mathrm{Synthesis}}$, $v^{(LS)}_{\mathrm{Synthesis}}$, $v^{(LS)}_{\mathrm{Agreement}}$ *on the typed propagators' windows; the Onset* $(r^\star, t^\star)$ *is the (scale,epoch) at which the meters cross their tolerance thresholds (cf. Definition 9.153). Law–side TT purity and helicity asymmetries are monitored via* $\mathcal{W}_{\mathrm{TT\text{–}purity}}$ *and* Δ_χ *(cf. Lemma 10.17 and Definition 10.26).*

(iv) T–L–O stamping

Record $\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$ *with Location taken from diagnostic realized reference configuration metadata (arena/sector/space tag/cone sheet) and Type from the quadrant; align with Chapter 11's TLO propositions (Propositions 10.22, 10.35 and 10.65).*

The resulting T–L–O augmentation is BRST/Nielsen–safe and unique by Proposition 10.90.

Physical interpretation of the diagonal components

Metric–channel (hh) propagator and TT graviton.

$$G^{hh}_{\mu\nu\rho\sigma}(x,x') := \Big\langle \Omega \Big| \, T\{\hat{h}_{\mu\nu}(x)\hat{h}_{\rho\sigma}(x')\} \, \Big| \Omega \Big\rangle. \tag{10.116}$$

This metric–channel correlator is the causal response of spatial–distinguishability fluctuations in the TT sector, with $\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \, \delta\hat{g}_{\mu\nu}$ the Chapter 11 graviton (Definitions 10.3 and 10.182 and eqs. (10.105) and (10.106)). The *graviton propagator* is the TT–projected object

$$G^{\mathrm{TT}}_{\mu\nu\rho\sigma}(x,x') := \Big\langle \Omega \Big| \, T\{\hat{h}_{\mu\nu}(x)\hat{h}_{\rho\sigma}(x')\} \, \Big| \Omega \Big\rangle, \tag{10.117}$$

and, using the TT projector explicitly,

$$G^{\mathrm{TT}}_{\mu\nu\rho\sigma} = \Pi^{[\mathrm{TT}]\,\alpha\beta}_{\bar{\Sigma}\,\mu\nu} \, \Pi^{[\mathrm{TT}]\,\gamma\delta}_{\bar{\Sigma}\,\rho\sigma} \, G^{hh}_{\alpha\beta\gamma\delta} \quad \text{(cf. eq. (10.114) and Definition 10.3).}$$

By eq. (10.115) (TT–closure and null cross–blocks), the mixed TT–temporal correlator vanishes, consistent with Lemma 10.17 and eq. (10.105).

Tau–kairos ($\tau\tau$) propagator $\langle T\{\hat{\tau}_{\mu\nu}(x)\hat{\tau}_{\rho\sigma}(x')\}\rangle$. This correlator tracks the propagation of temporal phase–flow fluctuations. It does not mediate a classical force; rather, it modulates quantum phase/coherence transport, influences entanglement dynamics, and can affect geometric–phase acquisition in embedded quantum systems. In the parasymmetric T–L–O pipeline, the typed entries $\chi \in \{\tau_S, \tau_A, K^{(\tau)}_{\mathrm{T}}, K^{(\tau)}_{\mathrm{L}}\}$ (Chapter 11 temporal class, Definitions 10.4 and 10.13) receive Onset windows $(r^\star, t^\star)$ from the meters (coherence activation scales), read from typed correlators $G^{[\chi\chi]}$ (Definitions 10.94, 10.113 and 10.183); but they remain TT–null by Lemmas 10.17 and 10.59, thereby leaving the graviton T–L–O entry $\mathrm{TLO}^{[\mathrm{TT}]}$ (two tensor polarizations) unaltered (Propositions 10.10, 10.22 and 10.35 and Section 10.15).

Graviton–Kairos Mixing and Off–Diagonal Correlators

The off–diagonal entries $\Big\langle \Omega \Big| \, T\{\hat{h}_{\mu\nu}(x)\hat{\tau}_{\rho\sigma}(x')\} \, \Big| \Omega \Big\rangle$ and its transpose encode *state–dependent conversion amplitudes* between spatial (metric) and temporal/coherence excitations. They are absent in classical GR and reflect the deeper relational structure of geometry in the IQR. Crucially, by the TT–null constraint for the temporal channel (Lemma 10.17 and eq. (10.105)) and TT–closure (Proposition 10.184 and eq. (10.115)), these mixings carry *no spin–2 content*:

$$\Big\langle \Omega \Big| \, T\{\hat{h}_{\mu\nu}(x) \, \hat{\tau}_{\rho\sigma}(x')\} \, \Big| \Omega \Big\rangle \; = \; 0, \tag{10.118}$$

with the same conclusion for the transpose. Equivalently, after projection with the Chapter 11 TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3), off–diagonal blocks cannot generate TT modes (eq. (10.106)).

Analogy. Just as phonons and non–propagating thermal excitations can mix in a lattice due to their common medium, the metric–channel and tau–kairos fluctuations mix because they are orthogonal components of the unified fluctuation $\delta\hat{\bar{\Sigma}}_{\mu\nu}$ (cf. eq. (10.95)), *not* because the graviton is sourced by the temporal sector. TT projection isolates the radiative tensor content uniquely in $\hat{h}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ (eqs. (10.103) and (10.105)), consistently with the GW operator and TT wave dynamics (eqs. (10.96) and (10.131)).

Propagator as a Matrix–Valued Green's Function

The full matrix $\mathbf{G}^{(2)}_{\Sigma}(x,x')$ solves the linearized coupled system for unified gravitational fluctuations:

$$\mathcal{D}(x)\,\mathbf{G}^{(2)}_{\Sigma}(x,x') \;=\; \mathbf{I}\,\delta^{(d)}(x-x'), \qquad \text{cf. } eq.\ (10.112). \tag{10.119}$$

Here $\mathcal{D}$ is the second–variation operator with off–diagonal couplings $\mathcal{C}_{h\tau}, \mathcal{C}_{\tau h}$ that generate the mixing entries (cf. Definition 10.182). Cone–gating and existence of fundamental solutions follow the standard theory for (matrix–valued) normally hyperbolic operators on curved backgrounds [156, 244, 245], together with the unified light–cone structure of $\bar{\Sigma}$ (Section 5.4.5) and the typed/triad provenance rules (Definitions 10.2 and 10.113 and Proposition 10.10).

Parasymmetric T–L–O view of mixing. On a certified plateau $\mathfrak{P}$ (Definition 10.1), the sector execution functor $\mathscr{E}_\bullet$ (Definition 9.153) reads the *typed* off–diagonal correlators $G^{[\chi\,\chi']}$ (with $\chi \in \{\gamma\}$ or $\chi \in \{\tau_S, \tau_A, K^{(\tau)}_{\mathrm{T}}, K^{(\tau)}_{\mathrm{L}}\}$) to assign quadrants and Onset windows via the parasymmetric meters, subject to typed admission and cone–gating (Definition 10.94 and eq. (10.65)). TT–null types never contribute to the γ T–L–O entry; $\mathrm{TLO}^{[\gamma]}$ remains the unique spin–2 stamp (Propositions 10.22, 10.35 and 10.90, Lemma 10.59, and Section 10.15). Typed/triad consistency across all legs is enforced via Definitions 10.2, 10.4 and 10.113.

Channel–Resolved Propagator for Chronogeometric Fluctuations (Bimodal–Triadic Form)

The two–point function $\mathbf{G}^{(2)}_{\Sigma}(x,x')$ (Definition 10.182) is naturally organized as a *bi–modal* split (metric vs. temporal) refined by a *triadic* source resolution $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, in the Chapter 11 typed/triad framework (Section 10.17.4, Definitions 10.2 and 10.113, and Proposition 10.10). The bimodal background/fluctuation structure is

$$\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}, \qquad \delta\hat{\bar{\Sigma}}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu} \quad (\text{cf. } eq.\ (10.95)),$$

with channel operators fixed by Chapter 11 as

$$\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}, \qquad \hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu},$$

so that $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$ (Definition 10.3 and Lemma 10.17) and $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{\bar{\Sigma}}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu} = \hat{h}_{\mu\nu}$ (eqs. (10.103), (10.105) and (10.106)). The GW operator and TT wave dynamics appear in eqs. (10.96) and (10.131).

Proposition 10.186 (Triadic channel resolution and structure)**.** *As a sum over interaction channels,*

$$\boxed{\mathbf{G}^{(2)}_{\Sigma}(x,x') \;=\; \sum_{a\in\{\mathrm{corr,vac,spec}\}} \mathbf{G}^{(2,a)}_{\Sigma}(x,x')\,,} \tag{10.120}$$

where each $\mathbf{G}^{(2,a)}_{\Sigma}$ *is a* 2×2 *matrix of time–ordered correlators,*

$$\mathbf{G}^{(2,a)}_{\Sigma}(x,x') = \begin{pmatrix} \langle\Omega|T\{\hat{h}^{(a)}_{\mu\nu}(x)\,\hat{h}^{(a)}_{\rho\sigma}(x')\}|\Omega\rangle & \langle\Omega|T\{\hat{h}^{(a)}_{\mu\nu}(x)\,\hat{\tau}^{(a)}_{\rho\sigma}(x')\}|\Omega\rangle \\ \langle\Omega|T\{\hat{\tau}^{(a)}_{\mu\nu}(x)\,\hat{h}^{(a)}_{\rho\sigma}(x')\}|\Omega\rangle & \langle\Omega|T\{\hat{\tau}^{(a)}_{\mu\nu}(x)\,\hat{\tau}^{(a)}_{\rho\sigma}(x')\}|\Omega\rangle \end{pmatrix},$$

with $T\{\cdot\}$ *as in Definition 11.53 and the vacuum* $|\Omega\rangle$ *as in Section 6.1.20. Each entry is a rank–4 bitensor, obeys reciprocity, and is causal with respect to the* $\bar{\Sigma}$ *cone (eq. (10.112) and Section 5.4.5); typed/triad provenance may be carried on each leg via Definitions 10.2 and 10.113.*

TT sector and selection rule. The physical (spin–2) propagator is the TT–projected metric correlator,

$$G^{\mathrm{TT}}_{\mu\nu\rho\sigma}(x,x') := \Big\langle\Omega\Big|\, T\{\hat{h}_{\mu\nu}(x)\hat{h}_{\rho\sigma}(x')\}\,\Big|\Omega\Big\rangle. \tag{10.121}$$

Cf. eqs. (10.114) and (10.131) and Definition 10.3.

and the selection rule

$$\Big\langle\Omega\Big|\, T\{\hat{h}_{\mu\nu}(x)\hat{\tau}^{(a)}_{\rho\sigma}(x')\}\,\Big|\Omega\Big\rangle = 0 \qquad \forall\, a\in\{\mathrm{corr,vac,spec}\}$$

follows from TT–nullity of the temporal class and TT–closure (Lemma 10.17, eqs. (10.90) and (10.115), and Proposition 10.184). Thus all radiative spin–2 content flows through the hh block (eqs. (10.105) and (10.106)).

Parasymmetric T–L–O augmentation (channel–wise). On $\mathfrak{P}$ (Definition 10.1), apply $\mathscr{E}_\bullet$ to the *typed*, channel–resolved correlators $G^{[\chi\chi']\langle a\rangle}$ (Definition 10.183) to: (i) enforce typed admission (Definition 10.94); (ii) compute typed visibilities $\vec{\Lambda}^{[\chi]}$ and assign quadrants (QI–QIV) consistent with Chapter 11's spin/polarization scope (Section 10.15); (iii) extract Onset windows $(r^\star,t^\star)$ from the parasymmetric meters (Definition 9.153); and (iv) stamp $\mathrm{TLO}^{[\chi]}$ with diagnostic realized reference configuration–derived Locations (Propositions 10.22, 10.35 and 10.65). Because $\chi\in\{\tau_S,\tau_A,K^{(\tau)}_{\mathrm{T}},K^{(\tau)}_{\mathrm{L}}\}$ are TT–null (Lemmas 10.17 and 10.59), their T–L–O entries never alter $\mathrm{TLO}^{[\mathrm{TT}]}$; law–side TT purity and helicity asymmetries are monitored via $\mathcal{W}_{\mathrm{TT\text{–}purity}}$ and Δ_χ (cf. Definition 10.26).

Consequence and channel count

For each $a\in\{\mathrm{corr,vac,spec}\}$ the operator content decomposes into the pair $(\hat{h}^{(a)}_{\mu\nu},\hat{\tau}^{(a)}_{\mu\nu})$ in the Chapter 11 bimodal split (Section 10.17.4 and Definition 10.182). Hence there are exactly six channel–separated modes:

$$(\hat{h},\hat{\tau})\times(\mathrm{corr,vac,spec}) = \{\,\hat{h}^{(\mathrm{corr})},\hat{h}^{(\mathrm{vac})},\hat{h}^{(\mathrm{spec})},\hat{\tau}^{(\mathrm{corr})},\hat{\tau}^{(\mathrm{vac})},\hat{\tau}^{(\mathrm{spec})}\,\}.$$

Among these, only the TT graviton sector

$$\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu} \quad \Rightarrow \quad G^{\mathrm{TT}}_{\mu\nu\rho\sigma} = \left\langle \Omega \middle| T\{\hat{h}_{\mu\nu}\hat{h}_{\rho\sigma}\} \middle| \Omega \right\rangle$$

supplies propagating tensor quanta (two polarizations) in the radiative channel (eqs. (10.96) and (10.131) and Section 10.15), with the projector definition and TT selection given by Definition 10.3 and eqs. (10.105), (10.106) and (10.114). The tau–kairos sector remains strictly non–TT (eq. (10.90), Lemmas 10.17 and 10.59, and Definition 10.4), contributing only spin–0 and spin–1 structure and no extra GW polarizations.

Origin Channel	**Graviton (Spin-2)** $\hat{h}^{(a)}_{\mu\nu}(x)$	**Tau-Kairos tensor (Spin-0,1)** $\hat{\tau}^{(a)}_{\mu\nu}(x)$
Correlational	$\hat{h}^{(\mathrm{corr})}_{\mu\nu}(x)$ *(eq. (11.74))*	$\hat{\tau}^{(\mathrm{corr})}_{\mu\nu}(x)$ *(temporal entanglement)*
Vacuum	$\hat{h}^{(\mathrm{vac})}_{\mu\nu}(x)$ *(Definition 11.43)*	$\hat{\tau}^{(\mathrm{vac})}_{\mu\nu}(x)$ *(vacuum coherence structure)*
Spectral	$\hat{h}^{(\mathrm{spec})}_{\mu\nu}(x)$ *(Definition 11.44)*	$\hat{\tau}^{(\mathrm{spec})}_{\mu\nu}(x)$ *(energy-induced phase dynamics)*

Table 10.3: The Six Fundamental Modes of Geometric Excitation

10.17.6 Triadic Decomposition of Gravitational Propagation

In the IQR framework, emergent geometry is encoded by the operator–valued chronogeometric tensor $\hat{\Sigma}_{\mu\nu}(x)$, with background $\bar{\Sigma}_{\mu\nu}$ and fluctuation $\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}$ (cf. eq. (10.95)). We adopt the *triadic channelization* introduced for the propagator (corr, vac, spec; see Definitions 10.2, 10.3, 10.25 and 10.113 and Proposition 10.10) as an organizing principle for fluctuations on $\bar{\Sigma}$. In Chapter 11 notation the bimodal operators are $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ and $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}_{\mu\nu} = 0$ (Definition 10.3, Lemma 10.17, and eqs. (10.103), (10.105) and (10.106)).

We now show that this triadic structure induces a corresponding decomposition of the metric and tau–kairos fluctuations—and hence of the full gravitational propagator matrix.

Definition 10.187 (Triadic decomposition of chronogeometric fluctuations and graviton sector)**.** The unified fluctuation decomposes by channels as

$$\boxed{\begin{aligned} \delta\hat{\Sigma}_{\mu\nu}(x) &= \delta\hat{\Sigma}^{(\mathrm{corr})}_{\mu\nu}(x) + \delta\hat{\Sigma}^{(\mathrm{vac})}_{\mu\nu}(x) + \delta\hat{\Sigma}^{(\mathrm{spec})}_{\mu\nu}(x), \\ \hat{h}_{\mu\nu}(x) &= \sum_{a\in\{\mathrm{corr},\mathrm{vac},\mathrm{spec}\}} \hat{h}^{(a)}_{\mu\nu}(x), \qquad \hat{\tau}_{\mu\nu}(x) = \sum_{a} \hat{\tau}^{(a)}_{\mu\nu}(x), \end{aligned}} \tag{10.122}$$

with $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ and $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ (Definition 10.3 and eq. (10.105)). The physical (spin–2) graviton in each channel is already TT by construction, while the temporal class is TT–null:

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{h}^{(a)}_{\mu\nu} = \hat{h}^{(a)}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}^{(a)}_{\mu\nu} = 0 \quad \text{(cf. Lemma 10.17 and eq. (10.90))},$$

so that $\hat{h}_{\mu\nu} = \sum_a \hat{h}^{(a)}_{\mu\nu}$ and no TT content arises from τ (cf. Corollary 10.20 and eq. (10.131)).

Each $\hat{h}^{(a)}_{\mu\nu}$ is a covariant symmetric TT tensor field and each $\hat{\tau}^{(a)}_{\mu\nu}$ a covariant symmetric non–TT tensor; the channels are mutually orthogonal in the sense induced by the triadic split and typed admission (Definitions 10.2, 10.25, 10.94 and 10.113).

Definition 10.188 (Triadic mode decomposition of the gravitational propagator)**.** The complete geometric propagator matrix $\mathbf{G}^{(2)}_{\Sigma}(x,x')$ (Definition 10.182) decomposes as

$$\boxed{\mathbf{G}^{(2)}_{\Sigma}(x,x') = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \mathbf{G}^{(2,a)}_{\Sigma}(x,x')\,,} \tag{10.123}$$

where each $\mathbf{G}^{(2,a)}_{\Sigma}$ retains the full 2×2 block structure over (h,τ) (cf. Section 10.17.5):

$$\mathbf{G}^{(2,a)}_{\Sigma}(x,x') = \begin{pmatrix} \langle\Omega|\,T\{\hat{h}^{(a)}_{\mu\nu}(x)\hat{h}^{(a)}_{\rho\sigma}(x')\}\,|\Omega\rangle & \langle\Omega|\,T\{\hat{h}^{(a)}_{\mu\nu}(x)\hat{\tau}^{(a)}_{\rho\sigma}(x')\}\,|\Omega\rangle \\ \langle\Omega|\,T\{\hat{\tau}^{(a)}_{\mu\nu}(x)\hat{h}^{(a)}_{\rho\sigma}(x')\}\,|\Omega\rangle & \langle\Omega|\,T\{\hat{\tau}^{(a)}_{\mu\nu}(x)\hat{\tau}^{(a)}_{\rho\sigma}(x')\}\,|\Omega\rangle \end{pmatrix}.$$

The TT–projected graviton propagator correspondingly decomposes as

$$G^{\mathrm{TT}}_{\mu\nu\rho\sigma}(x,x') = \sum_a \langle\Omega|\,T\{\hat{h}^{(a)}_{\mu\nu}(x)\hat{h}^{(a)}_{\rho\sigma}(x')\}\,|\Omega\rangle,$$

with no TT leakage into τ by $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}^{(a)} = 0$ (cf. Lemma 10.17 and eq. (10.90)); see also eqs. (10.105), (10.106) and (10.114).

Physical interpretation of the triadic channels. The three channels are distinct physical sources of curvature, yielding complementary gravitational responses:

(i) Correlational (corr) *Entanglement–induced geometry*—curvature sourced by inter–modal quantum correlations and informational structure (consistent with the channelization in Definitions 10.2, 10.3, 10.25 and 10.113).

(ii) Vacuum (vac) *Vacuum–deformation geometry*—curvature from vacuum–manifold structure and SSB in the Gaiamiti sector; the TT graviton's masslessness arises from tangential (Goldstone) directions (cf. Sections 9.17.2 and 10.5 and eqs. (10.96), (10.103) and (10.131); see also [415, 502]).

(iii) Spectral (spec) *Energy–induced geometry*—curvature sourced by spectral energy–momentum (i.e. matter/kymon excitations) in the operator Green–function framework on curved backgrounds [244, 7]; causal support follows the $\bar{\Sigma}$ cone (Section 5.4.5).

Remark 10.189 (Quantum gravity as operator–valued dynamics)**.** In this representation, quantum gravity is a state–relative, operator–valued response theory: the coupled operators $(\hat{h}_{\mu\nu}, \hat{\tau}_{\mu\nu})$ evolve via linearized second–variation equations (cf. eq. (10.112) and Section 10.17.7), and their *channel–resolved* propagators $\mathbf{G}_{\Sigma}^{(2,a)}$ encode causal, covariant responses to perturbations of distinct origin. Causality and support are governed by the $\bar{\Sigma}$–light cone (Section 5.4.5); the TT projector isolates the radiative spin–2 sector, ensuring that gravitational waves reside entirely in $\hat{h}_{\mu\nu}$ with two polarizations (cf. eqs. (10.28), (10.105), (10.114) and (10.131) and Corollary 10.20). For background–field and propagator conventions, see [244, 7].

10.17.7 Covariant Dynamics of Gravitational Fluctuations

Gravitational excitations in the IQR arise as quantum fluctuations of the operator–valued chronogeometric tensor $\hat{\Sigma}_{\mu\nu}(x) = \hat{g}_{\mu\nu}(x) + \hat{t}_{\mu\nu}(x)$ (cf. Section 5.2.6 and eqs. (10.94) and (10.95)). The observable TT (spin–2) sector is the Chapter 11 graviton $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}$, while the temporal/coherence sector is $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}_{\mu\nu} = 0$ (Definition 10.3, eqs. (10.90), (10.103) and (10.105), and Lemma 10.17). Microscopically, Σ is produced constitutively from the substrate fields (Φ, Θ) via $\Sigma_{\mu\nu}[\Phi, \Theta] = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi, \Theta]$ (eqs. (10.94) and (10.101)), so that, upon linearization, $\delta\Sigma_{\mu\nu} = (D_{\Phi}g)\cdot\delta\Phi + (D_{\Phi}t)\cdot\delta\Phi + (D_{\Theta}t)\cdot\delta\Theta$ (eq. (10.101)). The TT projection singles out the Gaiamiti variations:

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\Sigma = \Big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \circ D_{\Phi}g\Big)\cdot\delta\Phi \quad \text{(cf. eq. (10.106))}.$$

1. Linearization of the Gaiamiti action

We start from the Gaiamiti action (background connection $\bar{\nabla}$ and measure built from $\bar{\Sigma}_{\mu\nu}$; cf. eq. (10.87)):

$$S_{\Phi}[\hat{\mathbf{\Phi}}] = \int_{\mathcal{X}_q} d^d x \,\sqrt{-\det\big(\bar{\Sigma}\big)}\;\mathrm{Tr}\Big\{\bar{\Sigma}^{\mu\nu}\, g_T\Big(\bar{\nabla}_{\mu}\hat{\mathbf{\Phi}}, \bar{\nabla}_{\nu}\hat{\mathbf{\Phi}}\Big) + \mathcal{V}_{\Phi}(\hat{\mathbf{\Phi}})\Big\}\,.$$

Decompose about the expectation background (cf. eq. (10.87))

$$\hat{\mathbf{\Phi}}(x) = \bar{\Phi}(x)\,\mathbb{I} + \delta\hat{\mathbf{\Phi}}(x),$$

and expand $S_{\Phi} = S^{(0)} + S^{(1)} + S^{(2)} + \cdots$. Stationarity of $\bar{\Phi}$ sets $S^{(1)} = 0$. The quadratic action governing fluctuations is

$$\boxed{S^{(2)}[\delta\hat{\mathbf{\Phi}}] = \int d^d x \,\sqrt{-\det\big(\bar{\Sigma}\big)}\;\mathrm{Tr}\Big\{\bar{\Sigma}^{\mu\nu}\Big(\bar{\nabla}_{\mu}\delta\hat{\mathbf{\Phi}}\Big)^{\dagger}\Big(\bar{\nabla}_{\nu}\delta\hat{\mathbf{\Phi}}\Big) - \tfrac{1}{2}\,\delta\hat{\mathbf{\Phi}}^{\dagger}\,\mathcal{M}(x)\,\delta\hat{\mathbf{\Phi}}\Big\}\,,} \tag{10.124}$$

with the (generally position–dependent, operator–valued) mass kernel

$$\boxed{\mathcal{M}(x) := \left.\frac{\delta^2\mathcal{V}_{\Phi}}{\delta\hat{\mathbf{\Phi}}^{\dagger}(x)\,\delta\hat{\mathbf{\Phi}}(x)}\right|_{\bar{\Phi}}.} \tag{10.125}$$

Euler–Lagrange variation. Varying $S^{(2)}$ with respect to $\delta\hat{\mathbf{\Phi}}^\dagger$ gives

$$\frac{\delta S^{(2)}}{\delta\big(\delta\hat{\mathbf{\Phi}}^\dagger\big)} = -\,\bar{\nabla}_\mu\Big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\delta\hat{\mathbf{\Phi}}\Big) - \mathcal{M}(x)\,\delta\hat{\mathbf{\Phi}} = 0,$$

whence the covariant fluctuation equation

$$\boxed{\bar{\nabla}_\mu\Big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\delta\hat{\mathbf{\Phi}}\Big) - \mathcal{M}(x)\,\delta\hat{\mathbf{\Phi}} = 0.} \tag{10.126}$$

Introducing the unified d'Alembertian $\Box_{\bar{\Sigma}} := \bar{\nabla}_\mu\big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\,\cdot\,\big)$ (or equivalently $\bar{\nabla}^\mu\bar{\nabla}_\mu$ with indices raised by $\bar{\Sigma}^{\mu\nu}$), (10.126) is $(\Box_{\bar{\Sigma}} - \mathcal{M})\,\delta\hat{\mathbf{\Phi}} = 0$. This normally–hyperbolic form ensures well–posed propagation with respect to the $\bar{\Sigma}$ light–cones (cf. Section 5.4.5); it provides the dynamical seeds for the propagator matrix of Definition 10.182 and its Green's equation eq. (10.112).

From $\delta\hat{\mathbf{\Phi}}$ to observables. Via the constitutive chain rule (eq. (10.101)),

$$\delta\hat{g}_{\mu\nu} = \Big(D_\Phi g_{\mu\nu}\Big)\cdot\delta\hat{\mathbf{\Phi}}, \qquad \delta\hat{t}_{\mu\nu} = \Big(D_\Phi t_{\mu\nu}\Big)\cdot\delta\hat{\mathbf{\Phi}} + \Big(D_\Theta t_{\mu\nu}\Big)\cdot\delta\hat{\mathbf{\Theta}},$$

and, by TT isolation (Lemma 10.17 and eq. (10.105)), the radiative sector is

$$\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu} = \Big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\circ D_\Phi g\Big)\cdot\delta\hat{\mathbf{\Phi}} \quad \text{(cf. eqs. (10.103) and (10.106)).}$$

Thus (10.126) is the dynamical origin for all spin–2 quanta after TT projection, while $\hat{\tau}_{\mu\nu}$ remains non–TT (cf. Section 10.17.8 and Lemma 10.59).

Parasymmetric T–L–O view (typed, localized, onset–gated). The fluctuation equation (10.126) is admitted as a physical evolution only when the typed admission gate certifies hyperbolicity and cone–gating ($\Box_{\bar{\Sigma}}$ normally hyperbolic; BRST–closed) for the relevant types (γ in the TT sector; τ_S, τ_A in the temporal sector) (Definition 10.94). Upon admission, the sector–execution functor $\mathcal{E}_\bullet$ stamps $\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$ for each χ (Definition 9.153): Type is fixed by the projector (γ vs. τ); Location is read from the diagnostic realized reference configuration/arena metadata and cone–sheet tags; Onset $(r^\star, t^\star)$ is extracted from the parasymmetric meters and defines the coherence windows during which the corresponding solutions of (10.126) (pushed forward to δg and δt) are operational in readouts (cf. Propositions 10.22, 10.35 and 10.65). Law–side TT purity is monitored by $\mathcal{W}_{\mathrm{TT\text{–}purity}}$ (Lemma 10.17), ensuring no leakage of non–TT content into the graviton ledger and consistency with the null cross–blocks of Proposition 10.184.

Summary. The quadratic Gaiamiti action (10.124) yields the covariant fluctuation equation (10.126). Through the constitutive map and TT projection, its solutions generate the TT graviton sector $\hat{h}_{\mu\nu}$ (two polarizations) while the temporal/coherence response $\hat{\tau}_{\mu\nu}$ remains TT–null (eq. (10.90)). Parasymmetric T–L–O formalisms provide the operational gate (*admission*), the contextual placement (*location*), and the meter–derived thresholds (*onset*) for these fluctuations in experimental and cosmological settings (Definitions 9.153 and 10.94).

2. Interpretation of the Linearized Dynamics

Equation (10.126) is the covariant wave equation for Gaiamiti fluctuations ("Apeiron" modes), i.e. a curved–background generalization of a relativistic Klein–Gordon equation that controls how geometric disturbances propagate and seed observable responses (Section 10.17.7).

(i) Covariant chronogeometric propagation. The kinetic operator $\bar{\nabla}^{\mu}\bar{\nabla}_{\mu}$ is built from the background *chronogeometric tensor* $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (cf. Section 5.2.6 and eq. (10.94)). Thus the field–level Apeiron propagation is sensitive to both the metric background $\bar{g}_{\mu\nu}$ (spatial distinguishability) and the temporal/coherence background $\bar{t}_{\mu\nu}$ (phase flow). Through the constitutive map, this unified propagation feeds the two observable channels g and t (Section 10.17.4 and eq. (10.101)). *By contrast*, the radiative TT graviton obeys the TT–projected metric equation built with $\bar{g}_{\mu\nu}$, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\big[\delta\bar{G}_{\mu\nu}[\hat{h}] + \Lambda\,\hat{h}_{\mu\nu}\big] = 0$ (Definition 10.3 and eqs. (10.103) and (10.131)); any $\bar{t}_{\mu\nu}$ influence can only enter indirectly via non–TT mixing and background parameters, not as extra TT polarizations (cf. Lemma 10.17, eq. (10.90), and Proposition 10.184).

(ii) Operator mass term $\mathcal{M}(x)$ and Goldstone directions. The operator $\mathcal{M}(x)$ arises from the Hessian of the Gaiamiti potential $\mathcal{V}_{\Phi}$ (eq. (10.125)) and acts as a local restoring force. Flat directions of $\mathcal{V}_{\Phi}$ on the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ yield zero eigenvalues (Goldstone modes) [93, 94]. In our framework the *massless spin–2 graviton* is precisely the Goldstone arising from tangential variations of Φ projected to the TT sector (Sections 9.17.2 and 10.5 and eqs. (10.96), (10.103) and (10.106)). The tau–kairos sector, being TT–null ($\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau} = 0$; Lemma 10.17 and eq. (10.90)), is *not* a spin–2 Goldstone; its scalar/vector components may be massive or massless depending on model symmetries (e.g. a gauged Chrono–Kymon vs. Proca–type mass; cf. Definition 10.57 and Section 10.18.6).

(iii) Induced dynamics of gravitational operators. Via the linear response of the constitutive map (eq. (10.101)),

$$\delta\hat{\Sigma}_{\mu\nu} \;=\; \big(D_{\Phi}\Sigma\big)_{\mu\nu}\cdot\delta\hat{\mathbf{\Phi}} \;=\; \underbrace{\big(D_{\Phi}g\big)_{\mu\nu}\cdot\delta\hat{\mathbf{\Phi}}}_{\delta\hat{g}_{\mu\nu}} \;+\; \underbrace{\big(D_{\Phi}t\big)_{\mu\nu}\cdot\delta\hat{\mathbf{\Phi}}}_{\text{part of }\delta\hat{t}_{\mu\nu}} \;+\; \big(D_{\Theta}t\big)_{\mu\nu}\cdot\delta\hat{\mathbf{\Theta}},$$

so the operator excitations $\delta\hat{g}_{\mu\nu}$ and $\delta\hat{t}_{\mu\nu}$ inherit their dynamics from (10.126). The Chapter 11 graviton is obtained by TT projection

$$\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu} \quad \text{(cf. Definition 10.3 and eqs. (10.103), (10.105), (10.106) and (10.114)).}$$

(iv) Causal support and light–cone structure. Since $\bar{\nabla}^{\mu}\bar{\nabla}_{\mu}$ is constructed from $\bar{\Sigma}_{\mu\nu}$, the corresponding fundamental solutions respect the $\bar{\Sigma}$–causal cones. Accordingly, the matrix propagator $\mathbf{G}_{\Sigma}^{(2)}(x,x')$ (Definition 10.182 and Section 10.17.5) has retarded/advanced support contained in the future/past $\bar{\Sigma}$–domains, consistent with the two–layer causal architecture (Section 5.4.5) and the Green's equation eq. (10.112).

In summary, the gravitational sector emerges from the linearized dynamics of the Gaiamiti substrate. The Apeiron equation (10.126) provides the covariant seed; constitutive response splits that seed into the metric and temporal channels; and TT projection isolates the unique spin–2 Goldstone (the graviton) governed by eq. (10.131), while the tau–kairos remains strictly non–TT (Lemma 10.17, eq. (10.90), and Proposition 10.184) and influences coherence/phase rather than adding GW polarizations.

10.17.8 Gravitational Waves

We formalize gravitational waves entirely within the chronogeometric framework (cf. Sections 5.2.6, 10.17.2 and 10.17.4). We keep explicit the identities of the two key excitations: the *graviton* $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ (TT, spin–2; eqs. (10.96) and (10.103) and Definition 10.3) and the *tau–kairos* fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ (non–TT; eqs. (10.90) and (10.100) and Lemma 10.17).

Background and linearized split. Let the expectation–level chronogeometry be

$$\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}, \qquad \delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu}, \tag{10.127}$$

(cf. Section 5.2.6 and eq. (10.95)). The transverse–traceless projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is the Chapter 11 background–covariant projector (Definition 10.3) and satisfies

$$\bar{\nabla}^{\mu}\big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}X\big)_{\mu\nu} = 0, \qquad \bar{g}^{\mu\nu}\big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}X\big)_{\mu\nu} = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\circ\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}. \tag{10.128}$$

Definition 10.190 (Gravitational–wave operator (recall))**.** The *gravitational–wave operator* is the TT projection of the metric fluctuation,

$$\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\big[\delta\hat{g}_{\mu\nu}\big],$$

as defined once and for all in eqs. (10.96) and (10.103). By TT–isolation of the temporal channel (eqs. (10.90) and (10.105), Lemma 10.17, and Corollary 10.20),

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\big[\delta\hat{\Sigma}_{\mu\nu}\big] = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\big[\delta\hat{g}_{\mu\nu}\big] = \hat{h}_{\mu\nu}.$$

Corollary 10.191 (TT isolation of the temporal/coherence sector (proved))**.** *The temporal/coherence fluctuation carries no TT content:*

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\big[\delta\hat{t}_{\mu\nu}\big] = 0,$$

as stated in eq. (10.90); equivalently $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\circ D_{\Theta}\Sigma = 0$ *by the constitutive chain rule eq. (10.101). This follows from the Chapter 11 typed projector algebra and TT–purity,* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\circ\Pi_{t} = 0$ *(Definitions 10.3 and 10.4, Lemma 10.17, and eqs. (10.8) and (10.105)). Moreover, TT–closure implies no TT content arises from off–diagonal blocks (Proposition 10.184 and eq. (10.115)).*

Proposition 10.192 (Kinematic properties)**.** *By eq. (10.128) and the definition eq. (10.96),*

$$\bar{\nabla}^{\mu}\hat{h}_{\mu\nu} = 0, \qquad \bar{g}^{\mu\nu}\hat{h}_{\mu\nu} = 0, \tag{10.129}$$

and $\hat{h}_{\mu\nu}$ *transforms covariantly under background diffeomorphisms induced by* $\bar{g}_{\mu\nu}$*.*

Proposition 10.193 (Goldstone origin (Gaiamiti sourcing)). *With the constitutive identity* $\Sigma_{\mu\nu}[\Phi,\Theta] = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi,\Theta]$ *and the selection rule* $\Pi_{\bar\Sigma}^{[\mathrm{TT}]} \circ D_\Theta \Sigma = 0$ *(cf. Sections 10.17.2 and 10.17.4 and eq. (10.101)), the TT mode is sourced solely by tangential (Goldstone) variations of the Gaiamiti field:*

$$\hat h_{\mu\nu} = \Big(\Pi_{\bar\Sigma}^{[\mathrm{TT}]} \circ D_\Phi g\Big) \cdot \delta\Phi_{\mathrm{tang}}. \tag{10.130}$$

TT wave equation. Let $\delta\bar G_{\mu\nu}$ denote the linearized Einstein tensor built from the background $\bar g_{\mu\nu}$ (indices raised/lowered by $\bar g_{\mu\nu}$). TT–projecting the linearized field equations gives

$$\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Big[\delta\bar G_{\mu\nu}[\hat h] \;+\; \Lambda\,\hat h_{\mu\nu}\Big] = \kappa\,\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Big[\delta\bar T^{\mathrm{total}}_{\mu\nu}\Big], \tag{10.131}$$

and in vacuum (or when the TT part of the anisotropic stress vanishes),

$$\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Big[\delta\bar G_{\mu\nu}[\hat h] \;+\; \Lambda\,\hat h_{\mu\nu}\Big] = 0. \tag{10.132}$$

These equations are consistent with the TT selection rules and null cross–blocks of Chapter 11 (eqs. (10.105) and (10.115) and Proposition 10.184) and with the causal support determined by the unified cones (Section 5.4.5).

Parasymmetric T–L–O augmentation of the GW sector

Definition 10.194 (Typed GW entry and ledger admission). On a certified plateau $\mathfrak{P}$ (cf. Definition 10.1), admit the TT type $\chi = \mathrm{TT}$ via the gate of Definition 10.94. Here χ is the typed ledger tag for the transverse–traceless sector (the field/operator is $\hat h_{\mu\nu}$; cf. eqs. (10.103) and (10.105)). The corresponding typed projector is the Chapter 11 TT projector

$$\Pi^{[\chi]} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]} \quad \text{(cf. Definitions 10.3 and 10.25)}.$$

The sector execution functor $\mathscr{E}_\bullet$ (Definition 9.153) then constructs the typed visibilities $\vec\Lambda^{[\mathrm{TT}]}$, assigns a typed quadrant $\mathrm{Quad}^{[\mathrm{TT}]} \in \{\mathrm{QI},\mathrm{QII},\mathrm{QIII},\mathrm{QIV}\}$, and stamps

$$\mathrm{TLO}^{[\mathrm{TT}]} = \big(\mathrm{Type},\mathrm{Location},\mathrm{Onset}\big),$$

with Location read from diagnostic realized reference configuration metadata (arena/sector/space tag/cone sheet) and Onset $= (r^\star, t^\star)$ extracted from the parasymmetric meters $v^{(a)}_{\mathrm{Synthesis}}$, $v^{(LS)}_{\mathrm{Synthesis}}$, $v^{(LS)}_{\mathrm{Agreement}}$ (cf. Definition 9.153). Typed/triad provenance is preserved throughout (Definitions 10.2 and 10.113 and Proposition 10.10); when a preferred spatial direction exists, the TT tag may be refined to helicity tags $\mathrm{TT}_{\pm2}$ (alias $\gamma_{\pm2}$; cf. Definition 10.26 and Section 10.15).

Proposition 10.195 (Helicity register and stability). *When a* $\bar\Sigma$*-spatial direction is meaningful, refine the TT tag into* $\mathrm{TT}_{\pm2}$ *(cf. Definition 10.25 and Section 10.15) and monitor*

$$\Delta_\chi \;:=\; \Lambda_{\mathrm{state}}^{[\mathrm{TT}_{+2}]} \;-\; \Lambda_{\mathrm{state}}^{[\mathrm{TT}_{-2}]},$$

as in Definition 10.26. A stable nonzero Δ_χ *signals chiral/anisotropic spin–2 response without altering the* count *of tensor polarizations.*

Proposition 10.196 (Law–side guard for extra TT content)**.** *The witness*

$$\mathcal{W}_{\mathrm{TT\text{–}purity}} := \left| \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \circ D_\Theta \Sigma \right|_{\mathfrak{P}}$$

(cf. Lemma 10.17 and eq. (10.101)) monitors TT leakage from the temporal constitutive branch. If $\mathcal{W}_{\mathrm{TT\text{–}purity}} \approx 0$, $\mathrm{TLO}^{[\mathrm{TT}]}$ *exhausts the TT sector. If* $\mathcal{W}_{\mathrm{TT\text{–}purity}} > 0$ *persists in QIII/QIV, extend the typed family (e.g. admit* $\Pi^{[\mathrm{TT}_{\mathrm{mass}}]}$*) and re-run* $\mathcal{E}_\bullet$ *as in Definition 10.32, consistent with the null cross–blocks Proposition 10.184 and eq. (10.115).*

Corollary 10.197 (Closure of the TT sector under T–L–O)**.** *With* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \circ \Pi_t = 0$ *and* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \circ D_\Theta \Sigma = 0$ *(eqs. (10.8) and (10.101)), no type* χ *belonging to the temporal/coherence register* $(\tau_S, \tau_A, K_{\mathrm{T}}^{(\tau)}, K_{\mathrm{L}}^{(\tau)})$ *contributes to* $\mathrm{TLO}^{[\mathrm{TT}]}$ *(cf. Lemma 10.59). Thus the TT wave equation (10.131) governs the entire tensor radiative sector, with the graviton operator* $\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \delta\hat{g}_{\mu\nu}$ *(eqs. (10.103) and (10.106)).*

Remark 10.198 (Realized vs. pre–physical staging)**.** On the PQS band $[\ell_{\mathrm{PQS}}, \ell_P)$ (Definition 9.153) only operator–level audits are performed (typed hyperbolicity, cone–gating, hygiene). For $\ell \geq \ell_P$ one certifies $\mathfrak{P}$ (Definition 10.1), projects to H^0, and reports physical $\mathrm{TLO}^{[\mathrm{TT}]}$ and helicity diagnostics; BRST/Nielsen safety is inherited from the diagnostic realized reference configuration. Compatibility with causal support of the unified cones follows Section 5.4.5.

Summary and empirical status. Within this framework, *gravitational waves* are the TT–projected metric perturbations

$$\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu} \quad \text{(cf. eqs. (10.96) and (10.103) and Definition 10.3)},$$

massless Goldstone excitations of the Gaiamiti sector that uniquely populate the spin–2 channel; the temporal/coherence tensor obeys $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \hat{\tau}_{\mu\nu} = 0$ (see eq. (10.90) and Lemma 10.17). The GW sector receives a typed, BRST/Nielsen–safe $\mathrm{TLO}^{[\mathrm{TT}]}$ stamp (Type from QI–QIV; Location from diagnostic realized reference configuration metadata; Onset from parasymmetric meters), while law–side TT purity and potential helicity asymmetries are guarded by $\mathcal{W}_{\mathrm{TT\text{–}purity}}$ and Δ_χ, respectively (cf. Lemma 10.17 and Definition 10.26). The linear dynamics are governed by eq. (10.131), consistent with the TT closure and null cross–blocks (Proposition 10.184 and eq. (10.115)) and with typed provenance (Definition 10.113 and Proposition 10.10). Current observations remain consistent with a purely tensorial radiative sector: direct detections and polarization analyses favor two spin–2 GW polarizations [345, 502]; searches for an (approximately) isotropic stochastic background set stringent upper limits on non–tensor admixtures [512, 501]; the near–luminal GW propagation inferred from GW170817 excludes broad classes of models with extra polarizations or modified propagation [513, 514]; and strong–field/post–Newtonian tests support quadrupolar tensor emission as the dominant dissipative channel [515].

10.17.9 Tantrakyma and Kymon Contributions to Chronogeometry

We work on the realized weave configuration with the Chapter 11 typed projectors and triad (Definitions 10.1 to 10.4 and 10.113). Throughout we keep visible the identities of the two

key excitations: the *graviton* $\hat{\gamma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ (spin–2 TT) and the *tau–kairos* fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ (non–TT), as recalled in Section 10.17.2 and eq. (10.105).

Kinematic placement. At the expectation level the chronogeometric tensor splits as in (10.94):

$$\boxed{\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\bar{t}_{\mu\nu} = 0,} \tag{10.133}$$

so TT content resides entirely in the metric block (Section 10.17.2).

Remark 10.199 (Tantrakyma contribution to the temporal block (weave recall))**.** At the operator level $\hat{t}_{\mu\nu}$ is built from τ/CK typed images (and mixed correlators) defined in the weave (Definition 10.4); $\bar{t}_{\mu\nu} := \langle\hat{t}_{\mu\nu}\rangle$ collects their background profiles. All TT (spin–2) content belongs to the metric channel by (10.105).

Constitutive form and selection rule (recall). With $\Sigma_{\mu\nu}[\Phi,\Theta] = g_{\mu\nu}[\Phi] + t_{\mu\nu}[\Phi,\Theta]$ and linear response (10.101), tau–kairos TT–isolation reads

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \circ D_{\Theta}\Sigma \;=\; 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta t_{\mu\nu} = 0,} \tag{10.134}$$

so Tantrakyma variations populate only non–TT temporal structure.

Tensor structures generated by kymons

Typed τ-kairos decomposition (no new maps). Use the Chapter 11 τ-kairos decomposition (Definition 10.4):

$$\boxed{\hat{\tau}_{\mu\nu} = S^{(b)}_{\mu\nu}[\hat{\varphi}_b] \;\oplus\; S^{(L)}_{\mu\nu}[\hat{\varphi}_L] \;\oplus\; \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}] \;\oplus\; \sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}\big[\hat{K}^{(\tau)}_{\lambda}\big], \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\tau}_{\mu\nu} = 0,} \tag{10.135}$$

where $A^{(\pm)}$ are CK vector helicities and $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}$ are scalar/pseudoscalar images.

Symmetric vs. antisymmetric temporal tensors (type-only schematics). Writing $t_{(\mu\nu)}$ and $t_{[\mu\nu]}$ for the symmetric/antisymmetric parts, the weave types imply, schematically (type classification only),

$$\text{(i)}\quad t_{(\mu\nu)}: \quad \text{scalar gradients and symmetric CK bilinears,} \quad S^{(\cdot)}_{\mu\nu}[\cdot], \tag{10.136}$$

$$\text{(ii)}\quad t_{[\mu\nu)}: \quad \text{CK field strength } \hat{\mathcal{F}}^{(\tau)}_{\mu\nu} := 2\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]}, \quad A^{(\pm)}_{\mu\nu}[\cdot], \tag{10.137}$$

with $\hat{K}^{(\tau)}_{\mu}$ the Chrono–Kymon vector (see the CK usage in the weave).

Explicit TT annihilation (made concrete). Because (10.135) is built entirely from non–TT typed families,

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, t_{(\mu\nu)} = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, t_{[\mu\nu]} = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{t}_{\mu\nu} = 0,} \tag{10.138}$$

leaving the graviton $\hat{\gamma}_{\mu\nu}$ untouched (purely metric TT).

Remark 10.200 (Chrono–Kymon sourcing of temporal profiles (weave usage))**.** Coherent CK configurations $K_{\mu}^{(\tau)}$ source extended $\bar{t}_{\mu\nu}$ profiles via symmetry–allowed couplings to $\bar{\Sigma}$, $K^{(\tau)} \rightsquigarrow \bar{t}_{\mu\nu}[\bar{\Sigma}; K^{(\tau)}]$, while preserving TT isolation (10.134). The antisymmetric branch is proportional to the CK field strength, $\bar{t}_{[\mu\nu]} = \chi_{\tau}\, \hat{\mathcal{F}}_{\mu\nu}^{(\tau)}$ (CK section, weave).

Corollary 10.201 (Parasymmetric T–L–O accounting for Tantrakyma types)**.** *Running the sector execution with typed/triad provenance (Definitions 9.153 and 10.2) and admission (Definition 10.94) yields, on a certified plateau $\mathfrak{P}$:*

(i) *Typed T–L–O stamps. For each admitted $\chi \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ one obtains* $\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$*, with Type determined by the QI–QIV quadrant and Location taken from diagnostic realized reference configuration metadata (Propositions 10.22 and 10.65).*

(ii) *Onset from parasymmetric meters. The onset $(r^{\star}, t^{\star})$ is determined by the parasymmetric meters $v_{\mathrm{Synthesis}}^{(a)}$, $v_{\mathrm{Synthesis}}^{(LS)}$, $v_{\mathrm{Agreement}}^{(LS)}$ (Definition 9.153), defining the coherence windows for temporal responses.*

(iii) *TT nullity of Tantrakyma types. By $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$ and (10.138), no Tantrakyma type contributes to* $\mathrm{TLO}^{[\mathrm{TT}]}$ *(Lemmas 10.17 and 10.59).*

Dynamical implications (framework level)

(a) Variational field equations. Varying the action w.r.t. Σ yields field equations equating curvature functionals of $\bar{\Sigma}$ to total stress–energy from the substrates. The Tantrakyma sector contributes ordinary stress $\bar{T}_{\mu\nu}^{\Theta}$ and coherence stress via $\bar{t}_{\mu\nu}$ whenever that channel is dynamical, inducing a consistent back–reaction on $\bar{\Sigma}$ (consistent with Section 10.17.4).

(b) Closure of the TT sector. Because of (10.138), the TT (spin–2) sector is dynamically closed: off–diagonal metric–temporal couplings affect only non–TT content. Thus the Tantrakyma/kymon sector cannot generate spin–2 excitations; its influence is confined to the temporal/coherence channel and to non–TT back–reaction. TT purity is monitored by the weave witness (Lemma 10.17).

All Tantrakyma/kymon effects enter through the temporal/coherence block $t_{\mu\nu}$: they sculpt $\bar{t}_{\mu\nu}$ and $\hat{\tau}_{\mu\nu}$, contribute to total stress, and leave the TT graviton sector (spin–2, (10.103)) untouched. Parasymmetric T–L–O stamps for $\{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ record *when/where* these temporal influences turn on, without adding GW polarizations (Propositions 10.22 and 10.65).

Analytical Symmetry Argument

Set–up (weave kinematics and sources). Use the Chapter 11 fluctuation split and identifications

$$\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu} = \hat{h}_{\mu\nu} + \hat{\tau}_{\mu\nu} \quad \text{(cf. (10.95), (10.100))}.$$

The tau–kairos fluctuation is built from the τ-kairos decomposition (Definition 10.4):

$$\boxed{\hat{\tau}_{\mu\nu} = S^{(b)}_{\mu\nu}[\hat{\varphi}_b] \;\oplus\; S^{(L)}_{\mu\nu}[\hat{\varphi}_L] \;\oplus\; \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}] \;\oplus\; \sum_{\lambda=\pm} A^{(\lambda)}_{\mu\nu}\big[\hat{K}^{(\tau)}_{\lambda}\big], \qquad \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0,} \tag{10.139}$$

i.e. only scalar/pseudoscalar/vector images are present (Lemmas 10.17 and 10.59). Relative to $(\bar{g}, \bar{\nabla})$ one may use the representative trace/longitudinal forms

$$S^{(b)}_{\mu\nu}[\hat{\Phi}] = \frac{1}{d}\,\bar{g}_{\mu\nu}\,\hat{\Phi}, \qquad A_{\mu\nu}[\hat{K}] := \bar{\nabla}_{(\mu}\hat{K}_{\nu)} - \frac{2}{d}\,\bar{g}_{\mu\nu}\,\bar{\nabla}\cdot\hat{K},$$

which span the trace ($\mathbf{0}$) and longitudinal ($\mathbf{1}$) subspaces of Sym^2.

York/Helmholtz orthogonal splitting (weave statement). On $(\bar{g}, \bar{\nabla})$ equip Sym^2 with the L^2 inner product $\langle X, Y\rangle = \int \sqrt{-\bar{g}}\, X^{\mu\nu}Y_{\mu\nu}$ and define the trace–adjusted symmetrized gradient

$$\mathcal{L}[V]_{\mu\nu} := \bar{\nabla}_{(\mu}V_{\nu)} - \frac{2}{d}\,\bar{g}_{\mu\nu}\,\bar{\nabla}\cdot V.$$

Then any $X \in \mathrm{Sym}^2$ admits the orthogonal decomposition

$$\boxed{X_{\mu\nu} = X^{\mathrm{TT}}_{\mu\nu} + \mathcal{L}[V]_{\mu\nu} + \frac{1}{d}\,\bar{g}_{\mu\nu}\,(\mathrm{tr}\,X),} \tag{10.140}$$

with X^{TT} transverse–traceless and V solving $\bar{\nabla}^{\mu}\mathcal{L}[V]_{\mu\nu} = \bar{\nabla}^{\mu}\big(X_{\mu\nu} - \frac{1}{d}\bar{g}_{\mu\nu}\,\mathrm{tr}\,X\big)$. Thus

$$\mathrm{Sym}^2 = \underbrace{\mathrm{TT}}_{\text{spin-2}} \;\oplus\; \underbrace{\mathrm{Im}\,\mathcal{L}}_{\text{longitudinal (spin-1)}} \;\oplus\; \underbrace{\mathrm{span}\{\bar{g}\}}_{\text{trace (spin-0)}},$$

with L^2–orthogonality (integration by parts; standard elliptic arguments).

Projector action and TT isolation. Let $\mathcal{P}^{(i)}$ project onto the three orthogonal subspaces above ($i = 0, 1, 2$). By construction, $\mathcal{P}^{(2)}[\mathrm{Im}\,\mathcal{L}] = 0 = \mathcal{P}^{(2)}[\mathrm{span}\{\bar{g}\}]$; hence from (10.139),

$$\boxed{\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0 \quad \Rightarrow \quad \hat{\tau}_{\mu\nu} \in \mathbf{0} \oplus \mathbf{1} \;\; \text{(no spin–2 content)}.} \tag{10.141}$$

The TT graviton $\hat{\gamma}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{h}_{\mu\nu}$ is therefore purely metric (eq. (10.105)).

Parasymmetric T–L–O overlay. Because $\hat{\tau}_{\mu\nu}$ lives in $\mathbf{0} \oplus \mathbf{1}$, only the tau/CK types $\chi \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ are admissible candidates (Definition 10.94). On a certified plateau $\mathfrak{P}$, the execution functor stamps $\mathrm{TLO}^{[\chi]} = (\mathrm{Type}, \mathrm{Location}, \mathrm{Onset})$ (Definition 9.153 and Proposition 10.22), with Onset extracted from the parasymmetric meters; the TT graviton stamp $\mathrm{TLO}^{[\mathrm{TT}]}$ is unaffected (Lemma 10.59). TT purity is monitored by the weave witness (Lemma 10.17). □

Gauge and Variational Argument

Action and symmetries (weave–covariant). Let the Tantrakyma sector be governed by a gauge– and diffeomorphism–covariant action on the background chronogeometry $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$:

$$S_\Theta[\hat{\mathbf{\Theta}}] = \int d^d x \, \sqrt{-\det \bar{\Sigma}}\, \mathrm{Tr}\Big\{ \bar{\Sigma}^{\mu\nu}\, g_C\Big(\bar{\nabla}_\mu \hat{\mathbf{\Theta}}, \bar{\nabla}_\nu \hat{\mathbf{\Theta}}\Big) + \mathcal{V}_\Theta(\hat{\mathbf{\Theta}}) \Big\},$$

with the weave–covariant derivative $\bar{\nabla}$ acting on Θ–registers (weave usage). Euler–Lagrange equations are first order in $\bar{\nabla}\hat{\mathbf{\Theta}}$ and respect gauge/relational symmetries.

Structure of $t_{\mu\nu}$ and induced constraints. The temporal tensor $t_{\mu\nu}[\Phi, \Theta]$ is built from symmetry–allowed bilinears and covariant derivatives of scalar and CK vector registers (plus constitutive dependence on Φ), consistent with the typed images in (10.139). Linearizing about $(\bar{\Phi}, \bar{\Theta})$ yields $\hat{\tau}_{\mu\nu} = \delta\hat{t}_{\mu\nu}$ that decomposes *only* into trace/longitudinal pieces; no divergence–free, trace–free (TT) driver arises.

Projector consequence and TT closure. Applying the same TT projector that defines the graviton, $\hat{\gamma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}$, gives

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\tau}_{\mu\nu} = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{\Sigma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu} \quad \text{(TT sector purely metric).}} \tag{10.142}$$

Hence the tau–kairos/kymon sector contributes only spin–0/1 structure and cannot source spin–2 radiation; the GW sector remains entirely in the TT metric channel (eq. (10.103)).

Parasymmetric T–L–O perspective (ledger and admission). In the realized regime, the typed ledger admits precisely the tau/CK families that pass hyperbolicity and cone–gating (Definitions 10.1 and 10.94). The execution functor stamps $\mathrm{TLO}^{[\chi]}$ for $\chi \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$, with Onset from the parasymmetric meters and Location from diagnostic realized reference configuration metadata (Definition 9.153 and Propositions 10.22 and 10.65). Because $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$ for these types (Lemma 10.59), the resulting stamps define *coherence timers* for temporal responses without altering $\mathrm{TLO}^{[\mathrm{TT}]}$. TT purity is monitored by the weave witness (Lemma 10.17); persistent deviations trigger the controlled projector–family extension (weave law–side protocol). □

The Identity of the Geometric Goldstone Boson

Statement (weave view). On the realized weave configuration, the masslessness of the long–range gravitational interaction is *emergent* from SSB in the Gaiamiti sector (no prior masslessness assumption). The Goldstone carrier must be identified within the typed bimodal split of chronogeometric fluctuations,

$$\delta\hat{\Sigma}_{\mu\nu} = \delta\hat{g}_{\mu\nu} + \delta\hat{t}_{\mu\nu} = \hat{h}_{\mu\nu} + \hat{\tau}_{\mu\nu} \quad \text{(cf. (10.95), (10.100))}.$$

Here $\hat{h}_{\mu\nu}$ lives in the metric (Gaiamiti) channel and $\hat{\tau}_{\mu\nu}$ in the temporal/coherence (tau–kairos) channel; the two are typed–orthogonal.

The two candidates (typed identifications)

(i) Metric fluctuation (graviton) Its physical spin–2 content is the TT graviton field (Definitions 10.3 and 10.25):

$$\boxed{\hat{h}_{\mu\nu} \;:=\; \mathcal{P}^{(2)}_{\text{grav}}\,\delta\hat{g}_{\mu\nu} \;=\; \Pi^{[\text{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu},} \tag{10.143}$$

with propagation captured by the TT–typed ΦΦ correlator blocks $\hat{\mathbf{G}}^{[\Phi\to\Phi;\text{TT}]}_{\Lambda;a}$ (triad $a \in \{\text{spec}, \text{vac}, \text{corr}\}$; cf. Definition 10.158).

(ii) Tau–kairos fluctuation By TT–nullity, $\Pi^{[\text{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0$ (cf. eq. (10.97) and Definition 10.162), so it carries only scalar/pseudoscalar/vector structure (no spin–2) in the weave τ/CK families (Definitions 10.4 and 10.57).

Verdict from spin and sourcing

A conserved rank–2 source selects a *massless spin–2* carrier at low energies; in the weave this carrier is precisely the TT graviton field extracted from the metric fluctuation, $\hat{h}_{\mu\nu} = \mathcal{P}^{(2)}_{\text{grav}}\delta\hat{g}_{\mu\nu} = \Pi^{[\text{TT}]}_{\bar{\Sigma}}\delta\hat{g}_{\mu\nu}$ (Definitions 10.3 and 10.25, cf. eq. (10.143)). Since tau–kairos is TT–null ($\Pi^{[\text{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$; Definition 10.162, Lemma 10.17, and eq. (10.97)), it cannot realize a spin–2 Goldstone nor mediate classical gravitational radiation. All radiative tensor content is confined to the TT channel and recorded in the TT–typed ΦΦ blocks (Definition 10.158 and Theorem 10.169).

Channel–resolved Goldstone identity (triad decomposition)

Decompose the *metric fluctuation* by triad provenance (Definition 10.2):

$$\delta\hat{g}_{\mu\nu} = \sum_{a\in\{\text{spec,vac,corr}\}} \delta\hat{g}^{(a)}_{\mu\nu}, \qquad \hat{h}^{(a)}_{\mu\nu} := \Pi^{[\text{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}^{(a)}_{\mu\nu}.$$

Then the graviton field splits as $\hat{h}_{\mu\nu} = \sum_a \hat{h}^{(a)}_{\mu\nu}$ with each $\hat{h}^{(a)}_{\mu\nu}$ captured in the TT–typed ΦΦ correlator blocks $\hat{\mathbf{G}}^{[\Phi\to\Phi;\text{TT}]}_{\Lambda;a}$ (Definition 10.158). Under the Goldstone origin of the TT mode in the Gaiamiti sector (tangential directions), each channel component is massless

(Propositions 9.197 and 10.173). The tau–kairos sector stays typed–orthogonal to TT and contributes only scalar/vector observables in non–TT blocks (no TT leakage; Definition 10.162, eq. (10.97), and Theorem 10.169).

Alignment with the parasymmetric T–L–O ledger. Typed projectors implement the separation between graviton and tau–kairos channels. The graviton uses the TT type with a $\mathrm{TLO}^{[\mathrm{TT}]}$ stamp (Type/Location/Onset; Proposition 10.90 and Definitions 10.135 and 10.136), while tau–kairos entries $\chi \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(\pm)}\}$ are stamped in their own branches and satisfy $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \Pi^{[\chi]} = 0$ (Lemmas 10.17 and 10.59), so they never contribute to $\mathrm{TLO}^{[\mathrm{TT}]}$. Meters/visibilities are BRST/Nielsen–safe on the realized weave configuration (Definitions 10.1 and 10.82 and Lemma 10.83), monotone with unique onsets (Propositions 9.146 and 10.88 and Lemma 10.86), and reported in the quadrant map (Section 10.14).

Consequences. (i) The number of propagating tensor polarizations remains two, entirely in the TT graviton sector (Definitions 10.3 and 10.25); (ii) triad dependence enters only through amplitudes/phases and sourcing inside the TT blocks $\hat{\mathbf{G}}^{[\Phi\to\Phi;\mathrm{TT}]}_{\Lambda;a}$ (no creation of extra TT modes; Definition 10.158 and Proposition 10.9); (iii) tau–kairos provides non–radiative scalar/vector responses that shape temporal/coherence structure and background transport, with propagation causally gated by $\bar{\Sigma}$ (Definition 6.7 and Remark 9.83).

10.18 Matter Block of the Unified Correlator

We describe the self–correlations of the Tantrakyma field as the lower–right (matter) block of the Unified Inter–Modal Correlator, using typed insertion and triad provenance on the realized weave configuration (Definitions 10.1, 10.2 and 10.113). This block captures the propagation of matter–like degrees of freedom—*kymons*—across the emergent configuration space $\mathcal{X}_q$ and underwrites particle phenomenology within the PQS program, while remaining TT–orthogonal to the graviton sector.

10.18.1 Definition and Typed Placement

Definition 10.202 (Matter block via typed insertion)**.** Let $\hat{\mathbf{G}}_\Lambda$ denote the Unified Inter–Modal Correlator (weave form). The Tantrakyma (matter) block is

$$\boxed{\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda} := \Pi^{[\Theta]}_{\Lambda}\, \hat{\mathbf{G}}_\Lambda\, \Pi^{[\Theta]}_{\Lambda}, \qquad \hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda} = \bigoplus_{a\in\{\mathrm{spec,vac,corr}\}} \hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda;a},} \tag{10.144}$$

with triad idempotents $\Pi^{(a)}$ giving $\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda;a} := \Pi^{(a)}\, \hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda}\, \Pi^{(a)}$.

Definition 10.203 (Matter two–point kernel (QHS, connected))**.** Let $\hat{\mathbf{\Theta}}(x)$ be the Tantrakyma field operator and $\langle\cdot\rangle_\circ$ the QHS expectation on the realized weave configuration (Definitions 1.27 and 10.1). The *connected, time–ordered* matter kernel is

$$\boxed{\hat{G}_{\Theta\Theta}(x,x') := \Big\langle T\{\hat{\mathbf{\Theta}}(x)\,\hat{\mathbf{\Theta}}(x')\}\Big\rangle_\circ - \Big\langle\hat{\mathbf{\Theta}}(x)\Big\rangle_\circ \Big\langle\hat{\mathbf{\Theta}}(x')\Big\rangle_\circ,} \tag{10.145}$$

where $T\{\cdot\}$ denotes the *relational* time–ordering associated with the background $\bar{\Sigma}$ (i.e. chronological ordering along the $\bar{\Sigma}$–compatible time function; cf. Definitions 6.7 and 9.80 and Remark 9.83). In the position basis, $\hat{G}_{\Theta\Theta}(x,x')$ coincides with the kernel of the $\Theta\Theta$ block of the Unified Inter–Modal Correlator (Definition 6.4), as recorded in (10.144).

Explanation (time ordering and connectedness). The operator $T\{\cdot\}$ orders insertions by the relational time defined on the $\bar{\Sigma}$–geometry, so that the resulting two–point function matches the causal cones of $\bar{\Sigma}$ (hence the associated retarded/advanced kernels are Σ–causal; Remark 9.83). Subtracting the product of one–point functions makes the kernel *connected*; by the same algebra used for the geometric sector (eqs. (10.88) and (10.89)), this quantity equals the covariance of $\hat{\boldsymbol{\Theta}}$–fluctuations in the QHS state. Finally, identifying $\hat{G}_{\Theta\Theta}$ with the $\Theta\Theta$ block's kernel ties this definition directly to the unified correlator architecture (Definition 6.4), ensuring that typed insertions and triad provenance in Chapter 11 apply verbatim to the matter sector as well (Definitions 10.2 and 10.113).

Physical meaning. $\hat{G}_{\Theta\Theta}$ is the *kymon propagator* in the sense that its analytic structure (poles, residues, and continuous parts) encodes the emergent mass spectrum, widths, and mixing of matter excitations on the physical carrier $\mathcal{H}_{\text{phys}}$ (Definitions 10.1 and 10.203). On admitted bands, masses and quasi-particle projectors are isolated by the Riesz calculus applied to the gauge–fixed kinetic generalized eigen-operator pair in the $\Theta\Theta$ block (Definition 10.7), while spectral positivity is controlled by the Källén–Lehmann ledger on $\mathcal{H}_{\text{phys}}$ (cf. eq. (7.12) and scalar/vector specializations such as Proposition 10.77). Typed resolution sharpens this reading: scalar content (e.g. radial/Higgs and trace-like modes) is refined by CP projectors $\Pi^{(\text{CP}\pm)}$ (Definition 10.5), and vector content (Chrono–Kymon) is helicity- and parity-resolved by $A^{(\pm)}$ with diagnostic Δ_P (Definitions 10.57 and 10.58). Because the kernel is defined with $\bar{\Sigma}$-relational time ordering (Definition 10.203), its retarded/advanced parts are Σ-causal (support inside $\bar{\Sigma}$-cones; Remark 9.83), ensuring a consistent notion of propagation on the realized chronogeometric background (Definitions 6.7 and 9.80).

Stage vs. actors (and how we report them). Within the Unified Inter–Modal Correlator (Definition 6.4), the geometric block $\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Phi]}$ sets the *stage* by determining the realized chronogeometry $\bar{\Sigma}$ and the TT graviton channel (TT type; Definitions 10.25, 10.157 and 10.158), whereas the matter block $\hat{\mathbf{G}}_{\Lambda}^{[\Theta\to\Theta]}$ governs the *actors*—the kymons—through its typed spectral content (Definitions 10.2 and 10.113). Inter–sector couplings appear only through the off–diagonal $\Phi\Theta$ entries and are audited via typed insertion/mixing rules and selection constraints (parity/helicity/CP) so that no forbidden leakage contaminates the TT graviton readout (Proposition 10.126, Lemma 10.123, and Theorem 10.169). Operationally, both blocks feed the same Law/State ledgers and calibrated meters (Definitions 10.80 and 10.82), yielding finite, monotone visibilities with unique onsets (Lemmas 10.83 and 10.86 and Propositions 9.146 and 10.88). In reports, the kymon claims are issued as $\text{TLO}^{[\chi]}$ for the appropriate $\Theta\Theta$ types (e.g. rad$\pm$, $A^{(\pm)}$), while the graviton is certified solely in the TT $\Phi\Phi$ branch—cleanly separating the *actors* from the *stage* within the same weave scaffold (Definitions 10.135 and 10.136).

10.18.2 Background–fluctuation Decomposition

Definition 10.204 (Tantrakyma background–fluctuation split)**.** Relative to the Quantum Holo–State,

$$\boxed{\hat{\mathbf{\Theta}}(x) \;=\; \bar{\Theta}(x)\,\mathbb{I}_x \;+\; \delta\hat{\mathbf{\Theta}}(x), \qquad \langle \delta\hat{\mathbf{\Theta}}(x)\rangle_\circ = 0.} \tag{10.146}$$

Proposition 10.205 (Fluctuation reduction)**.** *With* (10.146)*,*

$$\boxed{\hat{G}_{\Theta\Theta}(x,x') \;=\; \Big\langle \delta\hat{\mathbf{\Theta}}(x)\,\delta\hat{\mathbf{\Theta}}(x')\Big\rangle_\circ .} \tag{10.147}$$

Proof. Insert $\hat{\mathbf{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\mathbf{\Theta}}$ into (10.145) and use $\langle\delta\hat{\mathbf{\Theta}}\rangle_\circ = 0$. □

10.18.3 Typed resolution and admissible matter channels

Definition 10.206 (Typed matter correlators in the τ/CK families)**.** Using the Chapter 11 tau–kairos/kymon types (Definition 10.4),

$$\boxed{\hat{\mathbf{G}}^{[\Theta\to\Theta;\chi]}_{\Lambda;a} \;:=\; \Pi^{(a)}\,\Pi^{[\chi]}\,\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda}\,\Pi^{[\chi]}\,\Pi^{(a)}, \qquad \chi\in\{S^{(b)},S^{(L)},\tilde{S}^{(p)},A^{(\pm)}\},} \tag{10.148}$$

which provide the scalar/pseudoscalar/vector kymon channels (no TT type appears in the Tantrakyma family).

Corollary 10.207 (Positivity and cone–gating on $\mathfrak{P}$)**.** *On a certified plateau $\mathfrak{P}$, each admitted typed block $\hat{\mathbf{G}}^{[\Theta\to\Theta;\chi]}_{\Lambda;a}$ is a positive semidefinite covariance on equal–time test functions of type $[\chi]$ and propagates within the $\bar{\Sigma}$–cones (admission & hyperbolicity: Definitions 10.1 and 10.94).*

Interpretation (ledger view). The typed blocks (10.148) feed the parasymmetric pipeline; the execution functor stamps $\mathrm{TLO}^{[\chi]}$ for admitted χ with Location inherited from diagnostic realized reference configuration metadata and Onset from the meters (Definition 9.153 and Propositions 10.22 and 10.65). TT–purity of the graviton sector is unaffected because $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Pi^{[\chi]} = 0$ for these matter types (Lemmas 10.17 and 10.59).

10.18.4 Relations to cross–blocks and spectrum

Cross–block coupling. Kymon propagation couples to geometry through the *typed off–diagonal* blocks $\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}$ and $\hat{\mathbf{G}}^{[\Theta\to\Phi]}_{\Lambda;a}$, built by typed insertion with triad provenance (Definitions 10.2 and 10.113). These kernels encode how localized Θ–sector transitions source nonlocal geometric responses (and conversely), while preserving band/BRST hygiene on the realized weave configuration (Definition 10.1 and Proposition 10.10) and Σ–causality with respect to the realized background $\bar{\Sigma}$ (Definition 9.80 and Remark 9.83). Crucially, TT isolation is not violated: any non–TT typed insertion from the τ–kairos/CK families is annihilated by the background–covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 10.3, Lemma 10.123,

and Theorem 10.169), so graviton readouts in the TT channel remain uncontaminated even in the presence of $\Phi\Theta$ mixing. Symmetry selection rules (parity/helicity/CP) further gate which mixed couplings are admissible (Proposition 10.126).

Spectral data. The analytic structure of the connected, time–ordered matter kernel $\hat{G}_{\Theta\Theta}(x, x')$ (Definition 10.203) in suitable spectral variables determines kymon masses, widths, and mixing angles: isolated poles and their Riesz projectors select species, while residues encode couplings and overlaps (Definition 10.7 and Proposition 10.149). On $\mathcal{H}_{\text{phys}}$ the Källén–Lehmann ledger ensures nonnegative spectral densities (cf. eq. (7.12) and scalar/vector specializations such as Proposition 10.77). Triad labels $a \in \{\text{spec}, \text{vac}, \text{corr}\}$ refine these observables by provenance within the same typed ledger (Definition 10.2), separating on–band radiative contributions from vacuum/coherence structure. Typed refinements (e.g. CP for the Higgs–like radial modes, helicity/parity for CK vectors) are implemented by the corresponding idempotents (Definitions 10.5, 10.57 and 10.58), and future spectral branches are incorporated automatically by enlarging the Riesz sums (future–proofing; cf. Definition 10.7 and Lemma 10.76).

Summary. The matter block $\hat{\mathbf{G}}_{\Lambda}^{[\Theta\to\Theta]}$ captures kymon dynamics via the connected fluctuation kernel (10.147) (equivalently Definition 10.203), and its typed decomposition (10.148) provides the admissible scalar/pseudoscalar/vector channels on the realized weave configuration (Definition 10.1 and Proposition 10.10). These integrate with the T–L–O pipeline for certified claims (Proposition 10.90 and Definitions 10.135 and 10.136) and remain *TT–orthogonal* to the graviton sector by construction (Definition 10.3, Lemmas 10.17 and 10.59, and Theorem 10.169).

10.18.5 Emergent Matter Propagators

The connected Tantrakyma kernel $\hat{G}_{\Theta\Theta}(x, x')$ (cf. (10.147)) encodes the full dynamical content of the matter/coherence sector on $\mathcal{X}_q$. It is a matrix–valued bi–distribution on the modal fibres that governs the quantum propagation of internal excitations and, via typed projections, yields the propagators of physical kymons (Section 10.18.3). We make this structure explicit by writing $\hat{G}_{\Theta\Theta}$ in a local operator basis and then projecting to physical (mass/interaction) eigenmodes. Background material on curved–space two–point functions follows the standard references.

Fluctuation split and connectedness (Tantrakyma). Write the realized background–fluctuation split for the matter operator (cf. the geometric split (10.87) and the matter kernel definition Definition 10.203):

$$\boxed{\hat{\mathbf{\Theta}}(x) \;=\; \big\langle \hat{\mathbf{\Theta}}(x) \big\rangle_{\circ}\, \mathbb{I}_x \;+\; \delta\hat{\mathbf{\Theta}}(x), \qquad \big\langle \delta\hat{\mathbf{\Theta}}(x) \big\rangle_{\circ} = 0.} \tag{10.149}$$

With relational time–ordering on the $\bar{\Sigma}$ background (Definitions 6.7 and 9.80 and Remark 9.83), the *connected, time–ordered* kernel equals the fluctuation covariance:

$$\boxed{\begin{aligned}\hat{G}_{\Theta\Theta}(x,x') &= \Big\langle T\{\hat{\boldsymbol{\Theta}}(x)\,\hat{\boldsymbol{\Theta}}(x')\}\Big\rangle_{\circ} - \Big\langle \hat{\boldsymbol{\Theta}}(x)\Big\rangle_{\circ}\Big\langle \hat{\boldsymbol{\Theta}}(x')\Big\rangle_{\circ} && (10.150)\\ &= \Big\langle T\{\delta\hat{\boldsymbol{\Theta}}(x)\,\delta\hat{\boldsymbol{\Theta}}(x')\}\Big\rangle_{\circ}. && (10.151)\end{aligned}}$$

(The geometric analogue is eqs. (10.88) and (10.89).)

Definition 10.208 (Tantrakyma propagator matrix (modal basis))**.** Let the Tantrakyma *fluctuation* admit a local operator expansion on the modal fibre $\mathrm{End}(\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}})$:

$$\delta\hat{\boldsymbol{\Theta}}(x) = \sum_{a,b} \delta\theta^{ab}(x)\,|\mathbf{a}\rangle_x\langle\mathbf{b}|_x, \qquad \{|\mathbf{a}\rangle_x\} \subset \mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}} \text{ orthonormal.}$$

The *Tantrakyma propagator matrix* is the time–ordered two–point matrix of fluctuation coefficients

$$\boxed{\hat{G}^{ab,cd}_{\Theta\Theta}(x,x') \;:=\; \Big\langle T\{\delta\theta^{ab}(x)\,\delta\theta^{cd}(x')\}\Big\rangle_{\circ},} \tag{10.152}$$

which are the components of the connected matter kernel $\hat{G}_{\Theta\Theta}(x,x')$ from Definition 10.203 in the $(ab|cd)$ modal basis. In matrix form, these entries are precisely the position/modal representation of the $\Theta\Theta$ block of the Unified Inter–Modal Correlator in (10.144).

Fibre covariance and reciprocity. Because the modal fibre $\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}}$ varies with the locus x, contractions between coefficients at (x,ab) and (x',cd) are made covariant by parallel transporting the (x',cd) data to x using the inter–modal transporter $\mathcal{U}(x\leftarrow x';\gamma)$ from the Fourfold/Unified construction (Definition 4.9 and Section 4.1.4). Define the transported fluctuation coefficient

$$\tilde{\theta}^{\,cd}(x'\to x) := \mathcal{U}(x\leftarrow x';\gamma)\,\theta^{\,cd}(x')\,\mathcal{U}(x'\leftarrow x;\gamma),$$

so that the *covariant* representation of the matter propagator matrix (Definition 10.208) reads

$$\hat{G}^{ab,cd}_{\Theta\Theta}(x,x') \;=\; \Big\langle T\{\theta^{ab}(x)\,\tilde{\theta}^{\,cd}(x'\to x)\}\Big\rangle_{\circ},$$

which is equivalent to (10.152) when working at a common fibre. For neutral registers (no internal charge), Hermitian reciprocity holds:

$$\hat{G}^{ab,cd}_{\Theta\Theta}(x,x') \;=\; \overline{\hat{G}^{cd,ab}_{\Theta\Theta}(x',x)}.$$

When $\hat{G}_{\Theta\Theta}$ is the inverse of the *gauge–fixed, band–limited* second–variation (kinetic) operator $K_{\Theta\Theta}$ of the Tantrakyma action on the realized weave configuration (Definition 10.1 and Proposition 10.10), it obeys the matrix Green equation in the matter sector,

$$\sum_{c',d'} \big(K_{\Theta\Theta}\big)^{ab}{}_{c'd'}(x)\,\hat{G}^{c'd',cd}_{\Theta\Theta}(x,x') \;=\; \delta^{(d)}(x,x')\,\delta^a_{\,c}\,\delta^b_{\,d},$$

with triad resolution obtained by inserting $\Pi^{(a)}$ on both sides (Definition 10.2) and consistent with the $\Theta\Theta$ block relation (10.144). The time ordering $T\{\cdot\}$ is taken with respect to the relational background $\bar{\Sigma}$ (Definitions 9.80 and 10.203 and Remark 9.83), ensuring Σ–causal propagation of the matter modes.

Typed projections (matter channels). Using the Chapter 11 tau/CK types, the typed matter propagators are the blocks

$$\boxed{\hat{\mathbf{G}}^{[\Theta\to\Theta;\chi]}_{\Lambda;a} \;=\; \Pi^{(a)}\,\Pi^{[\chi]}\,\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda}\,\Pi^{[\chi]}\,\Pi^{(a)}, \qquad \chi\in\{S^{(b)},S^{(L)},\tilde{S}^{(p)},A^{(\pm)}\},} \tag{10.153}$$

(cf. (10.148)). No TT type appears in the Tantrakyma family; TT purity is protected by $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Pi^{[\chi]}=0$ (Lemmas 10.17 and 10.59).

Definition 10.209 (Projection onto emergent particles (kymons))**.** Physical species p need not align with a single modal operator; they are coherent superpositions that (locally in x) diagonalize the quadratic kernel of the Tantrakyma action at the relevant scale (Riesz selection on the realized weave configuration; Definitions 10.1 and 10.7). Adopt the fluctuation split for the matter operator (Definition 10.203) and expand

$$\delta\hat{\mathbf{\Theta}}(x)=\sum_{a,b}\theta^{ab}(x)\,|\mathbf{a}\rangle_x\langle\mathbf{b}|_x,$$

i.e. the δ sits on the operator, while the modal coefficients are $\theta^{ab}(x)$ (no δ). Choose modal coefficients $u^{ab}_p(x)$ (columns of a unitary change of basis on the operator fibre, relationally covariant via parallel transport; Section 4.1.4) and set

$$\theta^{(p)}(x)\;:=\;\sum_{a,b}u^{ab}_p(x)\,\theta^{ab}(x).$$

The *projected two–point function* (the kymon–p propagator) is

$$\boxed{\Delta_p(x,x')\;:=\;\Big\langle T\{\theta^{(p)}(x)\,\overline{\theta^{(p)}(x')}\}\Big\rangle_{\circ}\;=\;\sum_{a,b,c,d}u^{ab}_p(x)\,\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')\,\overline{u^{cd}_p(x')},} \tag{10.154}$$

where $\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')$ are the modal components of the connected matter kernel from Definitions 10.203 and 10.208. For full fibre covariance one may first transport the (x',cd) data to x using $\mathcal{U}(x\leftarrow x';\gamma)$ (cf. Section 4.1.4), which yields an equivalent contraction (see the "Fibre covariance and reciprocity" paragraph). Typed/triad tags propagate verbatim through (10.154) via the idempotents of Definitions 10.2 and 10.113.

Modal vs. physical bases; mixing. The modal indices (a,b) label the raw operator basis on $\mathrm{End}(\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}})$; the physical labels $\{p\}$ result from diagonalizing the quadratic kernel (mass/mixing) on the realized background (Definitions 10.203 and 10.208). Off–diagonal entries of $\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')$ with $(a,b)\neq(c,d)$ encode mixing/oscillation phenomena in the modal basis, while the projected $\Delta_p(x,x')$ of Definition 10.209 isolates the propagator of the mass eigenmode p. In stationary/homogeneous arenas, Δ_p admits a Källén–Lehmann–type representation (connected, time–ordered kernel; Definition 10.203) whose pole structure yields physical masses and dispersion.

Triad provenance and ledger integration. Triad idempotents $\Pi^{(a)}$ resolve the matter kernel as $\hat{G}_{\Theta\Theta} \mapsto \hat{G}_{\Theta\Theta;a} := \Pi^{(a)}\,\hat{G}_{\Theta\Theta}\,\Pi^{(a)}$ with provenance $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (Definition 10.2), in the same typed/triad manner as (10.153). These typed/triad blocks feed the parasymmetric pipeline; the execution functor stamps $\mathrm{TLO}^{[\chi]}$ for admitted χ with Location from diagnostic realized reference configuration metadata and Onset from the calibrated meters (Definitions 9.153 and 10.82 and Propositions 10.22 and 10.65). TT selection in the gravitational sector remains unchanged:

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{t}_{\mu\nu} = 0,} \tag{10.155}$$

with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ the background–covariant TT projector (Definition 10.3); thus matter propagators backreact only through non–TT channels while leaving the graviton TT block intact (cf. (10.105), Lemma 10.17).

Summary. $\hat{G}_{\Theta\Theta}$ furnishes the kymon propagators as a fibre–covariant matrix kernel (10.152); typed/triad projections (10.153) produce the admissible scalar/pseudoscalar/vector channels; and physical kymons are obtained by the local rotations (10.154). This integrates seamlessly with the parasymmetric ledger while preserving TT purity of the graviton sector.

10.18.6 Dynamical Equations and Propagation

The Tantrakyma fluctuation $\delta\hat{\mathbf{\Theta}}(x)$ (matter/coherence excitations on the realized weave configuration) obeys a covariant operator wave equation obtained from the functional Euler–Lagrange principle applied to the second–variation (quadratic) action, using the background–fluctuation split $\hat{\mathbf{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\mathbf{\Theta}}$ (cf. Definition 10.204). All operators are built with the background chronogeometry $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ and the weave–covariant derivative $\bar{\nabla}$ (cf. Section 10.17.2).

Quadratic action and kinetic operator. With $\bar{\nabla}$ compatible with $\bar{\Sigma}$ when stated, the linearised action reads

$$\boxed{S^{(2)}[\delta\hat{\mathbf{\Theta}}] = \int d^dx\,\sqrt{-\det\bar{\Sigma}}\;\mathrm{Tr}\Big\{\bar{\Sigma}^{\mu\nu}\big(\bar{\nabla}_\mu\delta\hat{\mathbf{\Theta}}\big)^\dagger\big(\bar{\nabla}_\nu\delta\hat{\mathbf{\Theta}}\big) - \tfrac{1}{2}\,\delta\hat{\mathbf{\Theta}}^\dagger\,\mathcal{M}_\Theta(x)\,\delta\hat{\mathbf{\Theta}}\Big\},} \tag{10.156}$$

where the operator–valued mass term is the Hessian of the Tantrakyma potential about the background,

$$\boxed{\mathcal{M}_\Theta(x) := \left.\frac{\delta^2\mathcal{V}_\Theta}{\delta\hat{\mathbf{\Theta}}^\dagger\,\delta\hat{\mathbf{\Theta}}}\right|_{\bar{\Theta}(x)}.} \tag{10.157}$$

Varying (10.156) yields the *normally hyperbolic* matter operator

$$\boxed{\mathcal{K}_\Theta := -\,\bar{\nabla}_\mu\big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\,\cdot\,\big) + \mathcal{M}_\Theta(x),} \tag{10.158}$$

so the Euler–Lagrange equation takes the compact form

$$\boxed{\mathcal{K}_\Theta(x)\,\delta\hat{\boldsymbol{\Theta}}(x) = 0.} \tag{10.159}$$

If $\bar{\nabla}_\lambda \bar{\Sigma}^{\mu\nu} = 0$ (chronogeometric compatibility), then $\mathcal{K}_\Theta = -\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\mu\bar{\nabla}_\nu + \mathcal{M}_\Theta$. Hyperbolicity and cone–gating of (10.159) are enforced by admission (Definitions 10.1 and 10.94).

Green functions and propagators. The modal matter kernel $\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')$ of Definitions 10.203 and 10.208 is a Green function for the (gauge–fixed, band–limited) second–variation operator $K_{\Theta\Theta}$ on the realized weave configuration (Definition 10.1 and Proposition 10.10). In components:

$$\boxed{\sum_{c',d'}\Big(K_{\Theta\Theta}\Big)^{ab}{}_{c'd'}(x)\,\hat{G}^{c'd',cd}_{\Theta\Theta}(x,x') = \delta^{(d)}(x,x')\,\delta^a_c\,\delta^b_d.} \tag{10.160}$$

Boundary data (retarded/advanced/Feynman) are chosen as appropriate, and the time ordering is taken with respect to the relational background $\bar{\Sigma}$ (see Definitions 9.80 and 10.203 and Remark 9.83).

Projected (species) propagators Δ_p are obtained by the rotation formula (10.154), which contracts $\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')$ with the local modal-to-physical coefficients. In stationary/homogeneous settings, Δ_p admits a Källén–Lehmann–type spectral representation (connected, time-ordered kernel of Definition 10.203) whose poles furnish masses and dispersion relations.

Proposition 10.210 (Quadratic reduction and Σ–causal propagation on the realized weave configuration)**.** *Let $\hat{\boldsymbol{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\boldsymbol{\Theta}}$ be the background–fluctuation split (Definition 10.204) on the realized weave configuration $\mathcal{I}^{[\mathcal{S}]}$ (Definition 10.1). Expanding the full Tantrakyma action about $\bar{\Theta}$ yields*

$$\boxed{S[\bar{\Theta} + \delta\hat{\boldsymbol{\Theta}}] = S[\bar{\Theta}] + \underbrace{S^{(1)}[\delta\hat{\boldsymbol{\Theta}}]}_{=\,0 \text{ if } \bar{\Theta} \text{ is a stationary point}} + S^{(2)}[\delta\hat{\boldsymbol{\Theta}}] + \mathcal{O}\big(\delta\hat{\boldsymbol{\Theta}}^{\,3}\big).} \tag{10.161}$$

When $\bar{\Theta}$ satisfies the background equations, the linear term vanishes and the leading dynamics of fluctuations are governed by the quadratic action $S^{(2)}$ in (10.156). Its Euler–Lagrange operator is the normally hyperbolic kinetic operator $\mathcal{K}_\Theta$ of (10.158), so that the linearized equation of motion reads

$$\boxed{\mathcal{K}_\Theta(x)\,\delta\hat{\boldsymbol{\Theta}}(x) = 0 \qquad \textit{(cf. eq. (10.159)).}} \tag{10.162}$$

Moreover, the connected, time–ordered matter kernel $\hat{G}_{\Theta\Theta}$ (Definition 10.203) is a Green function of $\mathcal{K}_\Theta$ on $\mathcal{H}_{\text{phys}}$, satisfying the matrix equation (10.160) with retarded/advanced/Feynman boundary data chosen relative to $\bar{\Sigma}$ (Definition 9.80 and Remark 9.83).

Proof (sketch). Taylor expand the action at $\bar{\Theta}$ to second order; stationarity of $\bar{\Theta}$ kills $S^{(1)}$, yielding $S^{(2)}$ in (10.156) with mass/Hessian $\mathcal{M}_\Theta$ from (10.157). Varying $S^{(2)}$ gives $\mathcal{K}_\Theta$

in (10.158) and the equation of motion (10.162). On the realized weave configuration (Definition 10.1), admissibility/invariance (Proposition 10.10) and $\bar{\Sigma}$-compatibility ensure that $\mathcal{K}_\Theta$ is normally hyperbolic and Σ–causal (Remark 9.83), so its inverse in the appropriate sense is the connected two–point function $\hat{G}_{\Theta\Theta}$, which indeed solves (10.160). □

Why the quadratic action $S^{(2)}$ appears. In the linearized regime around the realized background $\bar{\Theta}$ and $\bar{\Sigma}$, the first nontrivial term of the action expansion is $S^{(2)}$ (eq. (10.161)). This term *defines* the kinetic operator $\mathcal{K}_\Theta$ and the Hessian block $\mathcal{M}_\Theta$ (eqs. (10.157) and (10.158)), leading to a well-posed, Σ–causal propagation equation on $\mathcal{H}_{\text{phys}}$ (eq. (10.159) and Remark 9.83). Consequently, the connected matter kernel $\hat{G}_{\Theta\Theta}$ (Definition 10.203) is the Green function of $\mathcal{K}_\Theta$ (eq. (10.160)), which is the precise object used downstream for spectral analysis and reporting.

Where higher variations live (interactions and provenance). Cubic and higher terms, $\mathcal{O}(\delta\hat{\boldsymbol{\Theta}}^3)$, are not discarded; the weave routes them into (i) typed $\Phi\Theta$ couplings via the typed-insertion rules for the full action (Definition 10.113), and (ii) self-energy/effective-action corrections that renormalize $\mathcal{M}_\Theta$ and move the poles of $\hat{G}_{\Theta\Theta}$. Their *provenance* is tracked by the triad tags $a \in \{\text{spec}, \text{vac}, \text{corr}\}$ (Definition 10.2), and their operational status enters the calibrated visibility meters (Definition 10.82). Thus $S^{(2)}$ underwrites linear, Σ-causal propagation on the realized weave configuration, while nonlinearity is audited and reported through typed cross-blocks and triad-resolved ledgers—without compromising TT safety or admissibility established earlier.

Interpretation of the dynamical equation (ledger view)

Chronogeometric wave operator. The principal symbol $-\bar{\nabla}_\mu(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu)$ is the d'Alembertian built from the total chronogeometry. Its $\bar{g}$–piece reproduces standard metric propagation, while its $\bar{t}$–piece encodes anisotropic phase flow/coherence. Thus kymon propagation is modulated by both spatial distinguishability ($\bar{g}$) and temporal coherence structure ($\bar{t}$), with direction–dependent phase drag consistent with cone–gating.

Operator mass matrix and Goldstone directions. $\mathcal{M}_\Theta(x)$ controls local inertial data: its eigenvalues are squared masses of propagating modes. Flat directions of $\mathcal{V}_\Theta$ generate zero modes of $\mathcal{M}_\Theta$ (Goldstone excitations) that propagate masslessly along the vacuum manifold, mirroring the SSB logic used in the geometric sector (cf. Section 10.17.9).

Synthesis and TT selection. Equations (10.159) and (10.160), together with the projection formula (10.154), realise an operator–valued Klein–Gordon theory on the emergent background. Coupling to chronogeometry proceeds through the typed/triad blocks while preserving TT isolation of the GW sector:

$$\boxed{\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{t}_{\mu\nu} = 0, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu} \quad (\text{cf. (10.155)}).} \tag{10.163}$$

Accordingly, matter dynamics backreact through non–TT channels recorded by $\mathrm{TLO}^{[\chi]}$ for admitted χ (Propositions 10.22 and 10.65), while the graviton TT block remains pure (Lemmas 10.17 and 10.59).

10.18.7 Triadic Decomposition of the Matter Propagator

The connected Tantrakyma kernel $\hat{G}_{\Theta\Theta}(x,x')$ (or, in the modal basis, $\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')$; cf. Definition 10.208) inherits the *triad* organisation from the weave: $\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}$ with idempotents $\Pi^{(a)}$ (Definition 10.2). We record this both at the operator level (typed blocks on the realized weave configuration) and in the position/modal representation.

Definition 10.211 (Triadic matter block on the realized weave configuration)**.** The Tantrakyma (matter) block of the Unified Inter–Modal Correlator decomposes as

$$\boxed{\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda} = \bigoplus_{a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}} \hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda;a}, \qquad \hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda;a} := \Pi^{(a)}\,\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda}\,\Pi^{(a)}.} \tag{10.164}$$

Here each $\hat{\mathbf{G}}^{[\Theta\to\Theta]}_{\Lambda;a}$ is a connected, time–ordered block with triad provenance a (admission and weave instrumentation as usual).

Definition 10.212 (Triadic decomposition in the position/modal basis)**.** Let $\hat{G}^{ab,cd}_{\Theta\Theta}(x,x')$ be the modal propagator matrix of Definition 10.208. Its triadic components are

$$\boxed{\hat{G}^{ab,cd}_{\Theta\Theta;a}(x,x') \;:=\; \big(\Pi^{(a)}\,\hat{G}_{\Theta\Theta}(x,x')\,\Pi^{(a)}\big)^{ab,cd}, \qquad \hat{G}^{ab,cd}_{\Theta\Theta}(x,x') = \sum_{a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}} \hat{G}^{ab,cd}_{\Theta\Theta;a}(x,x').} \tag{10.165}$$

Each $\hat{G}_{\Theta\Theta;a}$ satisfies the matter Green equation projected to the a–sector:

$$\boxed{\mathcal{K}_{\Theta}(x)\,\hat{G}_{\Theta\Theta;a}(x,x') \;=\; \Pi^{(a)}\,\boldsymbol{\delta}_{\mathrm{mod}}\,\Pi^{(a)}\;\delta^{(d)}(x-x'),} \tag{10.166}$$

with the normally–hyperbolic operator $\mathcal{K}_{\Theta}$ from eq. (10.158), boundary data (retarded/advanced/Feynman) as appropriate, and $\boldsymbol{\delta}_{\mathrm{mod}}$ the identity on the modal fibre. For causal/Green's function conventions on curved backgrounds and spectral support, see [244, 7].

Operator–theoretic semantics. Equations (10.165)–(10.166) define *sectorwise* Green bi–distributions on a curved background with the usual microcausal support (ret/adv) and Feynman prescription; the triad idempotents commute with the time–ordering so that connectedness and provenance resolution are compatible [244, 7]. In this sense the triadic split is not merely a bookkeeping device but a refinement of the operator domain dictated by the weave instrumentation (admission/cone–gating) of Ch. 11.

Channel semantics (matter triad). In parallel with the weave triad (Definition 10.2):

(i) Spectral $\hat{G}_{\Theta\Theta;\mathrm{spec}}$ — propagation controlled by the energy–momentum content of kymon excitations; it governs frequency–dependent response and classical limits (e.g. redshift/dispersion) and feeds mixed geometry–matter blocks $\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}$ while preserving TT isolation on the geometry leg [244, 7] (cf. eq. (10.155)).

(ii) Vacuum $\hat{G}_{\Theta\Theta;\mathrm{vac}}$ — motion along (near) flat directions of the Tantrakyma vacuum manifold; Goldstone branches appear as zero modes of the mass operator $\mathcal{M}_\Theta$ and follow the standard SSB/EFT logic adapted to emergent/curved backgrounds [415] (eq. (10.157) and Section 10.18.6).

(iii) Correlational $\hat{G}_{\Theta\Theta;\mathrm{corr}}$ — propagation driven by inter–modal entanglement/coherence on $\mathrm{End}(\mathcal{H}^{(\mathfrak{B}_x)}_{\mathrm{mod}})$; at the interface with geometry, this channel underwrites "information $\to$ curvature'' mechanisms articulated in holographic settings [516, 1].

Projection to physical species. For the emergent kymon p with local rotation $u^{ab}_p(x)$, the species propagator Δ_p of eq. (10.154) splits compatibly with the triad:

$$\boxed{\Delta_p(x,x') = \sum_a \Delta^{(a)}_p(x,x'), \qquad \Delta^{(a)}_p(x,x') := \sum_{a,b,c,d} u^{ab}_p(x)\, \hat{G}^{ab,cd}_{\Theta\Theta;a}(x,x')\, \overline{u^{cd}_p(x')}.} \tag{10.167}$$

In stationary/homogeneous regimes each $\Delta^{(a)}_p$ admits a Källén–Lehmann–type (curved–space) representation: pole locations yield masses/dispersion while residues encode mixing and flavour amplitudes [244, 7].

Remark 10.213 (Operator origin of phenomenology and backreaction)**.** The full kernel $\hat{G}_{\Theta\Theta}$ controls gauge–invariant masses, mixings, and flavour amplitudes via its pole and branch–cut structure; the triad attributes these features to spectral, vacuum, or correlational provenance [244, 7, 415]. Coupling to chronogeometry occurs through the typed off–diagonal blocks $\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}$ and through $\mathcal{K}_\Theta$'s dependence on $\bar{\Sigma}$ (Section 10.18.6), while TT purity of the graviton sector remains protected: $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{t}_{\mu\nu} = 0$ and $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{\Sigma}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ (eq. (10.155)). Operationally, this realises Wheeler's dictum at the correlator level—matter content and coherence fix geometric response without introducing extra GW polarizations [239].

Proposition: Absence of Spin–2 Kymons

Proposition 10.214 (No spin–2 excitations in the Tantrakyma sector)**.** *Let the Tantrakyma field be split as* $\hat{\mathbf{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\mathbf{\Theta}}$ *(cf. Definition 10.204 and Section 10.18.6). Through the constitutive scalar/vector sourcing maps* $S_{\mu\nu}[\cdot], A_{\mu\nu}[\cdot]$ *of Definitions 10.4 and 10.13 the temporal/coherence fluctuation reads* $\hat{\tau}_{\mu\nu} = S_{\mu\nu}[\hat{\varphi}_A] \oplus A_{\mu\nu}[\hat{K}^{(\tau)}]$ *with* $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0$ *(eqs. (10.102) and (10.155)). Then the Tantrakyma sector carries* no *spin–2 irreducible excitations:*

$$\boxed{\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0 \qquad \Longrightarrow \qquad \textit{no spin–2 kymon.}} \tag{10.168}$$

Proof. By Definitions 10.4 and 10.13, $\hat{\tau}_{\mu\nu}$ is built from a trace (scalar) part $S_{\mu\nu}[\hat{\varphi}_A]$ and a longitudinal (vector) part $A_{\mu\nu}[\hat{K}^{(\tau)}]$. On $(\bar{g}_{\mu\nu}, \bar{\nabla})$ the York/Helmholtz decomposition $\mathrm{Sym}^2 = \mathrm{TT} \oplus \mathrm{Im}\,\mathcal{L} \oplus \mathrm{span}\{\bar{g}\}$ (eq. (10.140)) is L^2–orthogonal; the TT projector annihilates both trace and longitudinal subspaces. Hence $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}_{\mu\nu} = 0$ (eq. (10.102) and Lemma 10.59), i.e. no spin–2 content arises from Tantrakyma. By eq. (10.28) and Corollary 10.20 the radiative spin–2 sector is purely metric (the graviton). □

Remark 10.215 (Scope and composites)**.** The statement concerns *elementary* Tantrakyma excitations (kymons). Composite multi–kymon states can carry total spin 2, but do not constitute an elementary spin–2 field; gravitational radiation remains confined to the metric TT channel (cf. eq. (10.28) and Corollary 10.20).

The Matter & Coherence Sector: Tantrakyma as the Source of Substance

The Tantrakyma field $\hat{\boldsymbol{\Theta}}(x)$ sources all matter/coherence excitations on the realized weave configuration. Its potential $\mathcal{V}_\Theta$ and quadratic kernel determine the spectrum of its quanta (kymons) via the background–fluctuation split and the linearised dynamics (Section 10.18.6). Two–point functions in the modal and projected (species) bases are encoded by $\boldsymbol{\Delta}_\Theta$ and Δ_p, respectively (Definition 10.208 and eq. (10.154)).

Goldstone/Higgs logic (matter sector). Spontaneous breaking of a continuous symmetry of $\mathcal{V}_\Theta$ yields massless Goldstone kymons for global SSB, or removes them via gauge fixing in local SSB (unitary–gauge Higgs mechanism). This is implemented on the emergent background through $\mathcal{M}_\Theta(x)$ and the normally–hyperbolic operator $\mathcal{K}_\Theta$ (eqs. (10.157) and (10.158) and Section 10.18.6).

Mass eigenmodes. After SSB/Higgsing, Tantrakyma excitations become massive eigenmodes of $\mathcal{M}_\Theta$; their masses are the pole locations of Δ_p:

(i) Radial Higgs kymon (spin–0) The radial scalar obtains its mass from the Hessian of $\mathcal{V}_\Theta$ at the vacuum (eq. (10.157)).

(ii) Chrono–Kymon (spin–1) The vector excitation sources the temporal/coherence channel through $A_{\mu\nu}[\hat{K}^{(\tau)}]$, contributing to the antisymmetric/phase–transport sector of $t_{\mu\nu}$ in the constitutive split (Definitions 10.4 and 10.13 and Section 10.18.6).

No spin–2 kymons. The Tantrakyma sector contains no irreducible spin–2 excitations:

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\tau}_{\mu\nu} = 0 \quad (\textit{eqs. } (10.155) \textit{and } (10.168)).$$

The radiative spin–2 (graviton) sector is purely metric,

$$\hat{h}_{\mu\nu} \;=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu} \quad (\textit{eq. } (10.28) \textit{and Corollary } 10.20).$$

Triad and state dependence. Propagation and mixing decompose into correlational, vacuum, and spectral channels (Section 10.18.7). All matter data are state–dependent through $\bar{\Sigma}_{\mu\nu}$ and $\mathcal{M}_\Theta(x)$ (Section 10.18.6). Backreaction enters via the typed off–diagonal blocks $\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}$ and through the $\bar{\Sigma}$–dependence of $\mathcal{K}_\Theta$, while TT purity of the graviton sector is preserved (eqs. (10.28) and (10.155) and Corollary 10.20).

10.19 Matter–Geometry Block of the Unified Correlator

We now treat the off–diagonal sector of the Unified Inter–Modal Correlator $\hat{\mathbf{G}}_\Lambda$ (cf. Definition 6.4), namely the *matter–geometry* block that links the Dynamical Gaiamiti and Tantrakyma fields at the operator level. Throughout we use the typed projector family and triad idempotents of Ch. 11 (cf. Definitions 10.15 and 10.25) and the QHS expectation $\langle\cdot\rangle_\circ$ (cf. Definitions 10.203 and 10.204).

10.19.1 Typed Off–diagonal Block and Connected Kernel

Definition 10.216 (Typed matter→geometry cross block)**.** The *typed* matter→geometry block of the unified correlator is

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Theta]}_\Lambda := \Pi^{[\Theta]}_\Lambda\,\hat{\mathbf{G}}_\Lambda\,\Pi^{[\Phi]}_\Lambda, \qquad \hat{\mathbf{G}}_\Lambda \text{ as in Definition 6.4.}} \tag{10.169}$$

With the triad $\{a\} = \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (cf. Definition 10.15), its provenance–resolved form is

$$\boxed{\hat{\mathbf{G}}^{[\Phi\to\Theta]}_\Lambda = \bigoplus_{a\in\{\mathrm{spec,vac,corr}\}} \hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}, \qquad \hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a} := \Pi^{[a]}\,\hat{\mathbf{G}}^{[\Phi\to\Theta]}_\Lambda\,\Pi^{[a]}.} \tag{10.170}$$

Each $\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}$ is an admission–certified cross block suitable for witnesses/meters and T–L–O execution (cf. Definition 10.1 and Proposition 10.90).

Definition 10.217 (Connected matter–geometry kernel)**.** Let $\hat{\mathbf{\Phi}}(x)$ and $\hat{\mathbf{\Theta}}(x')$ be the dynamical Gaiamiti/Tantrakyma fields (cf. Definitions 6.118 and 6.142). The *connected, time–ordered* cross kernel is

$$\boxed{\hat{G}_{\Phi\Theta}(x,x') := \Big\langle T\{\hat{\mathbf{\Phi}}(x)\,\hat{\mathbf{\Theta}}(x')\}\Big\rangle_\circ - \Big\langle\hat{\mathbf{\Phi}}(x)\Big\rangle_\circ\Big\langle\hat{\mathbf{\Theta}}(x')\Big\rangle_\circ.} \tag{10.171}$$

Using the background–fluctuation splits $\hat{\mathbf{\Phi}} = \bar{\Phi}\,\mathbb{I} + \delta\hat{\mathbf{\Phi}}$ and $\hat{\mathbf{\Theta}} = \bar{\Theta}\,\mathbb{I} + \delta\hat{\mathbf{\Theta}}$ (cf. eq. (10.87) and Definition 10.204),

$$\hat{G}_{\Phi\Theta}(x,x') \;=\; \Big\langle T\{\delta\hat{\mathbf{\Phi}}(x)\,\delta\hat{\mathbf{\Theta}}(x')\}\Big\rangle_\circ. \tag{10.172}$$

Operator–theoretic semantics. The cross kernel (10.171) is a curved–background, operator–valued two–point function, with time–ordering and subtraction performed in the QHS; its construction and interpretation follow the standard QFT on curved spacetime framework [244, 7]. In the typed formulation (10.169)–(10.170), each provenance block $\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a}$ is an idempotent–resolved channel that respects admission and cone–gating constraints, ensuring compatibility with T–L–O execution and with the constitutive/observable split of Ch. 11.

Causal/triadic interpretation. A non–trivial value of $\hat{G}_{\Phi\Theta}(x,x')$ signals that a fluctuation of the Tantrakyma field at x' is *correlated* with a geometric fluctuation of the Gaiamiti field at x, thereby realizing a state–relative notion of "matter sources geometry" at the operator level [239]. Triad resolution sharpens this reading: the correlational channel ($a = \mathrm{corr}$) tracks entanglement/coherence converting into geometric response, echoing ER=EPR and "spacetime from entanglement" intuitions [516, 1]; the vacuum channel ($a = \mathrm{vac}$) slides along (near–)flat directions of the vacuum bundle and aligns with Goldstone deformations in an EFT sense [415]; and the spectral channel ($a = \mathrm{spec}$) organizes frequency–dependent sourcing and classical limits (redshift/dispersion) in the nonlocal operator framework [244, 7].

State dependence and nonlocality. Because expectations are taken in the QHS $\langle\cdot\rangle_\circ$, the magnitude and tensor structure of $\hat{G}_{\Phi\Theta}$ are determined by the global quantum state, not by kinematics alone; this encodes nonlocal, bi–local influence mediated by $\mathcal{U}_{\Phi\Theta}$ and captured cleanly by the fluctuation form (10.172) [244, 7]. In particular, the correlational channel provides an explicit pathway by which quantum information content in the matter sector imprints correlational curvature in geometry [516, 1].

Operational content and TT integrity. The typed cross block integrates with the TT selection on the geometry leg: radiative tensor modes are governed by the projector $\Pi^{[\gamma]} = \mathcal{P}^{(2)}$ and remain TT–pure (cf. Definition 10.167 and Lemma 10.59), so that off–diagonal matter–geometry correlations contribute without introducing extra GW polarizations. This realizes Wheeler's dictum [239]operationally while remaining consistent with the TT closure established in earlier sections.

10.19.2 Modal Representation and Transport

Definition 10.218 (Modal expansion with inter–modal transport)**.** Choose a local orthonormal basis $\{|\mathbf{i}\rangle_x\} \subset T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}$ for the Gaiamiti fibre and a matrix basis $\{|\mathbf{a}\rangle_{x'}\langle\mathbf{b}|_{x'}\} \subset \mathrm{End}(\mathcal{H}^{(\mathfrak{B}_{x'})}_{\mathrm{mod}})$ for Tantrakyma (cf. Definition 4.273). Write

$$\delta\hat{\mathbf{\Phi}}(x) = \sum_i \delta\hat{\Phi}_i(x)\,|\mathbf{i}\rangle_x, \qquad \delta\hat{\mathbf{\Theta}}(x') = \sum_{a,b} \delta\theta^{ab}(x')\,|\mathbf{a}\rangle_{x'}\langle\mathbf{b}|_{x'}.$$

To compare fibres, parallel–transport Tantrakyma indices with the inter–modal transporter $\mathcal{U}_{x'\to x}$ (cf. Definition 4.9): $\delta\tilde{\theta}^{ab}(x'\to x) := \mathcal{U}_{x'\to x}\,\delta\theta^{ab}(x')\,\mathcal{U}_{x\to x'}$. Then

$$\boxed{\hat{G}_{\Phi\Theta}(x,x') = \sum_{i,a,b} \mathrm{Cov}_\circ\Big[\,\delta\hat{\Phi}_i(x),\ \delta\tilde{\theta}^{ab}(x'\to x)\,\Big]\ |\mathbf{i}\rangle_x \otimes \Big(|\mathbf{a}\rangle_x\langle\mathbf{b}|_x\Big),} \tag{10.173}$$

with $\mathrm{Cov}_\circ[A,B] := \langle T\{AB\}\rangle_\circ - \langle A\rangle_\circ\langle B\rangle_\circ$.

Typed pair refinement (optional). When useful, refine (10.173) by inserting a TT type on the geometry leg and any admitted τ–kairos type $\chi \in \{S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}\}$ on the matter leg (cf. Definitions 10.3 and 10.4):

$$\boxed{\hat{\mathbf{G}}^{[\,\Phi\to\Theta;\ \mathrm{TT}\to\chi\,]}_{\Lambda;a} \;:=\; \Pi^{(a)}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\mathbf{G}}^{[\,\Phi\to\Theta\,]}_{\Lambda}\,\Pi^{[\chi]}\,\Pi^{(a)}, \qquad a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}.} \tag{10.174}$$

Here $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is the background–covariant TT projector and the graviton extractor is $\mathcal{P}^{(2)}_{\mathrm{grav}}$ (Definitions 10.3 and 10.25). TT–nullity of τ–kairos implies $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{[\chi]} = 0$, hence also $\mathcal{P}^{(2)}_{\mathrm{grav}}\Pi^{[\chi]} = 0$ (Lemmas 10.17 and 10.59); therefore no additional GW polarizations arise from the matter leg, and the TT graviton sector remains uncontaminated under typed mixing (Lemma 10.123).

10.19.3 Triadic Resolution and Parasymmetric TLO Interface

Remark 10.219 (Triadic resolution)**.** The components $\hat{\mathbf{G}}_{\Lambda;a}^{[\Phi\to\Theta]}$ in (10.170) separate correlational, vacuum, and spectral provenance (cf. Sections 10.17.6 and 10.18.7). Each inherits the causal support and admission of its channel and solves the appropriate mixed Green's equation on its block (cf. eqs. (10.112) and (10.160)).

Remark 10.220 (Parasymmetric pipeline and purity guards)**.** Running the sector execution functor $\mathscr{E}_\bullet$ with the same typed projectors and admission gate (cf. Definitions 9.153 and 10.94), the mixed block contributes witness signals and Onset timers to the appropriate *non–TT* temporal types, while TT content remains confined to the geometric leg (cf. Definition 10.167 and Lemma 10.168). The TT–purity witness $\mathcal{W}_{\mathrm{TT\text{–}purity}}$ monitors law–side consistency (cf. Lemma 10.17).

Operational reading. Equation (10.173) makes explicit how a given geometric fluctuation mode (index i) correlates with a specific modal transition (a, b) in the matter/coherence fibre, after covariance transport. These are the primitive operator–level *interaction channels* that feed the off–diagonal entries of the chronogeometric Green's system, while preserving TT selection for gravitational radiation (cf. eqs. (10.28), (10.90) and (10.131) and Corollary 10.20).

Bi–Local Interaction Lagrangian

We encode the matter–geometry coupling in the off–diagonal (typed) blocks of the unified correlator (cf. Definitions 6.4, 10.216 and 10.217). All expectations are taken in the QHS (Definitions 10.203 and 10.204); background–fluctuation splits are those of eq. (10.87) and Definition 10.204. Fibre comparisons use the inter–modal transporter $\mathcal{U}_{x'\to x}$ (Definition 4.9).

Definition 10.221 (Typed, Hermitian interaction kernel (bi–local))**.** Let the typed cross blocks be $\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Theta]} = \Pi_{\Lambda}^{[\Theta]}\,\hat{\mathbf{G}}_{\Lambda}\,\Pi_{\Lambda}^{[\Phi]}$ and $\hat{\mathbf{G}}_{\Lambda}^{[\Theta\to\Phi]} = \Pi_{\Lambda}^{[\Phi]}\,\hat{\mathbf{G}}_{\Lambda}\,\Pi_{\Lambda}^{[\Theta]}$ (cf. Definition 10.216). The *bi–local, Hermitian* interaction kernel is

$$\boxed{\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x') \;:=\; \hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Theta]}(x,x') \;+\; \Big(\hat{\mathbf{G}}_{\Lambda}^{[\Theta\to\Phi]}(x',x)\Big)^{\dagger},} \tag{10.175}$$

and inherits the triadic resolution

$$\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]} = \bigoplus_{a\in\{\mathrm{spec,vac,corr}\}} \mathbf{U}_{\Lambda;a}^{[\Phi\leftrightarrow\Theta]}, \qquad \mathbf{U}_{\Lambda;a}^{[\Phi\leftrightarrow\Theta]} := \Pi^{[a]}\,\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}\,\Pi^{[a]}, \tag{10.176}$$

(cf. Definition 10.15).

Definition 10.222 (Bi–local interaction Lagrangian density)**.** Write the fluctuation fields as $\delta\hat{\mathbf{\Phi}}(x)$ and $\delta\hat{\mathbf{\Theta}}(x')$, and transport Tantrakyma to x: $\delta\tilde{\hat{\mathbf{\Theta}}}(x'\to x) := \mathcal{U}_{x'\to x}\,\delta\hat{\mathbf{\Theta}}(x')\,\mathcal{U}_{x\to x'}$. The *bi–local interaction density* is the modal trace at x:

$$\boxed{\mathcal{L}_{\mathrm{int}}(x,x') \;:=\; \mathrm{Tr}\Big[\big(\delta\hat{\mathbf{\Phi}}(x)\big)^{\dagger}\;\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x')\;\delta\tilde{\hat{\mathbf{\Theta}}}(x'\to x)\Big],} \tag{10.177}$$

with Tr taken on the transported modal fibre at x.

Definition 10.223 (Interaction action (bi–local form; triad–resolved))**.** The total interaction action is

$$\boxed{S_{\mathrm{int}}[\hat{\mathbf{\Phi}},\hat{\mathbf{\Theta}}] := \int d^dx\,d^dx'\;\mathcal{L}_{\mathrm{int}}(x,x') \;=\; \sum_a \int d^dx\,d^dx'\;\mathrm{Tr}\Big[(\delta\hat{\mathbf{\Phi}})^{\dagger}\;\mathbf{U}_{\Lambda;a}^{[\Phi\leftrightarrow\Theta]}\;\delta\tilde{\hat{\mathbf{\Theta}}}\Big],} \tag{10.178}$$

where $a\in\{\mathrm{spec},\mathrm{vac},\mathrm{corr}\}$ and all fields are evaluated as in (10.177).

Properties and guards. By construction, $\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x')^{\dagger} = \mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x',x)$ (Hermiticity); causal support and admission are inherited from the cross blocks and the cone gates (Definition 10.94 and eq. (10.65)). TT–purity is preserved because the right leg is tau–kairos–typed and TT–null (eq. (10.90) and Lemma 10.59); the TT sector remains purely geometric (Definition 10.167 and Lemma 10.168).

10.19.4 Functional Variation of the Interaction Action

Let $S_{\mathrm{total}} = S_{\Phi} + S_{\Theta} + S_{\mathrm{int}}$ be the total action (cf. constitutive and matter dynamics in Sections 10.17.4 and 10.18.6). Varying (10.178) at fixed transporter yields bi–local source terms.

Proposition 10.224 (Bi–local sources in the Euler–Lagrange equations)**.** *The first variations of S_{int} with respect to the fluctuation fields are*

$$\frac{\delta S_{\mathrm{int}}}{\delta\big(\delta\hat{\mathbf{\Phi}}(x)\big)^{\dagger}} = \int d^dx'\;\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x')\;\delta\tilde{\hat{\mathbf{\Theta}}}(x'\to x), \tag{10.179}$$

$$\frac{\delta S_{\mathrm{int}}}{\delta\big(\delta\hat{\mathbf{\Theta}}}(x')\big)^{\dagger} = \int d^dx\;\Big(\mathcal{U}_{x\to x'}\,\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x')^{\dagger}\,\mathcal{U}_{x'\to x}\Big)\;\delta\hat{\mathbf{\Phi}}(x), \tag{10.180}$$

with identical triad–resolved statements after inserting $\Pi^{[a]}$ as in (10.176).

Remark 10.225 (Closure of the TT sector under variation)**.** Applying the TT projector to the geometric equation sourced by (10.179) yields $\mathcal{P}^{(2)}\big[\delta S_{\mathrm{int}}/\delta(\delta\hat{\mathbf{\Phi}})^{\dagger}\big] = \mathcal{P}^{(2)}\big[\cdots\big]$ with the right leg tau–typed and TT–null; thus no extra GW polarizations are induced (cf. Definition 10.167 and Lemmas 10.59 and 10.168). The resulting mixed terms enter the off–diagonal blocks of the chronogeometric Green's system compatibly with eqs. (10.112) and (10.160).

Interpretation (operator/triad/T–L–O). Equations (10.177)–(10.180) implement the IQR tenet that interaction is entanglement–mediated and fundamentally bi–local. The triadic split (10.176) attributes the coupling to spec, vac, and corr provenance, while the sector execution functor $\mathscr{E}_\bullet$ records non–TT temporal responses via $\mathrm{TLO}^{[\chi]}$ with $\chi \in \{\tau_S, \tau_A, K_{\mathrm{T}}^{(\tau)}, K_{\mathrm{L}}^{(\tau)}\}$ (cf. Definition 9.153 and Proposition 10.22) and leaves $\mathrm{TLO}^{[\mathrm{TT}]}$ untouched (cf. Proposition 10.35).

Functional Variation and Coupled Source Currents

We vary the bi–local interaction action of Definition 10.223 with respect to the *conjugate fluctuation fields*, keeping the inter–modal transporter fixed (cf. Definition 4.9). All fields are background–split as in eq. (10.87) and Definition 10.204.

Definition 10.226 (Bi–local source currents (transported, typed/triad–ready))**.** Let $\delta\tilde{\hat{\mathbf{\Theta}}}(x' \to x) := \mathcal{U}_{x'\to x}\, \delta\hat{\mathbf{\Theta}}(x')\, \mathcal{U}_{x\to x'}$. The functional variations of S_{int} (Definition 10.223) define the operator–valued currents

$$\hat{\mathcal{J}}^{\Phi}_{(\Theta)}(x) := \frac{\delta S_{\mathrm{int}}}{\delta\Big(\delta\hat{\mathbf{\Phi}}(x)\Big)^{\dagger}} = \int d^d x'\; \mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x')\; \delta\tilde{\hat{\mathbf{\Theta}}}(x'\to x), \tag{10.181}$$

$$\hat{\mathcal{J}}^{\Theta}_{(\Phi)}(x') := \frac{\delta S_{\mathrm{int}}}{\delta\Big(\delta\hat{\mathbf{\Theta}}}(x')\Big)^{\dagger} = \int d^d x\; \Big(\mathcal{U}_{x\to x'}\, \mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}(x,x')^{\dagger}\, \mathcal{U}_{x'\to x}\Big)\; \delta\hat{\mathbf{\Phi}}(x). \tag{10.182}$$

They inherit the triadic resolution (eq. (10.176)): $\hat{\mathcal{J}}^{\bullet}_{(\circ)} = \bigoplus_a \hat{\mathcal{J}}^{\bullet}_{(\circ);a}$ with $\hat{\mathcal{J}}^{\bullet}_{(\circ);a} := \Pi^{[a]}\, \hat{\mathcal{J}}^{\bullet}_{(\circ)}\, \Pi^{[a]}$ for $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$.

Terminology (aligned with Ch. 10). $\hat{\mathcal{J}}^{\Phi}_{(\Theta)}$ is the *matter–sourced geometric current* (a source on the Gaiamiti leg); $\hat{\mathcal{J}}^{\Theta}_{(\Phi)}$ is the *geometry–sourced matter current* (a source on the Tantrakyma leg). Typed/helicity refinements follow the projector family of Definition 10.25.

Quantum–Covariant Coupled Field Equations (operator form)

Let $\mathcal{K}_\Theta$ be the normally hyperbolic matter operator of eq. (10.158) with linearized equation eq. (10.159). Let $\mathcal{K}_\Phi$ denote the geometric kinetic operator obtained from the quadratic part of S_Φ (chronogeometric wave operator in the sense of Definition 10.167 and eq. (10.131); constitutive background in Section 10.17.4). Then the coupled, bi–locally sourced operator equations read

$$\mathcal{K}_\Phi(x)\, \delta\hat{\mathbf{\Phi}}(x) = \hat{\mathcal{J}}^{\Phi}_{(\Theta)}(x), \tag{10.183}$$

$$\mathcal{K}_\Theta(x')\, \delta\hat{\mathbf{\Theta}}(x') = \hat{\mathcal{J}}^{\Theta}_{(\Phi)}(x'), \tag{10.184}$$

where the source operators $\hat{\mathcal{J}}^{\Phi}_{(\Theta)}$ and $\hat{\mathcal{J}}^{\Theta}_{(\Phi)}$ are constructed from the bi–local interaction kernel $\mathcal{U}_{\Phi\Theta}(x,x')$ (cf. Definition 10.229 and eq. (10.176)) within the standard operator framework of quantum fields on curved backgrounds [244, 7].

Corollary 10.227 (TT closure of the graviton sector)**.** *Applying the TT projector gives* $\mathcal{P}^{(2)}\big[\mathcal{K}_\Phi\,\delta\hat{\mathbf{\Phi}}\big] = \mathcal{P}^{(2)}\big[\hat{\mathcal{J}}^{\Phi}_{(\Theta)}\big] = 0$*, because the right leg is tau–typed and TT–null (eq. (10.90) and Lemma 10.59); hence the radiative TT mode* $\hat{\gamma}_{\mu\nu} = \mathcal{P}^{(2)}[\delta\hat{g}_{\mu\nu}]$ *evolves without additional GW polarizations (cf. Definition 10.167 and Lemma 10.168).*

Current–driven form (component notation). When $\mathcal{K}_\Phi \to -\bar{\nabla}_\mu(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\,\cdot\,) + \mathcal{M}_\Phi$ and $\mathcal{K}_\Theta \to -\bar{\nabla}_\mu(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\,\cdot\,) + \mathcal{M}_\Theta$ (chronogeometric compatibility; cf. Section 10.18.6),

$$-\bar{\nabla}_\mu\Big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\delta\hat{\mathbf{\Phi}}\Big) + \mathcal{M}_\Phi\,\delta\hat{\mathbf{\Phi}} = \hat{\mathcal{J}}^{\Phi}_{(\Theta)}, \qquad \text{(geometry)}, \tag{10.185}$$

$$-\bar{\nabla}_\mu\Big(\bar{\Sigma}^{\mu\nu}\bar{\nabla}_\nu\delta\hat{\mathbf{\Theta}}\Big) + \mathcal{M}_\Theta\,\delta\hat{\mathbf{\Theta}} = \hat{\mathcal{J}}^{\Theta}_{(\Phi)}, \qquad \text{(matter)}, \tag{10.186}$$

in alignment with the Ch. 10 current conventions while preserving the Ch. 11 typed/bi–local structure [244, 7].

Physical Interpretation. These equations instantiate the quantum analogue of Wheeler's dictum [239].

(i) "Matter tells geometry how to curve" Equation (10.183) shows that the Gaiamiti field is driven by the state of the Tantrakyma field through the operator–valued source $\hat{\mathcal{J}}^{\Phi}_{(\Theta)}$, which is built from the cross–correlator and interaction kernel $\mathcal{U}_{\Phi\Theta}$ (cf. Definition 10.229 and eq. (10.176)). In particular, the correlational channel of $\mathcal{U}_{\Phi\Theta}$ realizes the entanglement→geometry mechanism emphasized in holographic contexts [516, 1].

(ii) "Geometry tells matter how to move" Equation (10.184) shows that the Tantrakyma field propagates in (and responds to) the chronogeometric background generated by $\hat{\mathbf{\Phi}}$, with $\hat{\mathcal{J}}^{\Theta}_{(\Phi)}$ encoding how curvature and geometric fluctuations modulate matter dynamics in the curved-space operator formalism [244, 7].

Significance. The coupled system expresses a quantum–covariant feedback loop: geometry and matter are *co-constructed* by bi–local operator correlations rather than merely coupled by local densities. The interaction kernel $\mathcal{U}_{\Phi\Theta}(x, x')$ is the central mediator: it simultaneously sources, propagates, and encodes mutual influence between the two sectors and, in its correlational channel, provides a concrete route by which quantum information structure imprints geometry [516, 1]. From this perspective, the classical role of the local stress–energy tensor as the generator of curvature is supplanted by the off-diagonal operator correlator, a nonlocal object that carries both energetic and coherent content in the curved-background QFT setting [244, 7]. The TT closure of Corollary 10.227 then guarantees that no extra GW polarizations are introduced: correlational and vacuum responses feed back into geometry without violating the transverse–traceless selection on the metric radiative sector.

10.19.5 Mutually–Sourced Field Currents and Typed Reciprocity

Remark 10.228 (Typed, triad–resolved reading)**.** With the type projectors $\Pi^{[\chi]}$ (Definition 10.25) and triad idempotents $\Pi^{[a]}$ (Definition 10.15), one may record $\hat{\mathcal{J}}^{\Phi}_{(\Theta);a} = \Pi^{[a]}\hat{\mathcal{J}}^{\Phi}_{(\Theta)}\Pi^{[a]}$

and similarly for $\hat{\mathcal{J}}^{\Theta}_{(\Phi);a}$. TT purity implies $\Pi^{[\gamma]}\hat{\mathcal{J}}^{\Phi}_{(\Theta);a}\Pi^{[\gamma]} = 0$, while non–TT temporal types in $\{\tau_S, \tau_A, K^{(\tau)}_{\mathrm{T}}, K^{(\tau)}_{\mathrm{L}}\}$ are admissible (cf. Lemma 10.59 and Proposition 10.22).

Physical interpretation (Wheeler dictum, quantum form). Equation (10.183) is the operator incarnation of "matter tells geometry how to curve'': $\hat{\mathcal{J}}^{\Phi}_{(\Theta)}$ aggregates the nonlocal, state–dependent Tantrakyma influence on geometry through $\mathbf{U}_{\Lambda}^{[\Phi\leftrightarrow\Theta]}$ (Definition 10.221). Equation (10.184) is the reciprocal "geometry tells matter how to move'' via $\hat{\mathcal{J}}^{\Theta}_{(\Phi)}$. The feedback remains TT–safe by Corollary 10.227.

T–L–O ledger compatibility. Currents projected by $\Pi^{[\chi]}$ feed the same Type/Location/Onset stamps as their parent correlator blocks (cf. Definition 9.153 and Propositions 10.22 and 10.35); TT stamps $\mathrm{TLO}^{[\gamma]}$ remain unaffected by non–TT current components.

Summary. The bi–local currents (10.181)–(10.182) provide the Ch. 11–consistent, transporter–covariant sources for the coupled equations (10.183)–(10.184), align with the Ch. 10 current conventions at the operator level, and preserve TT purity of the graviton sector under the projector constraints of Definition 10.25 and Lemma 10.59.

10.19.6 Triadic Decomposition of the Interaction Channels

We work with the transported, off–diagonal block $\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Theta]}(x,x')$ of the Unified Inter–Modal Correlator (cf. Definition 10.113 and Section 10.19), whose legs live on a *common* modal fibre via $\mathcal{U}_{x'\to x}$ (see Definition 4.9). Both sides admit the triad idempotents $\{\Pi^{[a]}\}_{a\in\{\mathrm{spec,vac,corr}\}}$ (Definition 10.15), acting on the *geometric* (Φ) leg (left) and the *matter* (Θ) leg (right), respectively.

Definition 10.229 (Double–triad–resolved cross–correlator)**.** The matter–geometry cross–correlator is decomposed as

$$\boxed{\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Theta]}(x,x') = \sum_{a,b\in\{\mathrm{spec,vac,corr}\}} \hat{\mathbf{G}}_{\Lambda;a|b}^{[\Phi\to\Theta]}(x,x'), \qquad \hat{\mathbf{G}}_{\Lambda;a|b}^{[\Phi\to\Theta]} := \Pi_{\Phi}^{[a]}\,\hat{\mathbf{G}}_{\Lambda}^{[\Phi\to\Theta]}\,\Pi_{\Theta}^{[b]}.} \tag{10.187}$$

Here $\Pi_{\Phi}^{[a]}$ acts on the geometric leg and $\Pi_{\Theta}^{[b]}$ on the matter leg (after transport to x). The Hermitian reciprocity reads

$$\left(\hat{\mathbf{G}}_{\Lambda;a|b}^{[\Phi\to\Theta]}(x,x')\right)^{\dagger} = \hat{\mathbf{G}}_{\Lambda;b|a}^{[\Theta\to\Phi]}(x',x). \tag{10.188}$$

Remark 10.230 (Typed refinement commutes with the triad)**.** For any admitted geometry type $\Pi^{[\chi]}$ (Definition 10.25), the typed block $\hat{\mathbf{G}}_{\Lambda;a|b}^{[\Phi\to\Theta;\chi]} := \Pi_{\Lambda}^{[\chi]}\,\hat{\mathbf{G}}_{\Lambda;a|b}^{[\Phi\to\Theta]}\,\Pi_{\Lambda}^{[\chi]}$ is well–defined and satisfies the same reciprocity (10.188). In particular, TT purity on the geometry leg is enforced by $\Pi^{[\gamma]} = \mathcal{P}^{(2)}$.

Channel diagram. Equation (10.187) can be visualised as a 3×3 matrix $\left(\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a|b}\right)_{a,b}$ with rows (a) labelling the geometric triad origin and columns (b) the matter triad origin. Diagonal entries encode mode–preserving couplings; off–diagonals encode mode–mixing couplings.

Definition 10.231 (Triad–resolved interaction kernel (single–index))**.** The Hermitian interaction kernel of Definition 10.221 inherits a triad decomposition on the *geometric* leg:

$$\boxed{\mathbf{U}^{[\Phi\leftrightarrow\Theta]}_{\Lambda}(x,x') = \sum_{a\in\{\mathrm{spec,vac,corr}\}} \mathbf{U}^{[\Phi\leftrightarrow\Theta]}_{\Lambda;a}(x,x'), \qquad \mathbf{U}^{[\Phi\leftrightarrow\Theta]}_{\Lambda;a} := \sum_{b}\left(\hat{\mathbf{G}}^{[\Phi\to\Theta]}_{\Lambda;a|b} + \left(\hat{\mathbf{G}}^{[\Theta\to\Phi]}_{\Lambda;b|a}\right)^{\dagger}\right).} \tag{10.189}$$

Each $\mathbf{U}^{[\Phi\leftrightarrow\Theta]}_{\Lambda;a}$ is again triad–idempotent on the geometry leg: $\Pi^{[a]}_{\Phi}\,\mathbf{U}_{\Lambda;a} = \mathbf{U}_{\Lambda;a} = \mathbf{U}_{\Lambda;a}\,\Pi^{[a]}_{\Phi}$.

Remark 10.232 (Semantics of the triadic interaction channels)**.** In parallel with Sections 10.17.6 and 10.18.7, we interpret each channel of the single-index decomposition $\mathcal{U}^{(a)}_{\Phi\Theta}$ as follows.

(i) Correlational ($a = \mathrm{corr}$)
This channel captures entanglement- and coherence–driven curvature response: informational structure in the matter sector Θ imprints correlational geometry on the Gaiamiti field through the cross–correlator, realizing the idea that spacetime connectivity can be sourced by quantum correlations [516, 1]. Accordingly, $\mathbf{U}_{\Lambda;\mathrm{corr}}$ aggregates the contributions of $\hat{G}^{(\mathrm{corr}|b)}_{\Phi\Theta}$ that transduce relational entanglement into geometric response.

(ii) Vacuum ($a = \mathrm{vac}$)
This channel describes response along (near–)flat directions of the vacuum bundle $\mathcal{M}_{\mathrm{vac}}$ of the Gaiamiti sector, aligned with Goldstone deformations that parameterize spontaneous symmetry breaking of the matter sector on the emergent background; its dynamics follow standard effective–field–theory reasoning for Goldstone/Higgs modes adapted to curved or emergent geometries [415]. In particular, $\mathbf{U}_{\Lambda;\mathrm{vac}}$ isolates those geometric variations that slide along the vacuum manifold rather than exciting tensorial helicities.

(iii) Spectral ($a = \mathrm{spec}$)
This channel encodes energy–momentum (spectral) sourcing of curvature: frequency content in the matter sector drives frequency–dependent geometric response and controls classical limits such as gravitational redshift, dispersion, and localization within the nonlocal operator framework of quantum fields on curved backgrounds [244, 7]. Consequently, $\mathbf{U}_{\Lambda;\mathrm{spec}}$ collects the pieces of the kernel whose support is organized by spectral structure.

Off–diagonal blocks with $a \neq b$ in (10.187) represent triad *mode–mixing*: correlational, vacuum, and spectral characters can transmute across legs in the cross–correlator, and their contributions feed the interaction kernel according to (10.176) while never violating TT selection on the geometry leg because $\mathcal{P}^{(2)} \circ \Pi^{[\chi]} = 0$ when χ is non–TT (cf. Lemma 10.59).

Corollary 10.233 (Compatibility with currents and T–L–O stamps)**.** *The currents of Section 10.19.4 inherit the same triad split:* $\hat{\mathcal{J}}^{\Phi}_{(\Theta)} = \bigoplus_a \hat{\mathcal{J}}^{\Phi}_{(\Theta);a}$ *with* $\hat{\mathcal{J}}^{\Phi}_{(\Theta);a}$ *driven by* $\mathbf{U}_{\Lambda;a}$*. Running the sector execution functor (Definition 9.153) with the usual admission gate (Definition 10.94) stamps* $\mathrm{TLO}^{[\chi]}$ *per admitted type; TT stamps* $\mathrm{TLO}^{[\mathrm{TT}]}$ *remain unaffected by non–TT contributions within any* $(a|b)$ *block (cf. Propositions 10.22 and 10.35 and Lemma 10.168).*

Chapter 11

The Graviton and Chronogeometric Gravity

11.1 Quantization and Interaction of the Geometric Sector

The geometric sector is quantized on the *chronogeometric background* $\left(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu}\right)$ introduced in Chapter 6, where $\bar{\Sigma}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ is the expectation-level chronogeometric field obtained from the operator Hessians $(\hat{g}_{\mu\nu}, \hat{t}_{\mu\nu})$ of composite distinguishability/temporal functionals (Chapter 5; cf. $\bar{\Sigma}$ and the construction in Section 5.2). All covariant operations below use the *Relational Levi–Civita* connection $\bar{\nabla}$ uniquely compatible with $\bar{\Sigma}$ $\left(\bar{\nabla}_\lambda \bar{\Sigma}_{\mu\nu} = 0\right)$; see Definition 6.7. The *typed carrier* for radiative spin–2 is fixed once and for all by the *background-covariant TT projector* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ from Chapter 11 (York-type, $\bar{\Sigma}$-self-adjoint, idempotent, elliptic on the realized weave configuration). We *define* the graviton field operator by

$$\boxed{\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}}, \qquad \bar{g}^{\mu\nu}\hat{h}_{\mu\nu} = 0, \quad \bar{\nabla}^{\mu}\hat{h}_{\mu\nu} = 0,$$

so that transversality and tracelessness hold *by construction* (TT calculus of Chapter 11). Crucially, *temporal/coherence* fluctuations $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ are *TT-null* in the weave (Chapter 11) and therefore cannot radiate spin–2; this *insulates* the typed graviton $\hat{h}_{\mu\nu}$ from the τ-kairos sector in all physical readouts.

All quantization and interaction statements are carried out on a *certified plateau* $\mathfrak{P}$ in the sense of Chapter 8, using BRST-closed *band tags* $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = \left(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}\right)$ that commute with both the *triad projectors* $\Pi^{(a)}$ for $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ and the typed projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definitions 6.280 and 9.10; cf. the BRST/clean band formalism in eq. (7.10) and Proposition 7.3). On $\mathfrak{P}$ the *physical sector* is $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (Chapter 8); all realized kernels and spectra are *Nielsen-flat* (gauge-parameter independent), *hyperbolic* with respect to the $\bar{\Sigma}$-cone, and enjoy *Källén–Lehmann positivity* for gauge-invariant probes. In particular, canonical equal-time commutators and the *Peierls bracket* will be imposed *after* the typed/triadic selection, ensuring that their supports remain $\bar{\Sigma}$-causal (Chapters 8–10).

The *triadic composition* remains explicit at every stage. We decompose

$$\hat{h}_{\mu\nu} = \hat{h}_{\mu\nu}^{(\mathrm{corr})} + \hat{h}_{\mu\nu}^{(\mathrm{vac})} + \hat{h}_{\mu\nu}^{(\mathrm{spec})}, \qquad \hat{h}_{\mu\nu}^{(a)} := \Pi^{(a)}\,\hat{h}_{\mu\nu}, \quad [\Pi^{(a)}, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}] = 0,$$

so that creation–annihilation operators carry a *sector label* a and the *Fock space factorizes* across the triad (cf. the sector bookkeeping from Chapter 5 and the typed weave of Chapter 11). The *TT two-point* function admits a *triad-resolved Källén–Lehmann representation* on $\mathcal{H}_{\mathrm{phys}}$,

$$\Delta^{(2),a}(q) = \frac{Z_a}{q^2 + i\epsilon} + \int_0^\infty \frac{\rho_a^{(2)}(\mu^2)\, d\mu^2}{q^2 - \mu^2 + i\epsilon}, \qquad Z_a \geq 0,\ \rho_a^{(2)}(\mu^2) \geq 0,$$

with the *residue vector* $\vec{Z} = (Z_{\mathrm{corr}}, Z_{\mathrm{vac}}, Z_{\mathrm{spec}})$ read *on the plateau* (Chapter 8). This is the precise sense in which the realized graviton is *TT-typed* yet may carry a *triadic admixture* in its spectral weight; the admixture is physical only insofar as it survives the BRST/plateau certification (Proposition 7.3, positivity statements in Chapter 8).

Quantization proceeds in two complementary, equivalent languages. In the *canonical* approach, we impose the equal-time canonical algebra on the *typed* variables $(\hat{h}_{\mu\nu}, \hat{\Pi}^{\mu\nu})$ after band-sandwiching by $P_x(\lambda_{\mathrm{UV}})$ and projecting with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$; this preserves BRST hygiene and keeps commutators localized within the $\bar{\Sigma}$-induced foliation (Chapter 10). In the *covariant* approach, we use the *Peierls bracket* generated by the *TT-projected Lichnerowicz operator* on $\left(\mathcal{X}_q, \bar{\Sigma}\right)$, so that the commutator is the *difference of TT retarded/advanced Green operators* with support on the $\bar{\Sigma}$-*null cone* (Chapters 8 and 10). Both perspectives are strictly equivalent on $\mathfrak{P}$ and define the same realized propagator; we will use whichever is most convenient for the task at hand.

Interactions are organized as typed reductions of the *bi-local coupling* between the geometry- and matter-like blocks set up in Chapter 11 (the $\Phi\Phi \leftrightarrow \Theta\Theta$ off-diagonal of the unified correlator, Chapter 6). Concretely, the linearized graviton–Tantrakyma vertex in this part,

$$S_{\mathrm{int}}^{(1)}[\hat{h}, \hat{\Theta}] = \int d\mu(x)\ \hat{h}_{\mu\nu}(x)\, \hat{V}^{\mu\nu}(x; \hat{\Theta})\,,$$

is understood as the *TT-typed shadow* (left leg TT-projected) of that *bi-local parent*; Hermiticity, causal support restricted to the $\bar{\Sigma}$-cone, and *TT-preservation* under composition follow from the weave algebra and the TT-nullity of the τ-typed right leg (Chapter 11). This guarantees that *spin–2 radiative content* is purely metric and cannot be sourced by τ-kairos fluctuations, in agreement with the TT-purity results of Chapter 11.

Finally, we attach a *typed Parasymmetric TLO* layer (Chapter 9) *for the graviton only*. The *law witness* is the *TT-projected* linearized Einstein operator,

$$\mathbf{R}^{[\mathrm{TT}]} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big[\delta\bar{G}_{\mu\nu}[\hat{h}] + \Lambda\, \hat{h}_{\mu\nu} - \kappa\, \delta\bar{T}^{\mathrm{total}}_{\mu\nu}\Big], \qquad \Lambda_{\mathrm{law}}^{[\mathrm{TT}]} := 1 - \frac{\|\mathbf{R}^{[\mathrm{TT}]}\|_{\mathcal{I}}}{\|\cdot\|_{\mathrm{ref}}} \in [0,1],$$

which evaluates the *law channel* on $\mathfrak{P}$ (Nielsen-flat, Chapter 7). The *state visibility* $\Lambda_{\mathrm{state}}^{[\mathrm{TT}]}$ is read from the TT two-point KL content (pole residue Z_a and positive spectral density $\rho_a^{(2)}$ in each sector) and synthesized across the triad. Two *type-specific diagnostics* complete the ledger: the *TT-purity* residual $\|\Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]}\mathfrak{O}\|_{\mathcal{I}}$ (absence of non-TT contamination) and the *TT-leak* $\varepsilon_{\mathrm{TT}}$ (forbidden inflow from non-TT channels). The canonical *QI–QIV resolver* of Chapter 9 (Chapter 8) is then applied to $\left(\Lambda_{\mathrm{law}}^{[\mathrm{TT}]}, \Lambda_{\mathrm{state}}^{[\mathrm{TT}]}\right)$ with the standard plateau tolerances set in Chapter 8, ensuring that every claim about graviton propagation, coupling, and exchange is *diagnostic realized reference configuration-certified*, *typed*, and *sector-aware* before we proceed to mode decompositions, propagators, and scattering.

Definition 11.1 (Typed structure on the realized weave configuration)**.** Work on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$ with BRST projector $\mathsf{P}_{\mathrm{phys}}$, band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$, and realized background $(\mathcal{X}_q, \bar{\Sigma})$. A *typed* object is obtained by restricting (or decomposing) a field/operator to the image of a commuting family of idempotent projectors ("types"), drawn from:

- the TT projector on symmetric rank-2 tensors, $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (York–Lichnerowicz; eq. (10.4) and Definition 10.3);
- the triad provenance projectors $\Pi^{(\mathrm{spec})}, \Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{corr})}$ (Definition 10.2);
- the τ–kairos typed idempotents $S^{(b)}, S^{(L)}, \tilde{S}^{(p)}, A^{(+)}, A^{(-)}$ (scalar/vector split with helicity resolution; Definition 10.4);
- CP refinements in the scalar (radial) subspace, $\Pi^{(\mathrm{CP}\pm)}$ (Definition 10.5);
- Riesz spectral selectors for spin content, $\mathsf{P}^{(2)}_{\mathrm{spec}}, \mathsf{P}^{(0)}_{\mathrm{spec}}$ (Definition 10.7);
- the certified band projectors $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ (Definitions 6.280 and 9.10).

These projectors commute (commutation stability; Proposition 10.9), so any composition or "audit move" preserves type. A *typed operator* $O^{[\chi]}$ obeys $O^{[\chi]} = \Pi^{[\chi]} O \Pi^{[\chi]}$ and maps $\operatorname{Ran}\Pi^{[\chi]}$ to itself; a *typed field* is the corresponding restriction to $\operatorname{Ran}\Pi^{[\chi]}$.

Cross-reference to Chapters 9–10. The operational use of types with projector sandwiches and triad filters is set up in the Chapter-10 typed calculus (Definition 9.116), and the evaluation of *witnesses* (law/state visibilities and quadrant decisions) is organized in Chapter-9 (Definitions 8.4 and 8.5). In this chapter, all "typed" statements (ETCR, Peierls, propagators, and TT ledgers) are to be read with this convention and are compatible with the witness/quadrant machinery via the same $\Pi^{[\chi]}$ sandwiching.

Canonical examples (Chapter 12).

1. *Typed canonical pair and ETCR.* $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}$ and $\hat{\Pi}^{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\pi}^{\mu\nu}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 11.3) satisfy the equal-time commutator *restricted to the TT subspace* (Proposition 11.4), with the band sandwich $P_x(\lambda_{\mathrm{UV}})$.

2. *Typed Lichnerowicz/Peierls.* The kinetic operator $K^{[\mathrm{TT}],(a)}$ (with $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$) and the Pauli–Jordan bi-solution $\Delta^{[\mathrm{TT}]}$ are TT-typed, yielding typed microcausality and canonical–Peierls equivalence on $\mathfrak{P}$ (Definition 11.60 and Proposition 11.14).

3. *Typed propagators and KL.* $G^{\mathrm{F},[\mathrm{TT}],(a)}$ and the triad-resolved Källén–Lehmann form are constructed within the typed subspace (eq. (11.91)).

4. *Typed witnesses and ledgers.* TT law residual/visibility $\mathbf{R}^{[\mathrm{TT}]}$, $\Lambda_{\mathrm{law}}^{[\mathrm{TT}]}$ use TT-typed meters and remain stable under audit moves (Definition 11.6).

Orthogonal decompositions behind "typed". On the symmetric 2-tensor carrier,

$$\mathbf{1} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \oplus \Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]}, \qquad \Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]} \cong \underbrace{\operatorname{Ran} S^{(b)} \oplus \operatorname{Ran} S^{(L)} \oplus \operatorname{Ran} \tilde{S}^{(p)}}_{\text{scalar } \tau\text{-types}} \oplus \underbrace{\operatorname{Ran} A^{(+)} \oplus \operatorname{Ran} A^{(-)}}_{\text{vector } \tau\text{-types}},$$

with the scalar radial sector optionally refined by $\Pi^{(\mathrm{CP}\pm)}$ (Lemma 10.8 and Definition 10.5). Thus, "typed" statements insure that calculations, brackets, and propagators are carried out *inside* the intended projector image and are compatible with triad provenance and band/BRST structure.

Witnesses (reminder and Chapter-12 specialization). A *witness* is a band-/BRST-clean, gauge-invariant, *typed* functional producing a visibility $\Lambda \in [0,1]$ that certifies a law- or state-level property inside a projector-defined type; see the sectoral definitions and quadrant rule in Ch. 9 (Definitions 8.4 and 8.5) and the typed projector calculus in Ch. 10 (Definition 9.116). Concretely, all evaluations are performed on the certified plateau $\mathfrak{P}$ with projector sandwiches that commute (commutation stability; Proposition 10.9), hence are invariant under audit moves.

TT specialization used in this chapter. With the type fixed to the graviton carrier $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$, the witnesses employed are:

- **TT law residual/visibility** (Definition 11.6):

$$\mathbf{R}^{[\mathrm{TT}]} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big[\delta\bar{G}_{\mu\nu}[\hat{h}] + \Lambda\,\hat{h}_{\mu\nu} - \kappa\,\delta\bar{T}^{\mathrm{total}}_{\mu\nu}\Big], \qquad \Lambda^{[\mathrm{TT}]}_{\mathrm{law}} := 1 - \|\mathbf{R}^{[\mathrm{TT}]}\|_{\mathcal{I}}/\|\cdot\|_{\mathrm{ref}}.$$

  It admits the Peierls "hook" representation $\mathbf{R}^{[\mathrm{TT}]} \sim \{\cdot, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$ (Corollary 11.12), where $S^{[\mathrm{TT}]}$ is the TT-projected quadratic action on $\mathfrak{P}$.

- **TT purity/leak** (Definition 11.7): for any TT readout object $\mathfrak{O}$,

$$\varepsilon_{\mathrm{TT}} := \frac{\|\Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]}\mathfrak{O}\|_{\mathcal{I}}}{\|\mathfrak{O}\|_{\mathcal{I}}},$$

  which certifies TT-purity (small leak) and is Nielsen-flat on the plateau.

- **Quadrant assignment in the TT type:** the pair $\left(\Lambda^{[\mathrm{TT}]}_{\mathrm{law}}, \Lambda^{[\mathrm{TT}]}_{\mathrm{state}}\right)$ feeds the standard law/state quadrant decision inherited from Ch. 9 (QI–QIV; Definition 8.5), with the typed/triad projector sandwich from Ch. 10 (Definition 9.116).

All Peierls and ETCR statements in this chapter are to be read in the typed sense (TT sandwiches understood), cf. Definition 11.1 and Propositions 11.4 and 11.14.

Instrumentation (Chs. 9–10 reminder). *Sector-realized weave configuration* collects the standardized meters/tags and evaluation settings used to compute witness visibilities in a given sector $[\mathscr{S}]$. It fixes the arena $\mathcal{A}$ (bulk/boundary), an IR knob r, the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$, and the BRST projection $\mathsf{P}_{\mathrm{phys}}$, so that all law/state witnesses are evaluated on the same instrumental frame (Definitions 6.280, 8.4, 8.5, 9.10 and 9.116). In short, instrumentation specifies the calibrated *how* measurements are performed (meters, UV/IR windows, and BRST hygiene) before any typed restriction is applied.

Certified realized weave configuration (Chs. 11–12 usage). In the weave chapters, the instrumentation is *instantiated and frozen* as the *realized weave configuration* $\mathcal{I}^{[\mathcal{S}]}$, now including the realized chronogeometric background $\bar{\Sigma}$. This fixed frame is used for all typed decompositions, selection rules, and dynamical statements; it packages the band tag, the physical cohomology $\mathcal{H}_{\text{phys}}$, and the commuting projector family (TT, triad, τ-types, CP, spectral) with commutation stability (Definitions 10.1 and 10.3, Propositions 10.9 and 10.10, and eq. (10.4)). Operationally, working "on the rig" means every construction is band-/BRST-clean and $\bar{\Sigma}$-covariant by design.

Interaction with types and witnesses (bridge to Ch. 12). Types are the projector-defined subspaces inside which objects are restricted (e.g. TT) and are formalized here by Definition 11.1 (cf. Ch. 10 Definition 9.116). Witnesses are typed, gauge-invariant functionals that output visibilities in $[0,1]$ and drive the law/state quadrant logic from Ch. 9 (Definitions 8.4 and 8.5). In this chapter, TT-typed statements—canonical algebra and Peierls equivalence—are all read on the realized weave configuration with projector sandwiches understood (Propositions 11.4 and 11.14), and TT witnesses such as the law residual/visibility and the Peierls hook are evaluated in the same frame (Definition 11.6 and Corollary 11.12).

11.1.1 Canonical Quantization of the Gaiamiti Field

To quantize the geometric sector we work on the chronogeometric background $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$ of Chapter 6 with the Relational Levi–Civita connection $\bar{\nabla}$ (see Definition 6.7). We impose, *from the outset*, the background–covariant TT typing of Chapter 11 by projecting the metric fluctuation $\delta\hat{g}_{\mu\nu}$ with the York-type projector $\Pi_{\bar{\Sigma}}^{[\text{TT}]}$. All canonical statements are evaluated on a certified plateau $\mathfrak{P}$ (Chapter 8) and within BRST-closed band tags $\mathfrak{B}_{\lambda_{\text{UV}},\ell} = \left(P_x(\lambda_{\text{UV}}), K_{\text{IR}}^{(\ell)}\right)$ (Definitions 6.280 and 9.10), which commute with physical projectors (cf. Proposition 7.3).

Canonical Conjugate Momentum

Definition 11.2 (Canonical Conjugate Momentum of the Gaiamiti Field)**.** Let $S_\Phi[\hat{\mathbf{\Phi}}]$ be the action of the Gaiamiti field with operator-valued Lagrangian density $\mathcal{L}_\Phi$ (Definition 6.172). The *canonical momentum* conjugate to $\hat{\mathbf{\Phi}}(x)$ is

$$\boxed{\hat{\mathbf{\Pi}}_\Phi(x) := \frac{\delta \mathcal{L}_\Phi}{\delta\left(\nabla_0 \hat{\mathbf{\Phi}}(x)\right)}}, \tag{11.1}$$

where ∇_0 is the covariant derivative along the emergent temporal direction. For the quadratic Gaiamiti sector this yields $\hat{\mathbf{\Pi}}_\Phi(x) = 2\,\bar{\Sigma}^{0\nu}(x)\left(\nabla_\nu \hat{\mathbf{\Phi}}(x)\right)^\dagger$ up to conventional normalizations.

$S_\Phi[\hat{\mathbf{\Phi}}]$ (Gaiamiti action). The action of the Gaiamiti sector is the integral of the scalar Lagrangian density $\mathcal{L}_\Phi$ (built from the operator-valued kernel $\mathscr{L}_\Phi^{\text{op}}$) over the emergent configuration space $(\mathcal{X}_q, \bar{\Sigma})$:

$$S_\Phi[\hat{\mathbf{\Phi}}] \;=\; \int_{\mathcal{X}_q} d\mu(x)\; \mathcal{L}_\Phi(x) \;=\; \int_{\mathcal{X}_q} d^d x\, \sqrt{-\det \bar{\Sigma}(x)}\; \mathcal{L}_\Phi(x), \tag{11.2}$$

where $d\mu(x) = \sqrt{-\det \bar{\Sigma}(x)}\, d^d x$ is the relational volume element (see Definition 6.33), and $\mathcal{L}_\Phi$ is specified in Definition 6.172. The kinetic term uses the inverse chronogeometric tensor $\bar{\Sigma}^{\mu\nu}$ (see Definition 6.24) and the vacuum–tangent Hermitian form g_T.

$\mathcal{L}_\Phi$ (operator–trace scalar density).

$$\boxed{\mathcal{L}_\Phi(x) := \mathrm{Tr}\Big\{ \bar{\Sigma}^{\mu\nu}(x)\, g_T\Big(\nabla_\mu \hat{\mathbf{\Phi}}(x),\, \nabla_\nu \hat{\mathbf{\Phi}}(x)\Big) + \mathcal{V}_\Phi\Big(\hat{\mathbf{\Phi}}(x)\Big)\Big\}} \tag{11.3}$$

(see eq. (6.243)), with $\bar{\Sigma}^{\mu\nu}$ the inverse of $\bar{\Sigma}_{\mu\nu}$ (see Definition 6.24) and g_T the Hermitian inner product on $T\mathcal{M}_{\mathrm{vac}}$.

∇_0 (time component of the split covariant derivative). The total covariant derivative is the split connection

$$\nabla_\mu \;=\; \nabla_\mu^{(\mathrm{rel})} \;+\; D_\mu, \qquad D_\mu \;=\; \partial_\mu \;+\; i[\mathcal{A}_\mu, \cdot], \tag{11.4}$$

as in eq. (6.314), combining the torsion-free, $\bar{\Sigma}$-compatible Relational Levi–Civita piece $\nabla_\mu^{(\mathrm{rel})}$ with $\nabla_\mu^{(\mathrm{rel})}\bar{\Sigma}_{\alpha\beta} = 0$ (see Definition 6.7) and the operator–bundle (gauge) part D_μ (see Definitions 6.184 and 6.192). The symbol ∇_0 denotes the component along the emergent temporal direction used in canonical (equal-time) constructions.

$\bar{\Sigma}^{0\nu}$ (mixed time–space inverse components). The entries $\bar{\Sigma}^{0\nu}$ are the 0ν components of $\bar{\Sigma}^{\mu\nu}$, the inverse of $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$; they raise the index on the time derivative in the kinetic density and enter the canonical momentum (see Definitions 6.24 and 11.2).

$(\cdot)^\dagger$ (fiber adjoint on $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$). All operator kernels live in $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$ and are traced to produce c-number densities; $*$–compatibility of the bundle connection ensures Hermiticity of kinetic structures and invariance under fiber $*$–automorphisms within the action.

"Quadratic Gaiamiti sector." The part of $\mathcal{L}_\Phi$ quadratic in first derivatives of $\hat{\mathbf{\Phi}}$, namely the kinetic bilinear $\bar{\Sigma}^{\mu\nu}\, g_T(\nabla_\mu \hat{\mathbf{\Phi}}, \nabla_\nu \hat{\mathbf{\Phi}})$ (with potential $\mathcal{V}_\Phi$ omitted for defining the canonical momentum), as in eq. (6.243).

Functional/Fréchet derivative $\dfrac{\delta \mathcal{L}_\Phi}{\delta(\nabla_0 \hat{\mathbf{\Phi}})}$. Variations are taken at fixed background $\bar{\Sigma}$ and fixed bundle data $\mathcal{A}_\mu$, exactly as in the covariant variational principle leading to the Gaiamiti EL equations (cf. the discussion following $S_\Phi = \int d\mu\, \mathcal{L}_\Phi$ and Definition 11.2).

Short derivation (quadratic Gaiamiti sector) Work with the kinetic density (suppressing $\mathcal{V}_\Phi$):

$$\mathcal{T}_\Phi = \mathrm{Tr}\Big\{ \bar{\Sigma}^{\mu\nu}\, (\nabla_\mu \hat{\mathbf{\Phi}})^\dagger (\nabla_\nu \hat{\mathbf{\Phi}}) \Big\} + \mathrm{h.c.} \qquad \text{(Hermitian by } *\text{–compatibility)}. \tag{11.5}$$

This is the standard Hermitian realization of the bilinear g_T (compare the symmetrization pattern used for kinetic bilinears in Ch. 10).

Vary only the "velocity" variable $\nabla_0\hat{\mathbf{\Phi}}$ (holding $\bar{\Sigma}, \mathcal{A}_\mu$ fixed). The variation of the first trace gives

$$\delta\mathcal{T}_\Phi = \mathrm{Tr}\Big\{\bar{\Sigma}^{\mu\nu}\,(\nabla_\mu\hat{\mathbf{\Phi}})^\dagger\,\delta(\nabla_\nu\hat{\mathbf{\Phi}})\Big\} + \mathrm{h.c.} \tag{11.6}$$

so picking the $\nu = 0$ component and, from the Hermitian conjugate, the $\mu = 0$ component,

$$\delta\mathcal{T}_\Phi = \mathrm{Tr}\Big\{\bar{\Sigma}^{\mu 0}\,(\nabla_\mu\hat{\mathbf{\Phi}})^\dagger\,\delta(\nabla_0\hat{\mathbf{\Phi}})\Big\} + \mathrm{Tr}\Big\{\bar{\Sigma}^{0\nu}\,(\nabla_\nu\hat{\mathbf{\Phi}})^\dagger\,\delta(\nabla_0\hat{\mathbf{\Phi}})\Big\}\,. \tag{11.7}$$

Using the symmetry $\bar{\Sigma}^{\mu 0} = \bar{\Sigma}^{0\mu}$, the two contributions are identical; hence

$$\delta\mathcal{T}_\Phi = 2\,\mathrm{Tr}\Big\{\bar{\Sigma}^{0\nu}\,(\nabla_\nu\hat{\mathbf{\Phi}})^\dagger\,\delta(\nabla_0\hat{\mathbf{\Phi}})\Big\}\,. \tag{11.8}$$

By definition (cf. Definition 11.2),

$$\boxed{\hat{\mathbf{\Pi}}_\Phi := \frac{\delta\mathcal{L}_\Phi}{\delta(\nabla_0\hat{\mathbf{\Phi}})} \qquad \Rightarrow \qquad \hat{\mathbf{\Pi}}_\Phi(x) = 2\,\bar{\Sigma}^{0\nu}(x)\Big(\nabla_\nu\hat{\mathbf{\Phi}}(x)\Big)^\dagger} \tag{11.9}$$

(up to the overall normalization convention adopted for the symmetric kinetic bilinear). This uses the same variational conventions as in the Noether constructions (Fréchet derivative at fixed backgrounds).

Definition 11.3 (TT-projected canonical variables (project first, then quantize))**.** Let $\delta\hat{g}_{\mu\nu}$ be the Gaiamiti (metric) fluctuation. The *typed* TT graviton and its *typed* TT canonical momentum are defined using the background–covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (eq. (10.4) and Definition 10.3) as

$$\boxed{\begin{aligned}\hat{h}_{\mu\nu} &:= \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}\,, &(11.10)\\ \hat{\Pi}^{\mu\nu} &:= \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\pi}^{\mu\nu}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,, &(11.11)\end{aligned}}$$

where the unprojected canonical momentum $\hat{\pi}^{\mu\nu}$ is obtained by the covariant variational rule (cf. Gaiamiti momentum, Definition 11.2)

$$\hat{\pi}^{\mu\nu} := \frac{\delta\mathcal{L}_\Phi}{\delta\Big(\nabla_0\,\delta\hat{g}_{\mu\nu}\Big)}\,,$$

with ∇_0 the temporal component of the split connection $\nabla_\mu = \nabla^{(\mathrm{rel})}_\mu + D_\mu$ (eq. (6.314) and Definition 6.7).

By construction and the properties of $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (idempotent, trace/longitudinal annihilation), the TT variable satisfies

$$\bar{g}^{\mu\nu}\hat{h}_{\mu\nu} = 0, \qquad \bar{\nabla}^\mu\hat{h}_{\mu\nu} = 0$$

(*TT calculus*; see Definition 10.3), where $\bar{\nabla}$ is the $\bar{\Sigma}$-compatible Levi–Civita derivative (Definition 6.7). Moreover, the temporal/coherence fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ is *TT-null*:

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0,$$

so it does not contribute to $\hat{h}_{\mu\nu}$ (see the τ–kairos typing and TT–null statements in Definition 10.4).

Notation and mathematical meaning in Proposition 11.4. The equal-time commutator on a foliation slice $\Sigma_t \subset (\mathcal{X}_q, \bar{\Sigma})$ reads

$$[\hat{h}_{\mu\nu}(t,\mathbf{x}),\, \hat{\Pi}^{\rho\sigma}(t,\mathbf{y})] = i\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta_{\mu\nu}{}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,P_x(\lambda_{\mathrm{UV}})\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y}),$$

where t is the emergent temporal parameter that foliates $(\mathcal{X}_q, \bar{\Sigma})$ into Cauchy hypersurfaces Σ_t via the $\bar{\Sigma}$-compatible Levi–Civita connection $\bar{\nabla}$ (Definition 6.7); bold $\mathbf{x}, \mathbf{y}$ are spatial coordinates on Σ_t (dimension $d-1$). The Dirac distribution $\delta^{(d-1)}(\mathbf{x}-\mathbf{y})$ on Σ_t is characterized by $\int_{\Sigma_t} d^{d-1}\mathbf{y}\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y})\,f(\mathbf{y}) = f(\mathbf{x})$ for test fields f. The UV spectral projector $P_x(\lambda_{\mathrm{UV}})$ arises from the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$, enforces band support, and commutes with the typed/projected meters (tag hygiene; Definitions 6.280 and 9.10 and Lemma 9.11). The York–Lichnerowicz map $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is the background-covariant TT projector on symmetric rank–2 tensors (idempotent, self-adjoint, annihilating trace and longitudinal parts; eq. (10.4) and Definition 10.3). The bi-tensor $\delta_{\mu\nu}{}^{\rho\sigma}$ is the symmetric identity: $\delta_{\mu\nu}{}^{\rho\sigma}A_{\rho\sigma} = \frac{1}{2}(\delta_\mu{}^\rho\delta_\nu{}^\sigma + \delta_\mu{}^\sigma\delta_\nu{}^\rho)A_{\rho\sigma}$. The bracket $[\,\cdot\,,\,\cdot\,]$ denotes the operator commutator, and "equal time" means both operators are evaluated on the same slice Σ_t.

Index conventions (clarifying $\mu\nu$ and $\rho\sigma$). Greek indices μ, ν, ρ, σ label spacetime tensor components on $(\mathcal{X}_q, \bar{\Sigma})$, running over $\{0, 1, \ldots, d-1\}$; indices are raised/lowered with $\bar{\Sigma}^{\alpha\beta}$, $\bar{\Sigma}_{\alpha\beta}$. The foliation index 0 designates the emergent temporal direction; spatial components are indexed by Latin letters $i, j, k, l \in \{1, \ldots, d-1\}$ on Σ_t. In the canonical equal-time algebra, one may equivalently write

$$[\hat{h}_{ij}(t,\mathbf{x}),\, \hat{\Pi}^{kl}(t,\mathbf{y})] = i\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta_{ij}{}^{kl}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,P_x(\lambda_{\mathrm{UV}})\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y}),$$

with components carrying a 0-index playing the role of constraints/non-dynamical variables, while the TT projector restricts to the transverse–traceless *spatial* sector on Σ_t. Symmetrization and antisymmetrization follow the standard conventions $A_{(\mu\nu)} := \frac{1}{2}(A_{\mu\nu} + A_{\nu\mu})$, $A_{[\mu\nu]} := \frac{1}{2}(A_{\mu\nu} - A_{\nu\mu})$.

Canonical pair, distributional nature, and band/BRST structure. The typed variables $\hat{h}_{\mu\nu}$ and $\hat{\Pi}^{\rho\sigma}$ are the TT-projected canonical pair (Definition 11.3), obtained from the unprojected metric fluctuation $\delta\hat{g}_{\mu\nu}$ and its momentum $\hat{\pi}^{\rho\sigma} = \delta\mathcal{L}_\Phi/\delta(\nabla_0\delta\hat{g}_{\rho\sigma})$ (Definition 11.2), where ∇_0 is the temporal component of the split connection $\nabla_\mu = \nabla_\mu^{(\mathrm{rel})} + D_\mu$ (eq. (6.314)). Mathematically, Proposition 11.4 states that these TT-projected fields are operator-valued distributions on Σ_t obeying the standard equal-time canonical algebra *restricted to the TT subspace* by the projector sandwich $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}(\cdot)\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$. Band regularization appears explicitly through $P_x(\lambda_{\mathrm{UV}})$ and implicitly through the IR window $K_{\mathrm{IR}}^{(\ell)}$, which preserves $\bar{\Sigma}$-causal cones and ensures the existence of the equal-time limit (Remark 9.83). BRST cleanliness and invariance under gauge-parameter deformations on a certified plateau $\mathfrak{P}$ follow from the cohomological projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3) together with the commutation properties of the realized weave configuration operators (Proposition 10.9).

Proposition 11.4 (ETCR on the band; BRST-healthy, regulator-safe)**.** *On a certified plateau* $\mathfrak{P}$ *with band tags* $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ *that commute with* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ *(Definitions 6.280 and 9.10), the equal-time canonical commutator for the typed variables takes the form*

$$\boxed{\left[\hat{h}_{\mu\nu}(t,\mathbf{x}),\ \hat{\Pi}^{\rho\sigma}(t,\mathbf{y})\right] \;=\; i\;\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta_{\mu\nu}{}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,P_x(\lambda_{\mathrm{UV}})\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y})\,,} \tag{11.12}$$

with all other equal-time commutators vanishing. Here $\delta_{\mu\nu}{}^{\rho\sigma}$ *is the symmetric identity bitensor on rank-2 tensors. The BRST cleanliness and physical-sector projection are as in Proposition 7.3.*

Proof. Work on a certified plateau $\mathfrak{P}$ where the band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ are BRST-closed and commute with all typed/projected meters (Definitions 6.280 and 9.10, Lemma 9.11, and Proposition 10.9). Define the TT-typed variables as in Definition 11.3 using the background–covariant projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (eq. (10.4) and Definition 10.3).

Step 1 (unprojected ETCR on the band). By the canonical definition of the metric's conjugate momentum $\hat{\pi}^{\rho\sigma} := \delta\mathcal{L}_\Phi/\delta(\nabla_0\delta\hat{g}_{\rho\sigma})$ (Definition 11.2) and the equal-time canonical algebra constructed via the covariant (Peierls/Dirac) procedure on the band, the unprojected equal-time commutator reads

$$\left[\delta\hat{g}_{\mu\nu}(t,\mathbf{x}),\ \hat{\pi}^{\rho\sigma}(t,\mathbf{y})\right] \;=\; i\,\delta_{\mu\nu}{}^{\rho\sigma}\,P_x(\lambda_{\mathrm{UV}})\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y}), \qquad \left[\delta\hat{g},\delta\hat{g}\right] = \left[\hat{\pi},\hat{\pi}\right] = 0, \tag{11.13}$$

with the UV projector $P_x(\lambda_{\mathrm{UV}})$ explicitly present (band support), and where the equal-time limit is well-defined because the IR window does not enlarge $\bar{\Sigma}$-cones (Remark 9.83).

Step 2 (TT sandwiching). Using $\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ and $\hat{\Pi}^{\rho\sigma} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\pi}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 11.3), and the facts that $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is idempotent/self-adjoint, annihilates traces and longitudinal parts, and commutes with the band tags and typed/triad maps (eq. (10.4), Definition 10.3, and Proposition 10.9), we compute

$$\begin{aligned}
\left[\hat{h}_{\mu\nu},\,\hat{\Pi}^{\rho\sigma}\right] &= \left[\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu},\ \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\pi}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\right] \\
&= \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\left[\delta\hat{g}_{\mu\nu},\,\hat{\pi}^{\rho\sigma}\right]\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \qquad \text{(commutations from Proposition 10.9)} \\
&= i\;\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta_{\mu\nu}{}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,P_x(\lambda_{\mathrm{UV}})\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y}),
\end{aligned} \tag{11.14}$$

where in the last line we used (11.13). The vanishing $\left[\hat{h},\hat{h}\right] = \left[\hat{\Pi},\hat{\Pi}\right] = 0$ follows in the same way from (11.13) and the projector sandwiching.

Step 3 (BRST cleanliness and physical projection). Because the band tag is BRST-closed ($[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0$, Lemma 9.11) and $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is built from $\bar{\Sigma}$-covariant operators, the commutator is a BRST cocycle and descends to the physical Hilbert space $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ with gauge-parameter independence (Nielsen flatness) on $\mathfrak{P}$ (Propositions 7.3 and 10.10).

Collecting the results yields exactly the displayed ETCR on the band, with all other equal-time commutators vanishing. □

At a high level, Proposition 11.4 states that after first projecting into the physically relevant, background–covariant TT sector using $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 10.3 and eq. (10.4)) and defining the canonical pair as in Definition 11.3, the graviton field $\hat{h}_{\mu\nu}$ and its momentum $\hat{\Pi}^{\rho\sigma}$ obey the *standard* equal–time canonical commutator, but restricted to the TT subspace. The projector sandwich in the ETCR enforces that only transverse–traceless polarizations carry quantum degrees of freedom; all trace/longitudinal components (and the temporal/coherence sector) are removed prior to quantization, hence the algebra does not leak into non-TT directions (Proposition 10.9). The appearance of $P_x(\lambda_{\mathrm{UV}})$ indicates realization *on the band*, with UV/IR control provided by the band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definitions 6.280 and 9.10), while cone preservation guarantees a well-defined equal-time limit (Remark 9.83).

Equally important, the commutator is *BRST-healthy*: the band tags commute with the BRST charge (tag hygiene), and the TT construction is $\bar{\Sigma}$-covariant, so the algebra descends unchanged to the physical cohomology $\mathcal{H}_{\mathrm{phys}}$ and is gauge-parameter independent on a certified plateau $\mathfrak{P}$ (Lemma 9.11 and Proposition 7.3). In summary, the proposition formalizes the principle *project, then quantize*: imposing TT typing at the operator level and employing regulator-safe band tags realizes the canonical graviton structure precisely within the TT sector, without regulator artifacts or gauge contamination (Definitions 11.2 and 11.3).

Corollary 11.5 (Nielsen safety of the TT algebra)**.** *Along gauge-parameter deformations that preserve $\mathfrak{P}$, the typed ETCR of Proposition 11.4 is invariant (Nielsen-flat): any variation is ζ-exact and therefore trivial on $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (Chapter 8).*

Proof. Let α denote a gauge–fixing parameter, and consider deformations $\alpha \mapsto \alpha + \delta\alpha$ that preserve the certified plateau $\mathfrak{P}$ and the band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (hence tag hygiene and BRST closure remain valid; see Definitions 6.280 and 9.10 and Lemma 9.11). Define the typed canonical variables by $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}$ and $\hat{\Pi}^{\rho\sigma} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\pi}^{\rho\sigma}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ as in Definition 11.3, with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ the background–covariant TT projector (eq. (10.4) and Definition 10.3). The ETCR on the band is given by Proposition 11.4.

Step 1: BRST cocycle property. On $\mathfrak{P}$ the band tag is BRST–closed and commutes with all typed/triad projectors (Lemma 9.11 and Proposition 10.9). Since $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is built from $\bar{\Sigma}$–covariant operators, $[\,\hat{Q}_{\mathrm{BRST}}, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}] = 0$ as a consequence of the BRST–closed realized weave configuration (Proposition 10.9). Therefore the typed commutator kernel

$$\mathcal{C}_{\mu\nu}{}^{\rho\sigma}(t;\mathbf{x},\mathbf{y}) := \Big[\hat{h}_{\mu\nu}(t,\mathbf{x}),\, \hat{\Pi}^{\rho\sigma}(t,\mathbf{y})\Big]$$

is a BRST cocycle: $[\,\hat{Q}_{\mathrm{BRST}}, \mathcal{C}\,] = 0$. Hence $\mathcal{C}$ defines a class in $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3).

Step 2: Nielsen identity on the band. On a certified plateau the Slavnov–Taylor/Nielsen framework implies that the α–variation of any BRST–closed realized weave configuration observable is BRST–exact ("Nielsen flatness"): $\partial_\alpha \mathcal{O} = \{\hat{Q}_{\mathrm{BRST}}, \zeta_{\mathcal{O}}\}$ for some local $\zeta_{\mathcal{O}}$ (band version; see the invariance statement for calibrated meters/visibilities, Proposition 10.10, together with the BRST projection properties in Proposition 7.3). Applying this to $\mathcal{C}$ yields

$$\partial_\alpha \mathcal{C}_{\mu\nu}{}^{\rho\sigma}(t;\mathbf{x},\mathbf{y}) = \{\hat{Q}_{\mathrm{BRST}},\, \zeta_{\mu\nu}{}^{\rho\sigma}(t;\mathbf{x},\mathbf{y})\},$$

with ζ constructed from the same realized weave configuration operators (TT/projectors, band tag), which commute with $\hat{Q}_{\mathrm{BRST}}$ by Lemma 9.11 and Proposition 10.9. Therefore $\partial_\alpha \mathcal{C}$ is BRST–exact and vanishes in cohomology, i.e. it is trivial on $\mathcal{H}_{\mathrm{phys}}$.

Combining Steps 1–2 shows that the typed ETCR of Proposition 11.4 is invariant under gauge–parameter deformations that preserve $\mathfrak{P}$; equivalently, it is Nielsen–flat, establishing Corollary 11.5. □

Typed TLO attachment (TT only). In the sense of Chapter IX, diagnostics are attached to the TT sector *only*, using the background–covariant TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (eq. (10.4) and Definition 10.3) on a certified plateau $\mathfrak{P}$ (Section 7.3.9).

Definition 11.6 (TT law residual and visibility)**.** Let the TT–projected linearized Einstein operator about $\bar{\Sigma}$ act on the TT graviton $\hat{h}_{\mu\nu}$ defined in Definition 11.3. With the chronogeometric Einstein tensor $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ and total stress tensor $\bar{T}^{\mathrm{total}}_{\mu\nu}$ from Definition 11.106, define the *TT law residual*

$$\boxed{\mathbf{R}^{[\mathrm{TT}]} \;:=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big[\delta\bar{G}_{\mu\nu}[\hat{h}] + \Lambda\,\hat{h}_{\mu\nu} - \kappa\,\delta\bar{T}^{\mathrm{total}}_{\mu\nu}\Big]\,,} \tag{11.15}$$

and the associated *law visibility* $\Lambda_{\mathrm{law}}^{[\mathrm{TT}]} := 1 - \|\mathbf{R}^{[\mathrm{TT}]}\|_{\mathcal{I}}/\|\cdot\|_{\mathrm{ref}} \in [0,1]$, to be reported on $\mathfrak{P}$. Here $\|\cdot\|_{\mathcal{I}}$ is the norm specified by the realized weave configuration instrumentation $\mathcal{I}$ (Definition 10.1), and $\|\cdot\|_{\mathrm{ref}}$ is a fixed reference scale consistent with the acceptance pipeline (Section 7.3.9).

Definition 11.7 (TT purity and TT leak diagnostics)**.** Let $\mathfrak{O}$ denote any operator entering the TT readout (modes, propagators, vertices). With $\Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]} := \mathbf{1} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 10.3), the *TT–purity* residual is $\|\Pi_{\bar{\Sigma}}^{\perp[\mathrm{TT}]}\,\mathfrak{O}\|_{\mathcal{I}}$, and the *TT–leak* is a small positive number $\varepsilon_{\mathrm{TT}}$ that bounds any spurious inflow from non–TT channels. On a certified plateau these quantities are gauge–parameter independent (Nielsen–flat) by Corollary 11.5 together with the projector/realized weave configuration commutation properties in Proposition 10.9.

These constructions integrate the canonical TT algebra $\big($ETCR on the band, Proposition 11.4$\big)$ with the typed/triadic, BRST–healthy, plateau–stable framework of Chapters VII–XI (Definitions 10.1 and 10.2 and Propositions 7.3 and 10.9), ensuring that canonical statements descend consistently to the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ and admit Parasymmetric TLO diagnostics in the TT type (Definitions 8.4 to 8.6).

Equal-Time Commutation Relations (ETCR)

The essence of canonical quantization is that the field and its conjugate momentum no longer commute. We work on the chronogeometric background $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$ with Relational Levi–Civita connection $\bar{\nabla}$ (Definition 6.7), and we use the canonical momentum of the Gaiamiti field defined in Definition 11.2. Throughout, equal-time refers to the foliation determined by $\bar{\Sigma}$ (cf. Section 5.2.6).

Definition 11.8 (Equal-Time Commutation Relations for the Gaiamiti Field)**.** Let $x = (x^0, \vec{x})$ and $y = (y^0, \vec{y})$ be two points on a Cauchy hypersurface of constant emergent time $x^0 = y^0$. For

the components $\hat{\mathbf{\Phi}}^\lambda$ of the Gaiamiti field and their conjugate momenta $\hat{\mathbf{\Pi}}^\rho_\Phi$ (Definition 11.2), the *equal-time commutation relations* are

$$\boxed{\begin{aligned}\left[\hat{\mathbf{\Phi}}^\lambda(x^0,\vec{x}),\, \hat{\mathbf{\Pi}}^\rho_\Phi(x^0,\vec{y})\right] &= i\,\delta^\lambda{}_\rho\,\delta^{(d-1)}(\vec{x}-\vec{y})\,\mathbb{I}, &(11.16)\\ \left[\hat{\mathbf{\Phi}}^\lambda(x^0,\vec{x}),\, \hat{\mathbf{\Phi}}^\rho(x^0,\vec{y})\right] &= 0, &(11.17)\\ \left[\hat{\mathbf{\Pi}}^\lambda_\Phi(x^0,\vec{x}),\, \hat{\mathbf{\Pi}}^\rho_\Phi(x^0,\vec{y})\right] &= 0. &(11.18)\end{aligned}}$$

Meaning of the notation and of (11.16)–(11.18).

- $x=(x^0,\vec{x})$, $y=(y^0,\vec{y})$: spacetime points restricted to a common Cauchy hypersurface Σ_{x^0} of constant emergent time $x^0=y^0$, defined by the foliation induced by the chronogeometric background $\bar{\Sigma}_{\mu\nu}$; the compatible connection is the Relational Levi–Civita $\bar{\nabla}$ (see Definition 6.7).
- $\delta^{(d-1)}(\vec{x}-\vec{y})$: Dirac delta *on the slice* Σ_{x^0}, normalized so that $\int_{\Sigma_{x^0}} d^{d-1}\vec{y}\;\delta^{(d-1)}(\vec{x}-\vec{y})\,f(\vec{y})=f(\vec{x})$ for test fields f.
- $\hat{\mathbf{\Phi}}^\lambda$, $\hat{\mathbf{\Pi}}^\rho_\Phi$: the components (e.g. in the local/modal basis of Definitions 6.1 and 6.2) of the Gaiamiti field and its canonical momentum, with $\hat{\mathbf{\Pi}}_\Phi=\delta\mathcal{L}_\Phi/\delta(\nabla_0\hat{\mathbf{\Phi}})$ per Definition 11.2; here ∇_0 is the temporal part of the split connection $\nabla_\mu=\nabla^{(\mathrm{rel})}_\mu+D_\mu$ (eq. (6.314)).
- $\delta^\lambda{}_\rho$: the Kronecker symbol on the (field/modal) indices; $\mathbb{I}$ denotes the identity on the fiber $\mathrm{End}(\mathcal{H}_{\mathrm{em}})$.

Equation (11.16). This is the canonical equal–time bracket between the field and its conjugate momentum:

$$\left[\hat{\mathbf{\Phi}}^\lambda(x^0,\vec{x}),\, \hat{\mathbf{\Pi}}^\rho_\Phi(x^0,\vec{y})\right] = i\,\delta^\lambda{}_\rho\,\delta^{(d-1)}(\vec{x}-\vec{y})\,\mathbb{I}.$$

It expresses *locality* on the Cauchy slice through $\delta^{(d-1)}(\vec{x}-\vec{y})$ and *componentwise* pairing through $\delta^\lambda{}_\rho$. The normalization is consistent with $\hbar=1$. In band–regularized settings this bracket acquires the explicit UV projector $P_x(\lambda_{\mathrm{UV}})$ from the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (Definitions 6.280 and 9.10), analogously to the TT case in Proposition 11.4.

Equation (11.17).

$$\left[\hat{\mathbf{\Phi}}^\lambda(x^0,\vec{x}),\, \hat{\mathbf{\Phi}}^\rho(x^0,\vec{y})\right] = 0.$$

Equal–time field operators commute for the bosonic Gaiamiti sector; this encodes that no independent canonical pairing occurs among the field components themselves at equal time.

Equation (11.18).

$$\left[\hat{\mathbf{\Pi}}^\lambda_\Phi(x^0,\vec{x}),\, \hat{\mathbf{\Pi}}^\rho_\Phi(x^0,\vec{y})\right] = 0.$$

Equal–time conjugate momenta commute, reflecting that the only nontrivial canonical pairing is the field–momentum one in (11.16). For the quadratic Gaiamiti sector, the momentum reads $\hat{\mathbf{\Pi}}_\Phi = 2\,\bar{\Sigma}^{0\nu}(\nabla_\nu\hat{\mathbf{\Phi}})^\dagger$ up to conventions (Definition 11.2), where $\bar{\Sigma}^{0\nu}$ are components of the inverse chronogeometric tensor (Definition 6.24).

Remark 11.9 (Geometry and BRST projection)**.** All brackets are understood as operator–valued distributions on Σ_{x^0} determined by the foliation of $(\mathcal{X}_q, \bar{\Sigma})$ (cf. Section 5.2.6). On certified plateaux, BRST projection to the physical sector $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ preserves these equal–time relations and ensures gauge–parameter independence (Nielsen flatness) in the sense of Proposition 7.3.

Lemma 11.10 (TT-reduced ETCR and compatibility with typed variables)**.** *Let $\hat{h}_{\mu\nu}$ and $\hat{\Pi}^{\mu\nu}$ be the TT-typed canonical pair of Definition 11.3, obtained by projecting $\delta\hat{g}_{\mu\nu}$ and its momentum with the background–covariant projector $\Pi_{\bar{\Sigma}}^{[\rm TT]}$ (eq. (10.4) and Definition 10.3). On a certified plateau $\mathfrak{P}$ with BRST-closed band tags $\mathfrak{B}_{\lambda_{\rm UV},\ell} = (P_x(\lambda_{\rm UV}), K_{\rm IR}^{(\ell)})$ that commute with $\Pi_{\bar{\Sigma}}^{[\rm TT]}$ (Definitions 6.280 and 9.10, Lemma 9.11, and Proposition 10.9), restricting (11.16)–(11.18) to the TT sector yields exactly the typed equal-time algebra stated in Proposition 11.4.*

Proof. Step 1 (unprojected equal-time algebra). The canonical momentum for the metric fluctuation is defined covariantly by the same variational rule used for the Gaiamiti sector (cf. Definition 11.2), with ∇_0 the temporal component of the split connection $\nabla_\mu = \nabla_\mu^{(\rm rel)} + D_\mu$ (eq. (6.314) and Definition 6.7). Hence, the equal-time relations (11.16)–(11.18) apply componentwise to $(\delta\hat{g}_{\mu\nu}, \hat{\pi}^{\rho\sigma})$ on the Cauchy slice Σ_t, with the same Dirac delta $\delta^{(d-1)}(\vec{x} - \vec{y})$.

Step 2 (TT projection and commutation with the realized weave configuration). Define the typed variables as in Definition 11.3, $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\rm TT]}\,\delta\hat{g}_{\mu\nu}$ and $\hat{\Pi}^{\rho\sigma} := \Pi_{\bar{\Sigma}}^{[\rm TT]}\,\hat{\pi}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\rm TT]}$. Use that $\Pi_{\bar{\Sigma}}^{[\rm TT]}$ is idempotent and self-adjoint and annihilates trace/longitudinal parts (eq. (10.4) and Definition 10.3), and that it *commutes* with the band tags and the typed/triad projectors on $\mathfrak{P}$ (tag hygiene and weave commutations; Lemma 9.11 and Proposition 10.9). Then

$$\begin{aligned}
\Big[\hat{h}_{\mu\nu}(t,\mathbf{x}), \hat{\Pi}^{\rho\sigma}(t,\mathbf{y})\Big] &= \Big[\Pi_{\bar{\Sigma}}^{[\rm TT]}\delta\hat{g}_{\mu\nu},\ \Pi_{\bar{\Sigma}}^{[\rm TT]}\hat{\pi}^{\rho\sigma}\Pi_{\bar{\Sigma}}^{[\rm TT]}\Big] \\
&= \Pi_{\bar{\Sigma}}^{[\rm TT]}\Big[\delta\hat{g}_{\mu\nu}(t,\mathbf{x}), \hat{\pi}^{\rho\sigma}(t,\mathbf{y})\Big]\Pi_{\bar{\Sigma}}^{[\rm TT]} \\
&\quad \text{(via rigid commutations for TT component; Proposition 10.9)} \\
&= i\,\Pi_{\bar{\Sigma}}^{[\rm TT]}\,\delta_{\mu\nu}{}^{\rho\sigma}\,\Pi_{\bar{\Sigma}}^{[\rm TT]}\,P_x(\lambda_{\rm UV})\,\delta^{(d-1)}(\mathbf{x}-\mathbf{y}),
\end{aligned}$$

which is exactly the ETCR stated in Proposition 11.4. The vanishing brackets follow similarly:

$$\Big[\hat{h}, \hat{h}\Big] = \Pi_{\bar{\Sigma}}^{[\rm TT]}\Big[\delta\hat{g}, \delta\hat{g}\Big]\Pi_{\bar{\Sigma}}^{[\rm TT]} = 0, \qquad \Big[\hat{\Pi}, \hat{\Pi}\Big] = \Pi_{\bar{\Sigma}}^{[\rm TT]}\Big[\hat{\pi}, \hat{\pi}\Big]\Pi_{\bar{\Sigma}}^{[\rm TT]} = 0,$$

by (11.17)–(11.18).

Step 3 (BRST cleanliness and plateau stability). On $\mathfrak{P}$, the band tag $\mathfrak{B}_{\lambda_{\rm UV},\ell}$ is BRST-closed and the realized weave configuration operators (including $\Pi_{\bar{\Sigma}}^{[\rm TT]}$) commute with $\hat{Q}_{\rm BRST}$ (Lemma 9.11 and Proposition 10.9). Therefore the projected ETCR is a BRST cocycle and descends to $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ with gauge-parameter independence on the plateau (Proposition 7.3 and Corollary 11.5).

Combining Steps 1–3 proves that restricting (11.16)–(11.18) to the TT sector yields precisely the typed algebra of Proposition 11.4. □

Covariance and Interpretation

1. *Quantum uncertainty.* The non-vanishing commutator $\left[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Pi}}_{\Phi}\right] = i\,\mathbb{I}$ in (11.16) encodes the impossibility of simultaneously measuring the configuration and the conjugate rate of change of the geometric field with arbitrary precision, i.e. a geometric Heisenberg principle for the apeiron degrees of freedom.

2. *Locality and microcausality on a Cauchy slice.* The Dirac delta $\delta^{(d-1)}(\vec{x}-\vec{y})$ ensures that the field at $\vec{x}$ has non-trivial commutator only with its conjugate momentum at the *same* spatial point on the equal-time hypersurface; all other equal-time commutators vanish, cf. (11.17)–(11.18).

3. *Covariance via the Peierls bracket.* The notion of "equal time" is defined with respect to the $\bar{\Sigma}$-induced foliation (Section 5.2.6), so the ETCR formalism is not manifestly covariant. Covariance is restored by the *Peierls bracket* built from the TT-projected Lichnerowicz-type wave operator $K_{[\mathrm{TT}]}$ on $(\mathcal{X}_q, \bar{\Sigma})$ (cf. Chapter X and Definition 10.3). Define the advanced/retarded TT Green operators $G^{\mathrm{adv/ret}}_{[\mathrm{TT}]}$ and their causal difference $\Delta^{[\mathrm{TT}]} := G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]}$. For gauge-invariant functionals $F[h], G[h]$ supported on the certified plateau $\mathfrak{P}$,

$$\boxed{\begin{aligned} \{F,G\}_{\mathrm{P}} &= \left\langle \frac{\delta F}{\delta h_{\mu\nu}}, \Delta^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma} \left(\frac{\delta G}{\delta h_{\rho\sigma}} \right) \right\rangle, && (11.19)\\ \Delta^{[\mathrm{TT}]} &:= G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]}. && (11.20) \end{aligned}}$$

   Functional derivatives are taken at fixed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$ (Definitions 6.280 and 9.10); cone preservation of $K^{(\ell)}_{\mathrm{IR}}$ ensures well-defined causal support (Remark 9.83). The equal-time limit of (11.25) reproduces the typed ETCR of Proposition 11.4; thus the canonical ETCRs are the Cauchy-slice restriction of the Peierls construction (Proposition 11.11) [82, 155].

Meaning of F and G in the Peierls bracket. In Proposition 11.4 and the Peierls construction, F and G denote (gauge/BRST-invariant) *observables*, i.e. sufficiently regular functionals of the *TT carrier* $h_{\mu\nu}$. Concretely, they are maps

$$F, G : \ \mathcal{E}_{\mathrm{TT}} \longrightarrow \mathbb{C}, \qquad \mathcal{E}_{\mathrm{TT}} := \{\text{admissible TT configurations on } (\mathcal{X}_q, \bar{\Sigma})\},$$

that are (Gâteaux/Fréchet) differentiable so that their functional derivatives $\delta F/\delta h_{\mu\nu}$ and $\delta G/\delta h_{\rho\sigma}$ exist as tensor-valued (distributional) test objects with the band/realized weave configuration properties of $\mathcal{I}^{[\mathcal{J}]}$ (Definition 10.1). The Peierls bracket

$$\{F,G\}_{\mathrm{P}} = \left\langle \frac{\delta F}{\delta h_{\mu\nu}}, \Delta^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma} \left(\frac{\delta G}{\delta h_{\rho\sigma}} \right) \right\rangle, \qquad \Delta^{[\mathrm{TT}]} := G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]},$$

is then defined by pairing these derivatives with the TT Pauli–Jordan bi-solution ($\bar{\Sigma}$-microcausal support; Proposition 11.14). In spacetime form,

$$\left\langle \frac{\delta F}{\delta h_{\mu\nu}}, \Delta^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma} \left(\frac{\delta G}{\delta h_{\rho\sigma}} \right) \right\rangle = \int d\mu_{\bar{\Sigma}}(x) \int d\mu_{\bar{\Sigma}}(y)\, \frac{\delta F}{\delta h_{\mu\nu}(x)}\, \Delta^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma}(x,y)\, \frac{\delta G}{\delta h_{\rho\sigma}(y)}.$$

Regularity/typing requirements. To ensure the pairing is well-defined, F and G are taken to be *TT-typed, band-limited, microcausal* functionals on the realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$: their derivatives commute with the weave projectors, have support/wavefront compatible with $G^{\mathrm{ret/adv}}_{[\mathrm{TT}]}$, and are BRST-clean so that the bracket descends to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Propositions 7.3 and 10.9).

Typical examples. (i) *Smeared linear observable:* $F(h) = \int d\mu_{\bar{\Sigma}}\, f^{\mu\nu} h_{\mu\nu}$ with TT test tensor $f^{\mu\nu}$ (compact support on the band); then $\delta F/\delta h_{\mu\nu} = f^{\mu\nu}$. (ii) *Local polynomial:* $G(h) = \int d\mu_{\bar{\Sigma}}\, \frac{1}{2}\, h_{\mu\nu} Q^{\mu\nu\rho\sigma} h_{\rho\sigma}$, with Q a fixed TT-preserving kernel (e.g. a differential operator built from $\bar{\Sigma}$). (iii) *Curvature-linear observable:* $F(h) = \int d\mu_{\bar{\Sigma}}\, \alpha^{\mu\nu\rho\sigma}\, \delta R_{\mu\nu\rho\sigma}[h]$, with TT-compatible smearing α. All such choices satisfy the typed/triad commutation and band conditions used in the chapter.

Proposition 11.11 (Typed microcausality and cone support)**.** *Let $J^{\pm}_{\bar{\Sigma}}(x)$ be the causal future/-past with respect to the $\bar{\Sigma}$-cone. The TT causal kernel has support* $\operatorname{supp}\Delta^{[\mathrm{TT}]} \subset \{(x,y) \mid y \in J^{+}_{\bar{\Sigma}}(x) \cup J^{-}_{\bar{\Sigma}}(x)\}$. *Moreover, the IR window $K^{(\ell)}_{\mathrm{IR}}$ does not enlarge causal cones (cf. Definition 6.280); hence $\{F,G\}_{\mathrm{P}} = 0$ whenever the supports of F and G are $\bar{\Sigma}$-spacelike separated.*

Proof of Proposition 11.11. Work on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$ that commute with the realized weave configuration operators (Definitions 6.280 and 9.10, Lemma 9.11, and Proposition 10.9). Let $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ be the background–covariant York–Lichnerowicz projector (eq. (10.4) and Definition 10.3), and denote by $K^{[\mathrm{TT}]}$ the TT kinetic operator obtained by projecting the linearized chronogeometric Einstein operator about the background $\bar{\Sigma}$ (Definition 11.106) onto the TT type (cf. Definition 11.3).

Step 1 (Hyperbolicity and cone support). By the hyperbolicity condition of the band–limited equations of motion ($\sigma_{\mathrm{pr}}(\bar{\Sigma}^{\mu\nu}\nabla_\mu\nabla_\nu)(k) = \bar{\Sigma}^{\mu\nu}k_\mu k_\nu > 0$ on timelike covectors; see eq. (7.15)), the retarded/advanced fundamental solutions $G_{R/A}$ of the untyped linearized operator have support contained in the $\bar{\Sigma}$–cones (future/past) ($\operatorname{supp} G_{R/A} \subset \{(x,y) \,|\, y \in J^{\pm}_{\bar{\Sigma}}(x)\}$). Because $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ is a local, $\bar{\Sigma}$–covariant projector that commutes with the realized weave configuration (Proposition 10.9), the TT Green operators $G^{[\mathrm{TT}]}_{R/A} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, G_{R/A}\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ inherit the same support:

$$\operatorname{supp} G^{[\mathrm{TT}]}_{R/A} \;\subset\; \{(x,y) \mid y \in J^{\pm}_{\bar{\Sigma}}(x)\}.$$

Hence the TT Pauli–Jordan bi–solution $\Delta^{[\mathrm{TT}]} := G^{[\mathrm{TT}]}_R - G^{[\mathrm{TT}]}_A$ satisfies $\operatorname{supp}\Delta^{[\mathrm{TT}]} \subset \{(x,y) \mid y \in J^{+}_{\bar{\Sigma}}(x) \cup J^{-}_{\bar{\Sigma}}(x)\}$.

Step 2 (IR window and equal–time Peierls bracket). By construction of the IR window $K^{(\ell)}_{\mathrm{IR}}$ (Definition 6.280) and the cone–preservation statement for $\bar{\Sigma}$–covariant windowing (Remark 9.83), the band limitation does *not* enlarge the $\bar{\Sigma}$–cones. Therefore the (typed) Peierls bracket $\{F,G\}_{\mathrm{P}} = \langle \delta F/\delta\hat{h},\, \Delta^{[\mathrm{TT}]}\, \delta G/\delta\hat{h}\rangle$ (band version; cf. the inversion/propagator construction in eq. (7.10) and Proposition 7.16) vanishes whenever $\operatorname{supp} F$ and $\operatorname{supp} G$ are $\bar{\Sigma}$–spacelike separated, because $\Delta^{[\mathrm{TT}]}$ has no support across spacelike separations. This proves both the cone–support inclusion and the microcausality statement. □

Corollary 11.12 (TLO hook via Peierls)**.** *Let $S^{[\mathrm{TT}]}$ denote the TT-projected quadratic action on $\mathfrak{P}$. The TT law residual of Definition 11.6 can be written as a Peierls commutator with the action, $\mathbf{R}^{[\mathrm{TT}]} \sim \{\,\cdot\,, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$, and vanishes identically when the TT Ward identity holds on $\mathfrak{P}$.*

Proof of Corollary 11.12 (with a meter functional). Let $S^{[\mathrm{TT}]}$ be the TT–projected quadratic action on $\mathfrak{P}$ (typed by $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ and band–limited; cf. Definition 11.3 and Proposition 10.9). Denote the TT Euler–Lagrange operator by $E^{[\mathrm{TT}]} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta S/\delta\hat{h}$ (typed/cohomological EL equations on the band; see Proposition 7.3 and eq. (7.10)). For linearized chronogeometric gravity,

$$E^{[\mathrm{TT}]}[\hat{h}] = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\left[\delta\bar{G}_{\mu\nu}[\hat{h}] + \Lambda\hat{h}_{\mu\nu} - \kappa\,\delta\bar{T}^{\mathrm{total}}_{\mu\nu}\right],$$

hence the TT law residual of Definition 11.6 is $\mathbf{R}^{[\mathrm{TT}]} = E^{[\mathrm{TT}]}[\hat{h}]$.

On a certified plateau, the Peierls bracket is generated by the TT Pauli–Jordan bi–solution $\Delta^{[\mathrm{TT}]}$ (Propositions 7.16 and 11.11). For quadratic actions the Peierls identity yields, for any functional $\mathcal{F}[\hat{h}]$,

$$\{\mathcal{F}, S^{[\mathrm{TT}]}\}_{\mathrm{P}} = \left\langle \frac{\delta\mathcal{F}}{\delta\hat{h}},\, \Delta^{[\mathrm{TT}]}\, E^{[\mathrm{TT}]} \right\rangle.$$

Choose the *meter functional* $\mathcal{M}^{[\mathrm{TT}]}$ by $\delta\mathcal{M}^{[\mathrm{TT}]}/\delta\hat{h} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (a calibrated meter in the realized weave configuration sense; Definition 10.1 and Proposition 10.9). Then

$$\{\mathcal{M}^{[\mathrm{TT}]}, S^{[\mathrm{TT}]}\}_{\mathrm{P}} = \left\langle \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]},\, \Delta^{[\mathrm{TT}]}\, E^{[\mathrm{TT}]} \right\rangle \;\sim\; E^{[\mathrm{TT}]},$$

up to the fixed Green action, so $\mathbf{R}^{[\mathrm{TT}]} = E^{[\mathrm{TT}]} \sim \{\cdot, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$, which proves the Peierls "hook".

If the TT Ward identity holds on $\mathfrak{P}$ (law satisfied at the typed level; cf. the law witness framework in Definitions 8.4 and 8.5 and its TT specialization Definition 11.6), then $E^{[\mathrm{TT}]} = 0$ and hence $\mathbf{R}^{[\mathrm{TT}]} = 0$. Gauge–parameter independence (Nielsen flatness) follows from the plateau BRST/Nielsen framework (Proposition 7.3 and Corollary 11.5). □

11.1.2 Covariant Quantization via the Peierls Bracket

To restore manifest covariance beyond the equal-time formalism of Section 11.1.1, we define the quantum algebra from the causal structure of the linearized equations, encoded in Green operators for the fluctuation dynamics (Definition 9.268 and Section 6.5). All constructions below are performed on a certified plateau $\mathfrak{P}$ (Chapter 8) with BRST-closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = \left(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}\right)$ commuting with the typed projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definitions 6.280 and 9.10; typed projector from Chapter 11).

The Gaiamiti Green's Function and Causal Structure

Definition 11.13 (Gaiamiti Green's Function)**.** Let $\hat{\mathcal{D}}_\Phi$ denote the linearized fluctuation operator of the Gaiamiti sector derived from the second variation of S_Φ (Section 6.5). The (operator-valued) Green kernel $\hat{G}_{\Phi\Phi}(x,x')$ solves

$$\hat{\mathcal{D}}_\Phi(x)\,\hat{G}_{\Phi\Phi}(x,x') = \delta^{(d)}(x-x')\,\mathbb{I}\,. \tag{11.21}$$

For the spin–2 geometric carrier, we further define the *typed* Lichnerowicz-type wave operator

$$K_{[\mathrm{TT}]} \;:=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{\mathcal{D}}_{\Phi}\,\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,, \tag{11.22}$$

and its *TT-projected* advanced/retarded inverses $G_{[\mathrm{TT}]}^{\mathrm{adv/ret}}$ by

$$\boxed{K_{[\mathrm{TT}]}(x)\,G_{[\mathrm{TT}]}^{\mathrm{adv/ret}}(x,x') \;=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,P_x(\lambda_{\mathrm{UV}})\,\delta^{(d)}(x-x')\,,} \tag{11.23}$$

with support conditions $G_{[\mathrm{TT}]}^{\mathrm{ret}}(x,x') = 0$ unless $x \in J_{\bar{\Sigma}}^{+}(x')$ and $G_{[\mathrm{TT}]}^{\mathrm{adv}}(x,x') = 0$ unless $x \in J_{\bar{\Sigma}}^{-}(x')$. The *TT causal kernel* (Pauli–Jordan function) is

$$\Delta^{[\mathrm{TT}]}(x,x') \;:=\; G_{[\mathrm{TT}]}^{\mathrm{ret}}(x,x') - G_{[\mathrm{TT}]}^{\mathrm{adv}}(x,x')\,. \tag{11.24}$$

The Covariant Commutator and the Peierls Bracket

For gauge-invariant functionals $F[h]$ and $G[h]$ of the typed graviton $h_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$ (Definition 11.3), the *typed Peierls bracket* is defined by the TT causal kernel:

$$\boxed{\begin{aligned}\{F,G\}_{\mathrm{P}} &= \Big\langle \frac{\delta F}{\delta h_{\mu\nu}},\; \Delta^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma}\left(\frac{\delta G}{\delta h_{\rho\sigma}}\right)\Big\rangle,\\ \Delta^{[\mathrm{TT}]} &:= G_{[\mathrm{TT}]}^{\mathrm{ret}} - G_{[\mathrm{TT}]}^{\mathrm{adv}}.\end{aligned}} \tag{11.25}$$

where functional derivatives are taken at fixed band tags (Definitions 6.280 and 9.10) on $\mathfrak{P}$. In particular, the *covariant commutator* of the typed field is

$$\boxed{\big[\,\hat{h}_{\mu\nu}(x),\;\hat{h}_{\rho\sigma}(x')\,\big] \;=\; i\;\Delta_{\mu\nu\,\rho\sigma}^{[\mathrm{TT}]}(x,x')\,.} \tag{11.26}$$

The equal-time limit of (11.25) on a Cauchy slice recovers the typed ETCR of Proposition 11.4; thus the canonical ETCRs appear as a restriction of the Peierls construction [82, 155].

Proposition 11.14 (Typed microcausality and cone support)**.** *With respect to the $\bar{\Sigma}$-cone, the support of the TT causal kernel is*

$$\operatorname{supp}\Delta^{[\mathrm{TT}]} \;\subset\; \{(x,x') \mid x' \in J_{\bar{\Sigma}}^{+}(x) \;\text{or}\; x' \in J_{\bar{\Sigma}}^{-}(x)\}.$$

Consequently, if the supports of F and G are $\bar{\Sigma}$-spacelike separated then $\{F,G\}_{\mathrm{P}} = 0$. Moreover, the IR window $K_{\mathrm{IR}}^{(\ell)}$ does not enlarge causal cones (Definition 6.280), so microcausality is preserved under the band-limit on $\mathfrak{P}$.

Proof. Work on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ that commute with the realized weave configuration operators (Definitions 6.280 and 9.10, Lemma 9.11, and Proposition 10.9). Let $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ denote the background–covariant York–Lichnerowicz projector (eq. (10.4) and Definition 10.3). Denote by $K_{[\mathrm{TT}]}$ the TT–projected linearized chronogeometric Einstein operator about $\bar{\Sigma}$ (Definition 11.106).

Step 1: Cone support of retarded/advanced Green operators. The untyped linearized equations are (normally) hyperbolic with respect to the $\bar{\Sigma}$–cone, so their retarded and advanced Green operators $G_{R/A}$ obey $\operatorname{supp} G_{R/A} \subset \{(x,x') \,|\, x' \in J^{\pm}_{\bar{\Sigma}}(x)\}$ (standard hyperbolic support property; see the causal–response statement in Remark 9.83). Because $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ is a $\bar{\Sigma}$–covariant *local* projector that commutes with the realized weave configuration (Proposition 10.9), the TT Green operators

$$G^{[\mathrm{TT}]}_{R/A} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, G_{R/A}\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$$

inherit the same support: $\operatorname{supp} G^{[\mathrm{TT}]}_{R/A} \subset \{(x,x') \,|\, x' \in J^{\pm}_{\bar{\Sigma}}(x)\}$. Hence the TT Pauli–Jordan bi–solution $\Delta^{[\mathrm{TT}]} := G^{[\mathrm{TT}]}_R - G^{[\mathrm{TT}]}_A$ satisfies

$$\operatorname{supp} \Delta^{[\mathrm{TT}]} \subset \{(x,x') \mid x' \in J^{+}_{\bar{\Sigma}}(x) \text{ or } x' \in J^{-}_{\bar{\Sigma}}(x)\}.$$

Step 2: Peierls bracket and microcausality. By definition (eq. (11.25)), the typed Peierls bracket of gauge–invariant functionals $F[h]$, $G[h]$ supported on $\mathfrak{P}$ is

$$\{F,G\}_{\mathrm{P}} = \Big\langle \frac{\delta F}{\delta h_{\mu\nu}},\ \Delta^{[\mathrm{TT}]\,\mu\nu}{}_{\rho\sigma}\ \frac{\delta G}{\delta h_{\rho\sigma}} \Big\rangle.$$

If $\operatorname{supp} F$ and $\operatorname{supp} G$ are $\bar{\Sigma}$–spacelike separated, the distribution $\Delta^{[\mathrm{TT}]}$ has no support connecting the two regions (by Step 1), hence the pairing vanishes and $\{F,G\}_{\mathrm{P}} = 0$. This is typed microcausality.

Step 3: Stability under the band IR window. The IR window $K^{(\ell)}_{\mathrm{IR}}$ is chosen $\bar{\Sigma}$–covariantly so as *not* to enlarge causal cones (Definition 6.280); the cone–preservation statement in Remark 9.83 ensures that inserting $K^{(\ell)}_{\mathrm{IR}}$ (and the commuting UV projector $P_x(\lambda_{\mathrm{UV}})$) into the realized weave configuration leaves the retarded/advanced support properties unchanged. Therefore the support inclusion for $\Delta^{[\mathrm{TT}]}$ and the vanishing of $\{F,G\}_{\mathrm{P}}$ at $\bar{\Sigma}$–spacelike separation persist under the band–limit on $\mathfrak{P}$.

The stated support inclusion and microcausality properties follow. □

Remark 11.15 (TLO hook for the TT law residual)**.** The TT *law residual* of Definition 11.6 can be written as a Peierls commutator with the TT action $S^{[\mathrm{TT}]}$ on $\mathfrak{P}$, schematically $\mathbf{R}^{[\mathrm{TT}]} \sim \{\cdot, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$. It vanishes when the TT Ward identity holds, providing a covariant route to $\Lambda^{[\mathrm{TT}]}_{\mathrm{law}} \to 1$ in the exact law limit (Chapters 8–11).

Pauli–Jordan bi–solution (what it is and why it is vital).

Definition 11.16 (Typed Pauli–Jordan bi–solution)**.** Let $K_{[\mathrm{TT}]}$ be the TT–projected Lichnerowicz–type wave operator on $(\mathcal{X}_q, \bar{\Sigma})$ (cf. Definition 10.3 and eq. (10.4) and the linearized chronogeometric equations in Definition 11.106). Denote by $G^{\mathrm{ret/adv}}_{[\mathrm{TT}]}$ the retarded/advanced Green operators of $K_{[\mathrm{TT}]}$. The *typed Pauli–Jordan bi–solution* is the bi–distribution

$$\Delta^{[\mathrm{TT}]} \ := \ G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]}, \tag{11.27}$$

characterized by the homogeneous equations $K^{(x)}_{[\mathrm{TT}]}\,\Delta^{[\mathrm{TT}]}(x,x') = 0 = K^{(x')}_{[\mathrm{TT}]}\,\Delta^{[\mathrm{TT}]}(x,x')$, antisymmetry $\Delta^{[\mathrm{TT}]}(x,x') = -\Delta^{[\mathrm{TT}]}(x',x)$, and causal support $\operatorname{supp}\Delta^{[\mathrm{TT}]} \subset \{(x,x') \mid x' \in J^{+}_{\bar{\Sigma}}(x) \text{ or } x' \in J^{-}_{\bar{\Sigma}}(x)\}$ (Propositions 11.11 and 11.14).

Why it is vital.

- *Covariant Poisson structure.* The Peierls bracket for gauge–invariant functionals is mediated by $\Delta^{[\mathrm{TT}]}$:
$$\{F, G\}_{\mathrm{P}} = \Big\langle \frac{\delta F}{\delta h_{\mu\nu}},\ \Delta^{[\mathrm{TT}]\,\mu\nu}{}_{\rho\sigma}\ \frac{\delta G}{\delta h_{\rho\sigma}} \Big\rangle,$$
giving a manifestly covariant replacement of equal–time brackets (eq. (11.25)). Its causal support guarantees $\{F, G\}_{\mathrm{P}} = 0$ for $\bar{\Sigma}$–spacelike separated supports (typed microcausality; Proposition 11.14).

- *Bridge to canonical ETCR.* On a Cauchy slice the Peierls bracket induced by $\Delta^{[\mathrm{TT}]}$ reproduces the typed equal–time commutator of the TT canonical variables (Proposition 11.4), so $\Delta^{[\mathrm{TT}]}$ is the covariant kernel that encodes the canonical algebra and its TT restriction ("project, then quantize"; Definition 11.3).

- *Causality and regulator stability.* Because $\Delta^{[\mathrm{TT}]}$ is the difference of retarded/advanced Green operators, its support is confined to $\bar{\Sigma}$–causal pairs (Proposition 11.14). The IR window $K_{\mathrm{IR}}^{(\ell)}$ does not enlarge cones (Definition 6.280 and Remark 9.83), so typed microcausality persists under band–limiting on the plateau $\mathfrak{P}$.

- *Law diagnostics (TLO hook).* The TT law residual is a Peierls commutator with the typed action, $\mathbf{R}^{[\mathrm{TT}]} \sim \{\cdot, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$ (Corollary 11.12); thus $\Delta^{[\mathrm{TT}]}$ furnishes the kernel that links the linearized law (Ward identity) to observable diagnostics (Definition 11.6).

Interpretation and significance.

- *Manifest covariance (typed).* The covariant commutator in eq. (11.26) is expressed entirely through the TT causal kernel $\Delta^{[\mathrm{TT}]}$ built from the background geometry $\bar{\Sigma}_{\mu\nu}$ and its Relational Levi–Civita structure (Definition 6.7). It makes no reference to a preferred foliation beyond the $\bar{\Sigma}$-induced causal cone, and—by Proposition 11.14—vanishes for $\bar{\Sigma}$-spacelike separations, thereby enforcing microcausality. On a certified plateau with BRST-closed band tags (Definitions 6.280 and 9.10) the construction is Nielsen-flat and the IR window does not enlarge causal cones.

- *Relation to canonical quantization.* The typed Peierls bracket $\{\,\cdot\,,\,\cdot\,\}_{\mathrm{P}}$ in eq. (11.25) is the fundamental, covariant object. The equal-time canonical algebra for the typed variables is recovered by restricting eq. (11.25) to a Cauchy hypersurface and taking the equal-time limit, yielding the ETCR of Proposition 11.4; thus the ETCR formalism is a non-covariant specialization of the Peierls framework [82, 155].

- *Self-consistency within the IQR weave.* The same emergent chronogeometric structure $\bar{\Sigma}$ that governs causal propagation for the typed wave operator $K_{[\mathrm{TT}]}$ also determines the quantum algebra via $\Delta^{[\mathrm{TT}]}$. In particular, the TT law residual $\mathbf{R}^{[\mathrm{TT}]}$ of Definition 11.6 is evaluated against this causal structure and can be expressed through the Peierls construction; when the TT Ward identity holds on the plateau, the residual vanishes and the law visibility saturates. In this sense, the typed quantum algebra, causal propagation, and law diagnostics are mutually compatible and realized on the same certified plateau.

11.1.3 Graviton Mode Decomposition from Gaiamiti Fluctuations

We now isolate the physically propagating spin–2 degrees of freedom contained in the Gaiamiti fluctuation operator $\delta\hat{\mathbf{\Phi}}(x)$ [438, 502, 403, 114, 517]. In the IQR framework geometry is emergent rather than presupposed; hence the graviton is not a ripple *on* spacetime but a quantum excitation *of* the field whose expectation realizes the chronogeometric background $\bar{\Sigma}_{\mu\nu}$ (Chapter 5 and Section 5.2; see also [518, 425, 40, 1, 519]). Throughout this section we work on a certified plateau $\mathfrak{P}$ (Chapter 8) and use the typed (TT) projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ of Chapter 11 to define the graviton carrier $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$ (Definition 11.3); the temporal/coherence fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ is TT-null and does not contribute to $\hat{h}_{\mu\nu}$ (Chapter 11).

Background and Motivation

In classical GR, radiative gravitational degrees of freedom are massless, symmetric, transverse and traceless (TT) perturbations of the metric [7, 264, 502]. Our goal is to identify the *quantum* counterpart inside the Gaiamiti fluctuations on $(\mathcal{X}_q, \bar{\Sigma})$, respecting the typed/BRST structure (Chapters 8–11). This will yield a mode expansion for $\hat{h}_{\mu\nu}$ and the associated creation/annihilation operators, organized in a triad-resolved fashion $(\mathrm{corr}, \mathrm{vac}, \mathrm{spec})$, consistent with the sector projectors $\{\Pi^{(a)}\}$ commuting with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definitions 6.280 and 9.10).

Definition 11.17 (Gaiamiti fluctuation)**.** The dynamical Gaiamiti field (cf. Definition 6.2) splits as

$$\boxed{\hat{\mathbf{\Phi}}(x) = \bar{\Phi}(x)\,\mathbb{I}_x + \delta\hat{\mathbf{\Phi}}(x),} \tag{11.28}$$

with $\bar{\Phi}(x) := \langle\hat{\mathbf{\Phi}}(x)\rangle$ and $\langle 0|\delta\hat{\mathbf{\Phi}}(x)|0\rangle = 0$ (see eq. (10.87)). The quanta of $\delta\hat{\mathbf{\Phi}}$ are the *apeirons* (cf. Definition 9.246).

Spin–2 Polarization Basis (typed, background-covariant)

Definition 11.18 (Typed spin–2 (TT) polarization basis)**.** Fix the background $(\mathcal{X}_q, \bar{\Sigma})$ with $\bar{\Sigma}$-compatible Levi–Civita connection and TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (York–Lichnerowicz form; see Definitions 6.7 and 10.3 and eq. (10.4)). For each triad sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Definition 10.2) and each $(k; x)$, a *typed, background–covariant spin–2 polarization basis* is a set $\{e_{\mu\nu}^{(a,\lambda)}(k;x)\}_{\lambda=1}^{d_g} \subset \mathrm{Im}\left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{(a)}\right)$ satisfying:

$$e_{\mu\nu}^{(a,\lambda)}(k;x) = e_{\nu\mu}^{(a,\lambda)}(k;x) \qquad \text{(symmetry)}, \tag{11.29}$$

$$\bar{g}^{\mu\nu}(x)\, e_{\mu\nu}^{(a,\lambda)}(k;x) = 0 \qquad \text{(tracelessness)}, \tag{11.30}$$

$$k^{\mu} e_{\mu\nu}^{(a,\lambda)}(k;x) = 0 \qquad \text{(transversality)}, \tag{11.31}$$

$$\left\langle e^{(a,\lambda)}(k;x), e^{(a,\lambda')}(k;x)\right\rangle_{\bar{\Sigma}} = \delta_{\lambda\lambda'} \qquad \text{(orthonormality)}, \tag{11.32}$$

where indices are raised with $\bar{\Sigma}^{\mu\nu}$ (Definition 6.24) and $\langle A, B\rangle_{\bar{\Sigma}} := A_{\mu\nu}\, B^{\mu\nu}$ is the $\bar{\Sigma}$-induced inner product on symmetric, traceless rank–2 tensors at x (TT calculus; Definition 10.3). The polarization count is $d_g = \frac{d(d-3)}{2}$ (thus $d_g = 2$ for $d = 4$).

Completeness (typed TT subspace). The basis resolves the typed TT projector kernel:

$$\sum_{\lambda=1}^{d_g} e_{\mu\nu}^{(a,\lambda)}(k;x)\, e^{(a,\lambda)\,\rho\sigma}(k;x) = \left(\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\Pi^{(a)}\right)_{\mu\nu}{}^{\rho\sigma}, \tag{11.33}$$

with $\Pi^{(a)}$ the triad projectors and $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Pi^{(a)} = \Pi^{(a)}\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ (Definition 10.2 and Proposition 10.9). In geometric–optics regimes the label k is taken tangent to the $\bar\Sigma$-null cone and the resulting $(+,\times)$ content matches the E(2) template discussion (Remark 11.151).

Definition 11.19 (Triad-resolved TT mode expansion)**.** Decompose the typed graviton into sector components $\hat h_{\mu\nu}^{(a)} := \Pi^{(a)}\hat h_{\mu\nu}$ (with $[\Pi^{(a)}, \Pi_{\bar\Sigma}^{[\mathrm{TT}]}] = 0$) and expand each sector in TT modes:

$$\boxed{\hat h_{\mu\nu}(x) = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \sum_{\lambda=1}^{d_g} \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}} \left[e_{\mu\nu}^{(a,\lambda)}(k;x)\; \hat a_{a,\lambda}(\mathbf{k})\, e^{-ik\cdot x} + e_{\mu\nu}^{(a,\lambda)}(k;x)^*\; \hat a_{a,\lambda}^\dagger(\mathbf{k})\, e^{+ik\cdot x}\right]}, \tag{11.34}$$

where $k^0 = \omega_a(\mathbf{k})$ solves the on-shell condition of the typed wave operator $K_{[\mathrm{TT}]}$ (Chapter 10) and the normalization of the measure follows the $\bar\Sigma$-compatible relativistic convention.

Explanation of Definition 11.19.

- *Triad resolution and TT typing.* The graviton operator $\hat h_{\mu\nu}$ is first typed by the background–covariant TT projector $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ (York–Lichnerowicz form; eq. (10.4) and Definition 10.3), then decomposed by the triad projectors $\{\Pi^{(a)}\}_{a\in\{\mathrm{corr,vac,spec}\}}$ (Definition 10.2). The commutation $\Pi^{(a)}\Pi_{\bar\Sigma}^{[\mathrm{TT}]} = \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Pi^{(a)}$ is ensured by the realized weave configuration commutations on certified plateaux (Proposition 10.9), so $\hat h_{\mu\nu}^{(a)} := \Pi^{(a)}\hat h_{\mu\nu} \in \mathrm{Im}(\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Pi^{(a)})$.
- *Typed polarization basis.* For each triad sector a and pair $(k;x)$ there exists a complete $\bar\Sigma$–orthonormal TT basis $\{e_{\mu\nu}^{(a,\lambda)}(k;x)\}_{\lambda=1}^{d_g}$ obeying symmetry, tracelessness, transversality and orthonormality (Definition 11.18); completeness reads $\sum_\lambda e_{\mu\nu}^{(a,\lambda)} e^{(a,\lambda)\,\rho\sigma} = (\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\Pi^{(a)})_{\mu\nu}{}^{\rho\sigma}$ (eq. (11.33)).
- *On–shell condition and phase.* The typed wave operator $K_{[\mathrm{TT}]}$ (TT–projected Lichnerowicz type; cf. Chapter X and Definition 10.3) determines the dispersion relation in each sector: $k^0 = \omega_a(\mathbf{k})$ solves the on–shell equation of $K_{[\mathrm{TT}]}$. The phase is $k\cdot x := k_\mu x^\mu$, with indices moved by $\bar\Sigma$ ($k_\mu = \bar\Sigma_{\mu\nu}k^\nu$; Definition 6.24).
- *Measure and normalization.* The integration measure $\int d^{d-1}\mathbf{k}/(2\pi)^{d-1}$ is the $\bar\Sigma$–compatible relativistic convention on the Cauchy slice induced by the foliation of $(\mathcal{X}_q, \bar\Sigma)$ (cf. Definition 6.7).

- *Creation/annihilation algebra (typed ETCR).* The operators $\hat{a}_{a,\lambda}(\mathbf{k})$, $\hat{a}^\dagger_{a,\lambda}(\mathbf{k})$ are defined so that eq. (11.34) reproduces the typed equal–time commutation relations of the TT canonical pair (Proposition 11.4). This fixes

$$\left[\hat{a}_{a,\lambda}(\mathbf{k}), \hat{a}^\dagger_{b,\lambda'}(\mathbf{k}')\right] = (2\omega_a(\mathbf{k}))\,(2\pi)^{d-1}\,\delta_{ab}\,\delta_{\lambda\lambda'}\,\delta^{(d-1)}(\mathbf{k}-\mathbf{k}')\,, \tag{11.35}$$

$$\left[\hat{a}_{a,\lambda}(\mathbf{k}), \hat{a}_{b,\lambda'}(\mathbf{k}')\right] = \left[\hat{a}^\dagger_{a,\lambda}(\mathbf{k}), \hat{a}^\dagger_{b,\lambda'}(\mathbf{k}')\right] = 0\,, \tag{11.36}$$

  with all $\bar{\Sigma}$–indices contracted using the polarization orthonormality (eq. (11.32)) and completeness (eq. (11.33)). The consistency with the Peierls bracket (eq. (11.25)) follows from the identification of the covariant Pauli–Jordan kernel $\Delta^{[\mathrm{TT}]}$ and its cone support (Proposition 11.14).

- *Causality, band stability, and gauge independence.* Microcausality is guaranteed by the cone support of $\Delta^{[\mathrm{TT}]}$ (Proposition 11.14) and is preserved under the band IR window $K^{(\ell)}_{\mathrm{IR}}$ (Definition 6.280 and Remark 9.83). On a certified plateau $\mathfrak{P}$, the realized weave configuration operators commute with the BRST charge, so gauge–parameter variations are Nielsen–flat (Proposition 7.3 and Corollary 11.5); thus the mode expansion and the algebra (11.35) are physical (cohomological) statements.

Proposition 11.20 (Orthogonality of sectors and Fock factorization)**.** *With creation/annihilation operators labeled by the triad and polarization, the only non-vanishing commutators are*

$$\boxed{\left[\hat{a}_{a,\lambda}(\mathbf{k}),\, \hat{a}^\dagger_{b,\lambda'}(\mathbf{k}')\right] = \delta_{ab}\,\delta_{\lambda\lambda'}\,(2\pi)^{d-1}\,2\omega_a(\mathbf{k})\,\delta^{(d-1)}(\mathbf{k}-\mathbf{k}')\,,} \tag{11.37}$$

with all others vanishing. Consequently the graviton Fock space factorizes across triads:

$$\mathscr{F}_\Phi \simeq \mathscr{F}_\Phi^{(\mathrm{corr})} \,\hat{\otimes}\, \mathscr{F}_\Phi^{(\mathrm{vac})} \,\hat{\otimes}\, \mathscr{F}_\Phi^{(\mathrm{spec})},$$

and the typed physical sector is obtained by the BRST cohomology $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ *(Chapter 8).*

Proof. Step 1 (projected mode extraction of the CCR). Use the typed TT mode expansion (11.34) with the typed polarization basis of Definition 11.18 (orthonormality (11.32), completeness (11.33)) and the typed ETCR on the band $\left[\hat{h}_{\mu\nu}(t,\mathbf{x}), \hat{\Pi}^{\rho\sigma}(t,\mathbf{y})\right]$ from Proposition 11.4. Project the ETCR onto a pair of modes by contracting with $e^{(a,\lambda)\,\mu\nu}(k;x)\,e^{-ik\cdot x}$ and $e^{(b,\lambda')}_{\rho\sigma}(k';y)^*\,e^{+ik'\cdot y}$ and integrating over the Cauchy slice. Using (11.32)–(11.33) and the $\bar{\Sigma}$-compatible measure (foliation fixed by Definition 6.7), the only nonzero contribution picks out equal triad labels and equal polarizations. Matching to the right-hand side of Proposition 11.4 (with the standard relativistic normalization of the measure) yields

$$\left[\hat{a}_{a,\lambda}(\mathbf{k}),\, \hat{a}^\dagger_{b,\lambda'}(\mathbf{k}')\right] = \delta_{ab}\,\delta_{\lambda\lambda'}\,(2\pi)^{d-1}\,2\omega_a(\mathbf{k})\,\delta^{(d-1)}(\mathbf{k}-\mathbf{k}'), \qquad \left[\hat{a},\hat{a}\right] = \left[\hat{a}^\dagger,\hat{a}^\dagger\right] = 0, \tag{11.38}$$

which coincides with (11.35). All cross-sector ($a \neq b$) and cross-polarization ($\lambda \neq \lambda'$) commutators vanish by the orthogonality of the typed basis and the commuting triad/TT projectors $\Pi^{(a)}\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Pi^{(a)}$ (Definition 10.2 and Proposition 10.9).

Step 2 (orthogonal decomposition of the one-particle space). Let $\mathcal{H}_1$ be the one-particle space obtained by completing finite-energy linear combinations of TT modes. By (11.32)–(11.33) and the orthogonality of the triad projectors (Definition 10.2), $\mathcal{H}_1$ decomposes as an orthogonal Hilbert direct sum

$$\mathcal{H}_1 \;=\; \mathcal{H}_1^{(\mathrm{corr})} \;\oplus\; \mathcal{H}_1^{(\mathrm{vac})} \;\oplus\; \mathcal{H}_1^{(\mathrm{spec})}, \qquad \mathcal{H}_1^{(a)} = \overline{\mathrm{span}}\Big\{ e_{\mu\nu}^{(a,\lambda)}(k;\cdot) \Big\}. \tag{11.39}$$

The commutation relations (11.38) imply that the creation/annihilation operators with different triad labels act on mutually orthogonal one-particle subspaces and generate commuting subalgebras; explicitly, $[\,\hat{a}_{a,\lambda}(\mathbf{k}), \hat{a}^\dagger_{b,\lambda'}(\mathbf{k}')\,] = 0$ for $a \neq b$, and the number operators $N^{(a)} = \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}\,2\omega_a(\mathbf{k})} \sum_\lambda \hat{a}^\dagger_{a,\lambda}(\mathbf{k})\hat{a}_{a,\lambda}(\mathbf{k})$ commute for different a.

Step 3 (Fock factorization). For a bosonic field, the symmetric Fock functor $\Gamma_{\mathrm{s}}(\cdot)$ maps an orthogonal direct sum into a (completed) tensor product: $\Gamma_{\mathrm{s}}(\mathcal{H}_1^{(1)} \oplus \mathcal{H}_1^{(2)} \oplus \mathcal{H}_1^{(3)}) \simeq \Gamma_{\mathrm{s}}(\mathcal{H}_1^{(1)}) \widehat{\otimes} \Gamma_{\mathrm{s}}(\mathcal{H}_1^{(2)}) \widehat{\otimes} \Gamma_{\mathrm{s}}(\mathcal{H}_1^{(3)})$. Applying this to (11.39) gives

$$\mathcal{F}_\Phi \;=\; \Gamma_{\mathrm{s}}(\mathcal{H}_1) \;\simeq\; \mathcal{F}_\Phi^{(\mathrm{corr})} \,\widehat{\otimes}\, \mathcal{F}_\Phi^{(\mathrm{vac})} \,\widehat{\otimes}\, \mathcal{F}_\Phi^{(\mathrm{spec})}, \tag{11.40}$$

with $\mathcal{F}_\Phi^{(a)} := \Gamma_{\mathrm{s}}(\mathcal{H}_1^{(a)})$. The identification is implemented by the commuting CCR blocks in (11.38) and the vacuum vector annihilated by all $\hat{a}_{a,\lambda}(\mathbf{k})$.

Step 4 (typed physical sector). On a certified plateau $\mathfrak{P}$, the realized weave configuration operators (TT projector, triad projectors, band tags) are BRST-closed and commute as in Proposition 10.9; hence the construction is gauge-parameter independent (Nielsen-flat) and descends to the physical Hilbert space by cohomology $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3 and Corollary 11.5).

The stated CCR block-diagonality and the Fock factorization across triads follow. □

Definition 11.21 (Triadic residue vector from the TT two-point function)**.** Let $G^{[\mathrm{TT}]}$ be the typed graviton two-point function. In momentum space, each sector admits a Källén–Lehmann representation on $\mathcal{H}_{\mathrm{phys}}$,

$$\Delta^{(2),a}(q) = \frac{Z_a}{q^2 + i\epsilon} + \int_0^\infty \frac{\rho_a^{(2)}(\mu^2)\, d\mu^2}{q^2 - \mu^2 + i\epsilon}, \qquad Z_a \geq 0,\ \rho_a^{(2)}(\mu^2) \geq 0,$$

and we define the *triadic residue vector* $\vec{Z} := (Z_{\mathrm{corr}}, Z_{\mathrm{vac}}, Z_{\mathrm{spec}})$. This vector provides the sector-resolved pole strength used in the TT *state visibility* (Chapter 9) and is to be read on the certified plateau $\mathfrak{P}$.

Remark 11.22 (Physical interpretation and TLO hook)**.** Each $\hat{a}^\dagger_{a,\lambda}(\mathbf{k})$ creates a TT quantum of curvature with definite momentum and polarization in sector a. The sector weights are summarized by $\vec{Z}$ of Definition 11.21; together with the TT law residual $\mathbf{R}^{[\mathrm{TT}]}$ (Definition 11.6), they feed the typed Parasymmetric TLO resolver (Chapter 9), providing certified, sector-aware diagnostics for the radiative graviton within the IQR framework.

Support and Sectoral Projection

The full Gaiamiti fluctuation $\delta\hat{\mathbf{\Phi}}(x)$ (cf. Definition 11.17) contains spin-0, spin-1, and higher-rank excitations in addition to the radiative spin-2 content. To isolate the physically propagating spin-2 (graviton) degrees of freedom on the chronogeometric background $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$ with Relational Levi–Civita connection $\bar{\nabla}$ (Definition 6.7), we employ the typed background-covariant TT projector from Chapter 11 and the triad projectors from Chapters 8–10.

Definition 11.23 (Spin–2 (TT) projection operator)**.** Let $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ denote the background-covariant, self-adjoint, idempotent projector onto transverse–traceless rank-2 tensors with respect to $\bar{\Sigma}$ (Chapter 11). The *spin–2 projection* of the fluctuation is the covariant map

$$\boxed{\mathcal{P}^{(2)}[\delta\hat{\mathbf{\Phi}}](x) := \delta\hat{\mathbf{\Phi}}^{(2)}(x) := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{\mathbf{\Phi}}(x)\,,} \tag{11.41}$$

characterized by the TT constraints

$$\delta\hat{\mathbf{\Phi}}^{(2)}_{\mu\nu}(x) = \delta\hat{\mathbf{\Phi}}^{(2)}_{\nu\mu}(x) \qquad \text{(symmetry)}, \tag{11.42}$$

$$\bar{g}^{\mu\nu}(x)\,\delta\hat{\mathbf{\Phi}}^{(2)}_{\mu\nu}(x) = 0 \qquad \text{(tracelessness)}, \tag{11.43}$$

$$\bar{\nabla}^{\mu}\,\delta\hat{\mathbf{\Phi}}^{(2)}_{\mu\nu}(x) = 0 \qquad \text{(transversality)}, \tag{11.44}$$

where $\bar{g}$ and $\bar{\nabla}$ are those of $\bar{\Sigma}$. In particular, for the metric fluctuation $\delta\hat{g}_{\mu\nu}$ one obtains the typed graviton carrier $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$ (Definition 11.3), which is the field expanded in Definition 11.19.

Definition 11.24 (Triad (sectoral) projectors and commuting structure)**.** Let $\Pi^{(a)}$ for $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ denote the sector projectors introduced in Chapters 8–10 (see Definitions 6.280 and 9.10). They satisfy orthogonality and completeness:

$$\Pi^{(a)}\Pi^{(b)} = \delta^{ab}\,\Pi^{(a)}, \qquad \sum_a \Pi^{(a)} = \mathbb{I}.$$

$$\boxed{\sum_a \Pi^{(a)} = \mathbf{1}, \qquad \Pi^{(a)}\Pi^{(b)} = \delta_{ab}\,\Pi^{(a)}\,.} \tag{11.45}$$

On the certified plateau $\mathfrak{P}$ they commute with the typed projector,

$$\boxed{\left[\Pi^{(a)},\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\right] = 0\,,} \tag{11.46}$$

so the typed graviton decomposes sectorally as

$$\boxed{\hat{h}^{(a)}_{\mu\nu} := \Pi^{(a)}\,\hat{h}_{\mu\nu}\,, \qquad \hat{h}_{\mu\nu} = \sum_a \hat{h}^{(a)}_{\mu\nu}\,.} \tag{11.47}$$

Proposition 11.25 (Band support and no leakage between types)**.** *Fix the BRST-closed band tags* $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} := \left(P_x(\lambda_{\mathrm{UV}}),\, K^{(\ell)}_{\mathrm{IR}}\right)$ *(Definitions 6.280 and 9.10). On the certified plateau* $\mathfrak{P}$*, they commute with the TT projector* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ *and with each sector projector* $\Pi^{(a)}$*. Then the following hold:*

(i) (Typed support) *The realized TT field satisfies*

$$P_x(\lambda_{\rm UV})\, K_{\rm IR}^{(\ell)}\, \hat{h}_{\mu\nu} = \hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\rm TT]}\, P_x(\lambda_{\rm UV})\, K_{\rm IR}^{(\ell)}\, \delta\hat{g}_{\mu\nu}\,,$$

so the TT content is entirely supported on $\mathfrak{B}_{\lambda_{\rm UV},\ell}$.

(ii) (Sectoral support) *Each component* $\hat{h}_{\mu\nu}^{(a)}$ *is likewise band-supported:*

$$P_x(\lambda_{\rm UV})\, K_{\rm IR}^{(\ell)}\, \hat{h}_{\mu\nu}^{(a)} = \hat{h}_{\mu\nu}^{(a)}\,,$$

and there is no leakage *between types:* $\Pi_{\bar{\Sigma}}^{\perp[\rm TT]}\hat{h}_{\mu\nu} = 0$ *and* $\Pi^{(b)}\hat{h}_{\mu\nu}^{(a)} = 0$ *for* $b \neq a$.

Sketch. Use commutativity of $P_x, K_{\rm IR}$ with $\Pi^{[\rm TT]}$ and $\Pi^{(a)}$ on $\mathfrak{P}$ and idempotency/orthogonality of the projectors. BRST-closure guarantees that any residual commutators are ζ-exact and trivial on $\mathcal{H}_{\rm phys} := H^0(\hat{Q}_{\rm BRST})$ (cf. Proposition 7.3). □

Corollary 11.26 (Compatibility with mode expansion and Fock factorization)**.** *The triad-resolved TT mode expansion of Definition 11.19 is well-defined with all modes supported on* $\mathfrak{B}_{\lambda_{\rm UV},\ell}$*, and the commutation relations of sector-labeled creation/annihilation operators yield the Fock factorization stated in Proposition 11.20. In particular, the spectrum and residues entering the triadic Källén–Lehmann representation are to be read on* $\mathfrak{P}$ *(cf. Definition 11.21).*

Remark 11.27 (Causality of support)**.** Because $K_{\rm IR}^{(\ell)}$ does not enlarge $\bar{\Sigma}$-cones (Definition 6.280) and the typed causal kernel has support on $J_{\bar{\Sigma}}^{\pm}$ (Proposition 11.14), the TT sector obeys microcausality and its band restriction preserves the causal support used in Section 11.1.2.

Quantum Graviton Field Operator

$$\boxed{\hat{h}_{\mu\nu} \;:=\; \Pi_{\bar{\Sigma}}^{[\rm TT]}\,\delta\hat{g}_{\mu\nu} \quad\Rightarrow\quad \hat{h}_{\mu\nu} = \hat{h}_{(\mu\nu)},\;\; \bar{g}^{\mu\nu}\hat{h}_{\mu\nu} = 0,\;\; \bar{\nabla}^{\mu}\hat{h}_{\mu\nu} = 0,} \tag{11.48}$$

with $\Pi_{\bar{\Sigma}}^{[\rm TT]}$ the background–covariant TT projector of Chapter 11 (cf. Definition 11.3). Moreover, the temporal/coherence fluctuation $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ is TT-null and hence cannot contribute to $\hat{h}_{\mu\nu}$ (see Definition 11.3).

Definition 11.28 (Quantum Graviton Field Operator)**.** Let $\delta\hat{\Phi}(x)$ be the operator-valued fluctuation of the Gaiamiti field on $(\mathcal{X}_q, \bar{\Sigma})$ (Definition 11.17). Let $\mathcal{P}^{(2)}$ be the covariant spin–2 projection operator (Definition 11.23), and let $\mathbb{E}^{\dagger}_{\mu\nu}$ be the dual geometric embedding that extracts a symmetric TT tensor from the internal operator algebra (inverse to $\mathbb{E}^{\mu\nu}$ in Definition 11.19). We *define* the quantum graviton field operator by

$$\boxed{\hat{h}_{\mu\nu}(x) \;:=\; \mathcal{P}^{(2)}\big[\delta\hat{\Phi}\big](x)\;\cdot\;\mathbb{E}^{\dagger}_{\mu\nu},} \tag{11.49}$$

which, by the typed clause above, coincides with the background–covariant TT projection $\Pi_{\bar{\Sigma}}^{[\rm TT]}\delta\hat{g}_{\mu\nu}$ and therefore satisfies symmetry, tracelessness, and transversality with respect to $\bar{\Sigma}$.

Interpretation and Structure.

- $\delta\hat{\mathbf{\Phi}}(x) \in \Gamma\Big[\mathrm{End}\Big(T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}\Big)\Big]$: the total Gaiamiti fluctuation over $\mathcal{X}_q$ (cf. Definition 11.17).
- $\mathcal{P}^{(2)}[\delta\hat{\mathbf{\Phi}}](x)$: the covariant TT (spin–2) projection implementing symmetry, tracelessness, and transversality relative to $\bar{\Sigma}_{\mu\nu}$ (Definition 11.23).
- $\mathbb{E}^{\dagger}_{\mu\nu}$: $\mathrm{End}\Big(T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}}\Big) \to \mathrm{TT}^2(T^*_x\mathcal{X}_q)$: the dual embedding that recovers a rank–2 TT tensor, inverse to the embedding used in the mode expansion (Definition 11.19).
- $\hat{h}_{\mu\nu}(x)$: a typed, covariant $(0,2)$ operator field acting on the total Fock space; it is precisely the carrier expanded in eq. (11.34) and used in the propagator construction of Section 11.2.

Physical Role.

- *Canonical identification.* $\hat{h}_{\mu\nu}$ gives the canonical, typed identification of the quantum gravitational field without reference to a fixed metric background (it is defined via $\bar{\Sigma}$ and $\Pi^{[\mathrm{TT}]}$).
- *Kinematics → dynamics.* It sources the triad-resolved mode expansion and creation/annihilation algebra (eq. (11.34)), and it underlies the definition of the TT propagator (Section 11.2).
- *Linearized field equation.* $\hat{h}_{\mu\nu}$ satisfies the typed, linearized equation obtained from the matter–geometry kernel $\mathcal{U}_{\Phi\Theta}(x,x')$ (see eqs. (10.183) and (10.184)).
- *Quantum curvature.* It represents the spin–2 quantum excitation of the relational vacuum manifold and therefore encodes genuine quantum curvature fluctuations in the IQR framework.

Masslessness of the Graviton from Spontaneous Symmetry Breaking

Explanation of Proposition 11.29. The typed graviton $\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ is the background–covariant, transverse–traceless carrier obtained by projecting the metric fluctuation with the York–Lichnerowicz projector (eq. (10.4) and Definition 10.3) as formalized in Definition 11.3. The setting is a certified plateau $\mathfrak{P}$ (Chapter VIII), where the band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ commute with all realized weave configuration operators and are BRST–closed (Definitions 6.280 and 9.10 and Propositions 7.3 and 10.9). Assume the Gaiamiti vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ admits a continuous symmetry group G whose action on the field $\hat{\mathbf{\Phi}}$ is spontaneously broken by the realized background $\bar{\Phi}$ in the split $\hat{\mathbf{\Phi}} = \bar{\Phi}\,\mathbb{I} + \delta\hat{\mathbf{\Phi}}$ (Definitions 6.61 and 11.17 and eq. (11.28)). Then the broken generators define flat directions (Goldstone directions) in the fluctuation space. The *typed* (TT) content of those directions is obtained by applying $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$: if the Goldstone direction projects nontrivially onto the TT carrier, the linearized tensorial mass operator $\mathcal{M}^{\mu\nu}{}_{\alpha\beta}$ (defined via the second variation and projected onto the rank–2 sector; Proposition 11.32) annihilates $\hat{h}$, $\mathcal{M}^{\mu\nu}{}_{\alpha\beta}\hat{h}^{\alpha\beta} = 0$. Equivalently, the typed

equations reduce to a massless wave law $\bar{\nabla}^\lambda \bar{\nabla}_\lambda \hat{h}_{\mu\nu} = \hat{J}_{\mu\nu}$, consistent with TT–projected dynamics and microcausality on $(\mathcal{X}_q, \bar{\Sigma})$ (Definition 6.7 and Proposition 11.14).

The two–point function of the typed graviton on the physical Hilbert space $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ (plateau projection; Proposition 7.3) admits a triad–resolved Källén–Lehmann representation with nonnegative spectral weights (Definitions 10.2, 11.18 and 11.21). In the presence of a TT Goldstone direction, the TT spectral measure necessarily contains a pole at $q^2 = 0$ with residue $Z_a \geq 0$ in each triad sector a, so the total residue $Z_{\rm TT} = \sum_a Z_a > 0$ on $\mathfrak{P}$. Positivity follows from the cohomological (BRST–projected) positivity together with the orthonormality/completeness of the typed polarization basis and the canonical TT algebra (eqs. (11.32) and (11.33) and Proposition 11.4); regulator stability is ensured by Nielsen flatness of the realized weave configuration (Corollary 11.5) and cone–preserving band limitation (Definition 6.280 and Remark 9.83). Thus, spontaneous breaking of G in the Gaiamiti sector enforces a *massless* TT carrier with a positive–residue Goldstone pole in the typed graviton spectrum, exactly as stated in items *(i)–(ii)* of Proposition 11.29.

Proposition 11.29 (Masslessness of the graviton from typed SSB)**.** *Let $\hat{h}_{\mu\nu} := \Pi^{[\rm TT]}_{\bar{\Sigma}}\, \delta\hat{g}_{\mu\nu}$ be the typed (background–covariant TT) graviton carrier of Definitions 11.3 and 11.28 and eq. (11.49), defined on a certified plateau $\mathfrak{P}$ (Chapter 8) with BRST-closed band tags commuting with $\Pi^{[\rm TT]}_{\bar{\Sigma}}$ and the sector projectors (Definitions 6.280 and 9.10). Suppose the Gaiamiti vacuum manifold $\mathcal{M}_{\rm vac}$ (Definition 6.61) admits a continuous symmetry group G whose action on $\hat{\mathbf{\Phi}}$ is spontaneously broken by the realization $\bar{\Phi}$ appearing in the split $\hat{\mathbf{\Phi}} = \bar{\Phi}\,\mathbb{I} + \delta\hat{\mathbf{\Phi}}$ (Definition 11.17 and eq. (11.28)). Then, in the* typed *(TT) sector:*

*(i) (*Goldstone in TT type*) The broken generators produce a Goldstone direction that projects non-trivially onto the TT carrier; equivalently, the linearized tensorial mass operator $\mathcal{M}^{\mu\nu}{}_{\alpha\beta}$ of Proposition 11.32 annihilates $\hat{h}$,*

$$\boxed{\mathcal{M}^{\mu\nu}{}_{\alpha\beta}(x)\, \hat{h}^{\alpha\beta}(x) = 0\,,} \tag{11.50}$$

so the typed field obeys a massless wave equation (up to sources) $\bar{\nabla}^\lambda \bar{\nabla}_\lambda \hat{h}_{\mu\nu} = \hat{J}_{\mu\nu}$.

*(ii) (*Massless pole with positive residue*) The TT two-point function on $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ admits a triad-resolved Källén–Lehmann representation (Definition 11.21) with a massless pole,*

$$\Delta^{(2),a}(q) = \frac{Z_a}{q^2 + i\epsilon} + \int_0^\infty \frac{\rho_a^{(2)}(\mu^2)\, d\mu^2}{q^2 - \mu^2 + i\epsilon}, \qquad Z_a \geq 0\,.$$

Writing $Z_{\rm TT} := \sum_{a\in\{\rm corr,vac,spec\}} Z_a$, one has

$$\boxed{Z_{\rm TT} > 0 \quad \text{on } \mathfrak{P}\,,} \tag{11.51}$$

so the TT spectral measure contains a Goldstone pole at $q^2 = 0$ with positive residue.

Proof of Proposition 11.29. Preliminaries. Work on a certified plateau $\mathfrak{P}$ where the realized weave configuration operators (TT projector, triad projectors, band tags) commute and are

BRST–closed (Propositions 7.3 and 10.9 and Definitions 6.280 and 9.10). The typed Peierls bracket is

$$\{F,G\}_{\mathrm{P}} = \Big\langle \frac{\delta F}{\delta h_{\mu\nu}},\ \Delta^{[\mathrm{TT}]\,\mu\nu}{}_{\rho\sigma}\,\frac{\delta G}{\delta h_{\rho\sigma}} \Big\rangle, \qquad \Delta^{[\mathrm{TT}]} := G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]}, \tag{11.52}$$

(eq. (11.25)), with cone support and microcausality as in Proposition 11.14. The TT carrier is $\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ (Definition 11.3).

Step 1 (SSB and TT projection). The background–fluctuation split $\hat{\mathbf{\Phi}} = \bar{\Phi}\,\mathbb{I} + \delta\hat{\mathbf{\Phi}}$ (Definition 11.17 and eq. (11.28)) realizes SSB by $\bar{\Phi} \in \mathcal{M}_{\mathrm{vac}}$ (Definition 6.61), selecting a coset G/H. Let Q^A be a broken generator. Its action on fields is generated by the Peierls bracket at fixed band tags (Definitions 6.280 and 9.10): for any gauge–invariant F, $\delta_{Q^A}F = \{F, Q^A\}_{\mathrm{P}}$. Applying the York–Lichnerowicz projector (eq. (10.4) and Definition 10.3) and using realized weave configuration commutations (Proposition 10.9) gives a typed variation $\delta_{Q^A}\hat{h} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta_{Q^A}(\delta\hat{g})$, with $\hat{\tau}_{\mu\nu}$ TT–null (TT calculus, Chapter XI).

Step 2 (Typed Ward identity and soft matrix element). The TT law residual is the Peierls commutator with the typed action ($\mathbf{R}^{[\mathrm{TT}]} \sim \{\cdot, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$; Corollary 11.12); invariance under the unbroken subgroup and SSB for the broken directions yield the *typed Ward identity* on $\mathfrak{P}$: for the broken Q^A,

$$\{\,\hat{h},\ Q^A\,\}_{\mathrm{P}} \neq 0 \quad \text{and} \quad \{\,S^{[\mathrm{TT}]},\ Q^A\,\}_{\mathrm{P}} = 0, \tag{11.53}$$

the latter expressing stationarity of the action along the symmetry direction. Fourier transforming the two–point function and inserting (11.53) shows that the soft matrix element of the broken charge between the vacuum and a one–TT–quantum state saturates the *soft limit* of the typed two–point distribution, producing a $1/q^2$ singularity in the TT channel (see also Proposition 11.4 for the canonical normalization and Proposition 11.14 for the covariant kernel).

Step 3 (Vanishing of the typed tensorial mass operator). Let $\mathcal{M}^{\mu\nu}{}_{\alpha\beta}$ denote the linearized tensorial mass operator obtained from the second variation of the action and projected onto symmetric rank–2 tensors (Proposition 11.32). Along a broken direction, the Hessian has a null vector (Goldstone flat direction). Projecting this direction with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and using $[\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}},\ \cdot\,] = 0$ on $\mathfrak{P}$ (Proposition 10.9) yields

$$\mathcal{M}^{\mu\nu}{}_{\alpha\beta}\,\hat{h}^{\alpha\beta} = 0, \tag{11.54}$$

which is item (i). Consequently, up to sources, the typed equation of motion is the massless wave law $\bar{\nabla}^{\lambda}\bar{\nabla}_{\lambda}\hat{h}_{\mu\nu} = \hat{J}_{\mu\nu}$ (Definition 6.7).

Step 4 (Källén–Lehmann representation and positivity). On the physical Hilbert space $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3) the typed two–point function admits a triad–resolved Källén–Lehmann representation with nonnegative spectral weights (Definitions 10.2, 11.18 and 11.21):

$$\Delta^{(2),a}(q) = \frac{Z_a}{q^2 + i\epsilon} + \int_0^\infty \frac{\rho_a^{(2)}(\mu^2)\,d\mu^2}{q^2 - \mu^2 + i\epsilon}, \qquad Z_a \geq 0.$$

Using the orthonormality and completeness of TT polarizations (eqs. (11.32) and (11.33)) and the block–diagonal CCR (Propositions 11.4 and 11.20) shows that the residue is the modulus squared of the TT order–parameter matrix element associated with the broken charge, hence strictly positive if the TT projection of the Goldstone direction is nonzero. Summing over triads gives $Z_{\mathrm{TT}} = \sum_a Z_a > 0$, which is item (ii).

Step 5 (Stability and covariance). Nielsen flatness (Corollary 11.5) ensures gauge–parameter independence on $\mathfrak{P}$, and cone–preserving band limitation (Definition 6.280 and Remark 9.83) preserves the support and the Peierls construction (Proposition 11.14). Thus both (i) and (ii) are regulator–safe and covariant.

This completes the proof of Proposition 11.29. □

Corollary 11.30 (GMOR-style typed mass relation under explicit breaking)**.** *Introduce a small explicit breaking ϵ of the G-symmetry in the Gaiamiti potential (or source sector). On $\mathfrak{P}$ there exists a plateau constant $C_{\mathfrak{P}} > 0$ such that the TT pole shifts to*

$$\boxed{m^2_{\mathrm{TT}} \;=\; \mathcal{O}(\epsilon), \qquad 0 \;\le\; m^2_{\mathrm{TT}} \;\le\; C_{\mathfrak{P}}\,\epsilon\,,} \tag{11.55}$$

and the two-point becomes $\Delta^{(2)}_{\mathrm{TT}}(q) \simeq \dfrac{Z_{\mathrm{TT}}}{q^2 - m^2_{\mathrm{TT}} + i\epsilon}$ *+ regular. Plateau/Nielsen safety (Chapter 8) ensures the bound is gauge-parameter independent.*

Proof. Setup and notation. Work on a certified plateau $\mathfrak{P}$ where the realized weave configuration operators (TT projector, triad projectors, band tags) commute and are BRST–closed (Propositions 7.3 and 10.9 and Definitions 6.280 and 9.10). Introduce a small explicit breaking ϵ of the G-symmetry in the (typed) action,

$$S^{[\mathrm{TT}]}_\epsilon := S^{[\mathrm{TT}]} \;+\; \epsilon\, B^{[\mathrm{TT}]}, \qquad B^{[\mathrm{TT}]} := \Pi^{[\mathrm{TT}]}_{\bar\Sigma}\, B\, \Pi^{[\mathrm{TT}]}_{\bar\Sigma}, \tag{11.56}$$

with B a $\bar\Sigma$-covariant functional (potential or source) calibrated on $\mathfrak{P}$. The typed Euler–Lagrange map is then

$$E^{[\mathrm{TT}]}_\epsilon[\hat h] := \Pi^{[\mathrm{TT}]}_{\bar\Sigma}\, \frac{\delta S^{[\mathrm{TT}]}_\epsilon}{\delta \hat h} = E^{[\mathrm{TT}]}[\hat h] \;+\; \epsilon\, B^{[\mathrm{TT}]}_{,h}[\hat h], \tag{11.57}$$

where $E^{[\mathrm{TT}]}[\hat h] = 0$ are the unbroken typed equations (massless carrier; Proposition 11.29). By the Peierls "hook" (Corollary 11.12) and the typed bracket definition (eq. (11.25)), $\mathbf{R}^{[\mathrm{TT}]}_\epsilon \sim \{\cdot, S^{[\mathrm{TT}]}_\epsilon\}_{\mathrm{P}}$ and thus $E^{[\mathrm{TT}]}_\epsilon = 0$ encodes the linear response and the pole structure of the TT two–point.

Step 1 (modified Ward identity and soft saturation). Let Q^A be a generator broken spontaneously at $\epsilon = 0$ (Definitions 6.61 and 11.17) and explicitly by $\epsilon \neq 0$. On $\mathfrak{P}$, the typed Ward identity is deformed by

$$\{\, S^{[\mathrm{TT}]}_\epsilon,\, Q^A \,\}_{\mathrm{P}} = \epsilon\, \{\, B^{[\mathrm{TT}]},\, Q^A \,\}_{\mathrm{P}}, \qquad \{\cdot,\cdot\}_{\mathrm{P}} \text{ as in } eq.\ (11.25). \tag{11.58}$$

Fourier transforming the TT two–point and inserting (11.58) shows that the massless pole at $q^2 = 0$ (present at $\epsilon = 0$; Proposition 11.29) shifts to $q^2 = m^2_{\mathrm{TT}}$ of order ϵ, controlled by

the explicit–breaking insertion $B^{[\mathrm{TT}]}$. This is the typed, covariant analogue of the GMOR mechanism.

Step 2 (first–order pole shift and bound). Linearizing (11.57) around the unbroken vacuum yields, in momentum space,

$$K_{[\mathrm{TT}]}(q)\,\tilde{h}(q) + \epsilon\,\Sigma_{[\mathrm{TT}]}(q)\,\tilde{h}(q) = 0,$$

with $K_{[\mathrm{TT}]}$ the typed wave operator (York–Lichnerowicz type; Chapter X) and $\Sigma_{[\mathrm{TT}]} \equiv (B^{[\mathrm{TT}]}_{,h})_{,h}$ the typed explicit–breaking Hessian. At $\epsilon = 0$, $K_{[\mathrm{TT}]}(q)$ has a zero eigenvalue at $q^2 = 0$ in the Goldstone TT direction (Proposition 11.29); let ψ denote a normalized TT polarization vector in that kernel (constructed from Definition 11.18). Rayleigh–Schrödinger perturbation theory (or Feshbach reduction on the TT subspace) gives the pole shift

$$m^2_{\mathrm{TT}} = \epsilon\,\frac{\langle \psi,\ \Sigma_{[\mathrm{TT}]}(0)\,\psi\rangle_{\bar{\Sigma}}}{\langle \psi,\ (\partial K_{[\mathrm{TT}]}/\partial q^2)_{q^2=0}\,\psi\rangle_{\bar{\Sigma}}} \ +\ \mathcal{O}(\epsilon^2). \tag{11.59}$$

The denominator equals the positive TT residue Z_{TT} of the Källén–Lehmann representation (Definition 11.21 and Proposition 11.29), while the numerator is bounded by the instrumentation norm on $\mathfrak{P}$ (Definition 10.1): there exists $C'_{\mathfrak{P}} > 0$ such that $\langle \psi,\ \Sigma_{[\mathrm{TT}]}\,\psi\rangle_{\bar{\Sigma}} \le C'_{\mathfrak{P}}$. Hence, for ϵ sufficiently small,

$$0 \ \le\ m^2_{\mathrm{TT}} \ \le\ \frac{C'_{\mathfrak{P}}}{Z_{\mathrm{TT}}}\,\epsilon \ =:\ C_{\mathfrak{P}}\,\epsilon, \qquad m^2_{\mathrm{TT}} = \mathcal{O}(\epsilon). \tag{11.60}$$

Positivity $m^2_{\mathrm{TT}} \ge 0$ follows from the spectral positivity of the TT two–point on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3 and Definition 11.21) and from $Z_{\mathrm{TT}} > 0$ (Proposition 11.29).

Step 3 (two–point structure and covariance). Inserting (11.60) into the typed Källén–Lehmann form yields

$$\Delta^{(2)}_{\mathrm{TT}}(q) \simeq \frac{Z_{\mathrm{TT}}}{q^2 - m^2_{\mathrm{TT}} + i\epsilon} + \text{regular},$$

with microcausality preserved by cone support of $\Delta^{[\mathrm{TT}]}$ (Proposition 11.14) and stability under the band IR window (Definition 6.280 and Remark 9.83). Finally, gauge–parameter independence of m^2_{TT} and of the bound $C_{\mathfrak{P}}$ on $\mathfrak{P}$ follows from Nielsen flatness (Corollary 11.5) and BRST descent to $\mathcal{H}_{\mathrm{phys}}$ (Proposition 7.3).

Equations (11.60) establish the claimed GMOR–style typed mass relation. □

Remark 11.31 (Law visibility in the SSB limit)**.** Recall the TT law residual and visibility from Definition 11.6: $\mathbf{R}^{[\mathrm{TT}]} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\big[\delta\bar{G}_{\mu\nu}[\hat{h}] + \Lambda\,\hat{h}_{\mu\nu} - \kappa\,\delta\bar{T}^{\mathrm{total}}_{\mu\nu}\big]$ and $\Lambda^{[\mathrm{TT}]}_{\mathrm{law}} := 1 - \|\mathbf{R}^{[\mathrm{TT}]}\|_{\mathcal{I}}/\|\cdot\|_{\mathrm{ref}} \in [0,1]$, with instrumentation norm $\|\cdot\|_{\mathcal{I}}$ and reference scale $\|\cdot\|_{\mathrm{ref}}$ calibrated on the certified plateau $\mathfrak{P}$ (Definition 10.1 and Section 7.3.9). On $\mathfrak{P}$, the Peierls "hook" identifies the residual with the typed equations of motion, $\mathbf{R}^{[\mathrm{TT}]} \sim \{\cdot, S^{[\mathrm{TT}]}\}_{\mathrm{P}}$ (Corollary 11.12 and eq. (11.25)), and cone preservation of the band realized weave configuration ensures regulator safety (Definition 6.280 and Remark 9.83).

In the exact SSB limit ($\epsilon \to 0$), the typed Ward identity holds and the TT Goldstone direction implies vanishing typed mass operator (Proposition 11.29); therefore the typed equations of motion are satisfied and $\mathbf{R}^{[\mathrm{TT}]} = 0$, which yields

$$\boxed{\Lambda_{\mathrm{law}}^{[\mathrm{TT}]} \longrightarrow 1.} \tag{11.61}$$

For small explicit breaking ϵ, the GMOR–style estimate gives $m_{\mathrm{TT}}^2 = \mathcal{O}(\epsilon)$ with $0 \le m_{\mathrm{TT}}^2 \le C_{\mathfrak{P}}\epsilon$ (Corollary 11.30). Linear response of the typed EL map on $\mathfrak{P}$ then bounds the residual by the same plateau constants, $\|\mathbf{R}^{[\mathrm{TT}]}\|_{\mathcal{I}} \le C'_{\mathfrak{P}}\, m_{\mathrm{TT}}^2 = \mathcal{O}(\epsilon)$, so $\Lambda_{\mathrm{law}}^{[\mathrm{TT}]} = 1 - \mathcal{O}(\epsilon)$. Gauge–parameter independence of these statements follows from BRST/Nielsen safety (Proposition 7.3 and Corollary 11.5), and covariance from the typed Peierls construction with causal support (Proposition 11.14).

The Tensorial Graviton Mass Operator

Proposition 11.32 (The Tensorial Graviton Mass Operator)**.** *Let the emergent chronogeometric tensor be the symmetric functional $\hat{\Sigma}_{\mu\nu}(x) = \mathcal{S}_{\mu\nu}[\hat{\mathbf{\Phi}}(x)]$, and let the linear response of Σ to Gaiamiti fluctuations at the background $\bar{\Phi}$ be $\delta\hat{\Sigma}_{\mu\nu}(x) = \sum_i \mathcal{E}^i_{\mu\nu}(x)\,\delta\hat{\Phi}^i(x)$ with $\mathcal{E}^i_{\mu\nu}(x) := \frac{\delta\mathcal{S}_{\mu\nu}}{\delta\hat{\Phi}^i(x)}\Big|_{\bar{\Phi}}$. Write the quadratic mass term in the Gaiamiti basis as*

$$S^{(2)}_{mass} = \frac{1}{2}\int d^dx\,\sqrt{-\det\bar{\Sigma}}\,\sum_{i,j}\left(\delta\hat{\Phi}^i\right)^\dagger \mathcal{M}_{ij}\,\delta\hat{\Phi}^j, \qquad \mathcal{M}_{ij} := \frac{\delta^2\mathcal{V}_\Phi}{\delta(\hat{\Phi}^i)^\dagger\delta\hat{\Phi}^j}\Big|_{\bar{\Phi}}.$$

If $\mathcal{E}^{-1}$ denotes the inverse kernel expressing $\delta\hat{\Phi}$ in terms of $\delta\hat{\Sigma}$, then the tensorial *graviton mass operator appearing in the geometric quadratic form*

$$S^{(2)}_{mass} = \frac{1}{2}\int d^dx\,\sqrt{-\det\bar{\Sigma}}\,\left(\delta\hat{\Sigma}_{\mu\nu}\right)^\dagger \mathcal{M}^{\mu\nu}{}_{\alpha\beta}\,\delta\hat{\Sigma}^{\alpha\beta}$$

is given by the congruence of $\mathcal{M}_{ij}$ through the response map:

$$\boxed{\mathcal{M}^{\mu\nu}{}_{\alpha\beta}(x) := \sum_{i,j}\Big((\mathcal{E}^{-1})^i_{\rho\sigma}(x)\Big)^\dagger \bar{\Sigma}^{\rho\mu}(x)\,\bar{\Sigma}^{\sigma\nu}(x)\,\mathcal{M}_{ij}(x)\,\Big((\mathcal{E}^{-1})^j_{\alpha\beta}(x)\Big).} \tag{11.62}$$

This congruence inherits the null directions of $\mathcal{M}_{ij}$, so Goldstone directions in the Gaiamiti basis remain null in the geometric tensor basis, consistently with Proposition 11.29.

Proof (typed/TT refinement). **Step 1: Mass term in the Gaiamiti basis.** As in the original argument, expand the potential to quadratic order to obtain

$$S^{(2)}_{\mathrm{mass}} = \frac{1}{2}\int d^dx\,\sqrt{-\det\bar{\Sigma}}\,\sum_{i,j}(\delta\hat{\Phi}^i)^\dagger\,\mathcal{M}_{ij}\,\delta\hat{\Phi}^j,$$

with $\mathcal{M}_{ij}$ defined at $\bar{\Phi}$.

Step 2: Change of basis to geometric fluctuations. Use the inverse linear response kernel $(\mathcal{E}^{-1})^{i}_{\alpha\beta}$ (at $\bar{\Phi}$) to express $\delta\hat{\Phi}^{i} = (\mathcal{E}^{-1})^{i}_{\alpha\beta}\,\delta\hat{\Sigma}^{\alpha\beta}$. Substituting gives a quadratic form in $\delta\hat{\Sigma}$ whose coefficient is the tensorial mass kernel

$$\mathcal{M}^{\mu\nu\alpha\beta} := \sum_{i,j} \Big((\mathcal{E}^{-1})^{i}_{\mu\nu}\Big)^{\dagger} \mathcal{M}_{ij} \Big((\mathcal{E}^{-1})^{j}_{\alpha\beta}\Big), \qquad \mathcal{M}^{\mu\nu}{}_{\alpha\beta} = \mathcal{M}^{\mu\nu\rho\sigma}\,\bar{\Sigma}_{\rho\alpha}\,\bar{\Sigma}_{\sigma\beta},$$

which is equivalent to eq. (11.62).

Step 3: Typed projection of the mass operator. Project onto the typed graviton carrier $\hat{h}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\delta\hat{g}_{\mu\nu}$ (Definitions 11.3, 11.23 and 11.28). Define the TT block

$$\mathcal{M}^{[\mathrm{TT}]} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\;\mathcal{M}\;\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}},$$

so that the mass term acting on $\hat{h}$ is governed by $\mathcal{M}^{[\mathrm{TT}]}$ (Definition 11.33).

Step 4: SSB and null directions. If $\mathcal{M}_{ij}$ has Goldstone null directions (spontaneous breaking $G\to H$ at $\bar{\Phi}$; Proposition 11.29), then the congruence through $\mathcal{E}^{-1}$ maps these nulls into null symmetric tensors of $\mathcal{M}^{\mu\nu}{}_{\alpha\beta}$. Upon TT projection, any component that overlaps the typed carrier yields a null of $\mathcal{M}^{[\mathrm{TT}]}$. Hence, in the exact SSB limit,

$$\operatorname{Spec}\mathcal{M}^{[\mathrm{TT}]} \;=\; \{0\} \quad \text{on } \mathfrak{P},$$

and the typed equation of motion is massless (up to sources), consistent with the Goldstone pole in the TT two-point function (Proposition 11.29 and Definition 11.21).

Step 5: Small explicit breaking (GMOR-style). If a deformation of size ϵ explicitly breaks the symmetry, the TT block acquires a small eigenvalue $m^2_{\mathrm{TT}} = \mathcal{O}(\epsilon)$ bounded on the plateau, $0 \le m^2_{\mathrm{TT}} \le C_{\mathfrak{P}}\epsilon$ (Corollary 11.30).

Certification notes. Positivity on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ and hyperbolicity of the TT kinetic principal symbol are *plateau checks* and are verified as in Remark 11.35 (Nielsen-flat on $\mathfrak{P}$). □

Definition 11.33 (TT-projected graviton mass operator)**.** Let $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ be the background–covariant TT projector (Chapter 11; cf. Definitions 11.3 and 11.23). The *typed* mass operator acting on the graviton carrier $\hat{h}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\delta\hat{g}_{\mu\nu}$ is

$$\boxed{\mathcal{M}^{[\mathrm{TT}]} \;:=\; \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\;\mathcal{M}\;\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,,} \tag{11.63}$$

i.e. the TT block of $\mathcal{M}^{\mu\nu}{}_{\alpha\beta}$ obtained by projection on both indices. In the exact SSB setting of Proposition 11.29 one has

$$\boxed{\operatorname{Spec}\mathcal{M}^{[\mathrm{TT}]} \;=\; \{0\} \qquad \text{on the certified plateau } \mathfrak{P},} \tag{11.64}$$

so the typed mass operator vanishes on $\hat{h}$ and yields the massless TT equation of motion.

Corollary 11.34 (Typed spectrum under small explicit breaking)**.** *If a symmetry-breaking deformation of size ϵ is introduced in $\mathcal{V}_{\Phi}$, then the TT block acquires a small spectral shift $0 \le m^2_{\mathrm{TT}} \le C_{\mathfrak{P}}\,\epsilon$ on $\mathfrak{P}$ (cf. Corollary 11.30).*

Remark 11.35 (Plateau certification: positivity and hyperbolicity)**.** On the physical Hilbert space $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ (Chapter 8), the quadratic TT form induced by $\mathcal{M}^{[\text{TT}]}$ is non-negative, and the principal symbol of the typed kinetic operator $K_{[\text{TT}]}$ is hyperbolic with respect to the $\bar{\Sigma}$-cone. Both statements are *plateau checks* (see Definitions 6.280 and 9.10 and Proposition 7.3): they are evaluated with BRST-closed band tags and are Nielsen-flat on $\mathfrak{P}$.

Channel Projection of the Graviton

In preparation for vertices and scattering, we refine the typed TT carrier $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\text{TT}]}\,\delta\hat{g}_{\mu\nu}$ (Definitions 11.3 and 11.28) by projecting it onto *coupling channels* determined by the background–covariant bi–local parent interaction of Chapter 11 (cf. the $\Phi\Phi \leftrightarrow \Theta\Theta$ off–diagonal) and its linearized TT shadow $S_{\text{int}}^{(1)}[\hat{h}, \hat{\Theta}]$ (Section 11.1). All statements are made on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\text{UV}},\ell}$ commuting with $\Pi_{\bar{\Sigma}}^{[\text{TT}]}$ and the triad projectors $\{\Pi^{(a)}\}_{a\in\{\text{corr,vac,spec}\}}$ (Definitions 6.280 and 9.10).

Definition 11.36 (Typed channel projectors)**.** Let $\mathscr{C}$ denote the finite (or countable) index set of *TT–preserving* coupling channels extracted from the TT–linearized vertex kernel $\hat{V}^{\mu\nu}(x;\hat{\Theta})$ (Chapter 11). A family of bounded projectors $\{\Pi^{\langle c\rangle}\}_{c\in\mathscr{C}}$ on the graviton carrier Hilbert space is called a *typed channel decomposition* if, on $\mathfrak{P}$,

$$\Pi^{\langle c\rangle}\Pi^{\langle c'\rangle} = \delta_{cc'}\Pi^{\langle c\rangle}, \qquad \sum_{c\in\mathscr{C}} \Pi^{\langle c\rangle} = \mathbf{1}, \tag{11.65}$$

$$\left[\Pi^{\langle c\rangle}, \Pi_{\bar{\Sigma}}^{[\text{TT}]}\right] = 0, \qquad \left[\Pi^{\langle c\rangle}, \Pi^{(a)}\right] = 0, \qquad \left[\Pi^{\langle c\rangle}, P_x(\lambda_{\text{UV}})\right] = \left[\Pi^{\langle c\rangle}, K_{\text{IR}}^{(\ell)}\right] = 0. \tag{11.66}$$

The channel–resolved graviton and sector fields are

$$\hat{h}_{\mu\nu}^{\langle c\rangle} := \Pi^{\langle c\rangle}\hat{h}_{\mu\nu}, \qquad \hat{h}_{\mu\nu}^{(a,\langle c\rangle)} := \Pi^{(a)}\Pi^{\langle c\rangle}\hat{h}_{\mu\nu} = \Pi^{\langle c\rangle}\Pi^{(a)}\hat{h}_{\mu\nu}. \tag{11.67}$$

Remark 11.37 (Construction by spectral calculus of the vertex)**.** When $\hat{V}[\cdot]$ admits a self–adjoint TT reduction on $\mathfrak{P}$, the $\Pi^{\langle c\rangle}$ can be obtained as spectral projectors of a commuting family of Hermitian coupling operators (e.g. charge, spin, or representation labels carried on the right leg Θ and pulled back to the TT left leg via the bi–local kernel). TT–nullity of $\hat{\tau}_{\mu\nu}$ (Chapter 11) ensures channels are purely metric on the left leg.

Proposition 11.38 (Orthogonality, support, and microcausality)**.** *On $\mathfrak{P}$ with BRST–closed $\mathfrak{B}_{\lambda_{\text{UV}},\ell}$,*

*(i) (*Orthogonality*) The only non–vanishing mode algebra across channels and triad labels is*

$$\left[\hat{a}_{a,\lambda}^{\langle c\rangle}(\mathbf{k}),\, \hat{a}_{b,\lambda'}^{\langle c'\rangle\,\dagger}(\mathbf{k}')\right] = \delta_{ab}\delta_{cc'}\delta_{\lambda\lambda'}(2\pi)^{d-1}2\omega_a(\mathbf{k})\,\delta^{(d-1)}(\mathbf{k}-\mathbf{k}')\,,$$

so the Fock space factorizes as $\mathscr{F}_\Phi \simeq \widehat{\bigotimes}_{c\in\mathscr{C}}\left(\mathscr{F}_\Phi^{(\text{corr},\langle c\rangle)}\widehat{\otimes}\mathscr{F}_\Phi^{(\text{vac},\langle c\rangle)}\widehat{\otimes}\mathscr{F}_\Phi^{(\text{spec},\langle c\rangle)}\right)$ (cf. Proposition 11.20).

(ii) (Band support) $P_x(\lambda_{\mathrm{UV}})K_{\mathrm{IR}}^{(\ell)}\hat{h}_{\mu\nu}^{(a,\langle c\rangle)} = \hat{h}_{\mu\nu}^{(a,\langle c\rangle)}$.

(iii) (Microcausality) *Channel projection commutes with the typed Peierls kernel, hence* $\Delta^{[\mathrm{TT}],\langle c\rangle} := \Pi^{\langle c\rangle}\Delta^{[\mathrm{TT}]}\Pi^{\langle c\rangle}$ *has support on the* $\bar{\Sigma}$*–null cone and vanishes for* $\bar{\Sigma}$*–spacelike separations (Proposition 11.14).*

Definition 11.39 (Channel–resolved residues and visibilities)**.** Let $G^{[\mathrm{TT}],\langle c\rangle}$ be the channel–projected TT two–point function. In momentum space each triad sector admits a KL representation on $\mathcal{H}_{\mathrm{phys}}$,

$$\Delta^{(2),a,\langle c\rangle}(q) = \frac{Z_a^{\langle c\rangle}}{q^2+i\epsilon} + \int_0^\infty \frac{\rho_a^{(2)\,\langle c\rangle}(\mu^2)\,d\mu^2}{q^2-\mu^2+i\epsilon}, \qquad Z_a^{\langle c\rangle} \geq 0,\ \rho_a^{(2)\,\langle c\rangle} \geq 0.$$

Define the *channel residue vector* $\vec{Z}^{\langle c\rangle} := \left(Z_{\mathrm{corr}}^{\langle c\rangle}, Z_{\mathrm{vac}}^{\langle c\rangle}, Z_{\mathrm{spec}}^{\langle c\rangle}\right)$. The typed Parasymmetric TLO state visibility refines to $\Lambda_{\mathrm{state}}^{[\mathrm{TT}],\langle c\rangle}$ by replacing sector residues with $\vec{Z}^{\langle c\rangle}$ in the readout (Chapter 9).

Definition 11.40 (Channel purity and cross–talk leak)**.** The *channel purity* residual is $\|\Pi^{\perp\langle c\rangle}\hat{h}_{\mu\nu}\|_{\mathcal{I}}$ with $\Pi^{\perp\langle c\rangle} := \mathbf{1} - \Pi^{\langle c\rangle}$. For $c \neq c'$, the *cross–talk* leak is the minimal $\varepsilon_{c\to c'} \geq 0$ such that $\|\Pi^{\langle c'\rangle}\mathfrak{O}\,\Pi^{\langle c\rangle}\|_{\mathcal{I}} \leq \varepsilon_{c\to c'}\|\mathfrak{O}\|_{\mathcal{I}}$ for all observables $\mathfrak{O}$ entering the TT readouts. On $\mathfrak{P}$ these diagnostics are Nielsen–flat and band–stable (Chapter 8).

Remark 11.41 (Law channel in each coupling channel)**.** The TT law residual $\mathbf{R}^{[\mathrm{TT}]}$ (Definition 11.6) refines to $\mathbf{R}^{[\mathrm{TT}],\langle c\rangle} := \Pi^{\langle c\rangle}\mathbf{R}^{[\mathrm{TT}]}\Pi^{\langle c\rangle}$, with associated $\Lambda_{\mathrm{law}}^{[\mathrm{TT}],\langle c\rangle} \in [0,1]$. In the exact SSB typed limit (Proposition 11.29) one expects $\Lambda_{\mathrm{law}}^{[\mathrm{TT}],\langle c\rangle} \to 1$ for channels aligned with the Goldstone TT carrier, while small explicit breakings shift the visibility according to the GMOR–style bounds (Corollary 11.30).

This channel decomposition will be used immediately in Sections 11.3.3 to 11.3.5, where the vertex is written in the channel basis and dispersion/positivity analyses (Section 11.3.6) are evaluated per–channel, per–triad, on the same certified plateau $\mathfrak{P}$.

Full typed graviton and equivalence of constructions. Using the background–covariant TT projector (Chapter 11) and the spin–2 projection of the Gaiamiti fluctuation, the full graviton carrier is

$$\boxed{\hat{h}_{\mu\nu}(x) \;:=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}(x) \;\equiv\; \mathcal{P}^{(2)}\Big[\delta\hat{\mathbf{\Phi}}\Big](x)\cdot\mathbb{E}_{\mu\nu}^{\dagger},} \tag{11.68}$$

in agreement with Definitions 11.23 and 11.28 and eq. (11.49). By construction $\hat{h}_{\mu\nu} = \hat{h}_{(\mu\nu)}$, $\bar{g}^{\mu\nu}\hat{h}_{\mu\nu} = 0$, $\bar{\nabla}^{\mu}\hat{h}_{\mu\nu} = 0$, and the temporal/coherence fluctuation $\hat{\tau}_{\mu\nu}$ is TT-null (Chapter 11).

Step 1: Sector and channel projectors (interaction–sourced)

Let $\{\Pi^{(a)}\}_{a\in\{\mathrm{corr,vac,spec}\}}$ be the triad (sector) projectors and $\{\Pi^{\langle c\rangle}\}_{c\in\mathscr{C}}$ the typed channel projectors extracted from the TT-linearized vertex (Chapter 11), with commutation and

orthogonality as in Definitions 11.24 and 11.36. They commute with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ and with the band tags on $\mathfrak{P}$ (Definitions 6.280 and 9.10). The interaction kernel admits a triadic decomposition $\mathcal{U}_{\Phi\Theta} = \mathcal{U}_{\Phi\Theta}^{(\mathrm{corr})} + \mathcal{U}_{\Phi\Theta}^{(\mathrm{vac})} + \mathcal{U}_{\Phi\Theta}^{(\mathrm{spec})}$ (Section 10.19.6), which induces the corresponding decomposition of the *typed* response.

Step 2: Sectoral and channel–resolved gravitons

We define the sectoral and channel–resolved graviton fields purely by commuting projections,

$$\hat{h}_{\mu\nu}^{(a)} := \Pi^{(a)}\,\hat{h}_{\mu\nu}, \qquad \sum_a \Pi^{(a)} = \mathbf{1}, \quad \Pi^{(a)}\Pi^{(b)} = \delta_{ab}\Pi^{(a)}, \quad [\Pi^{(a)}, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}] = 0, \tag{11.69}$$

$$\hat{h}_{\mu\nu}^{(a,\langle c\rangle)} := \Pi^{\langle c\rangle}\Pi^{(a)}\,\hat{h}_{\mu\nu} = \Pi^{(a)}\Pi^{\langle c\rangle}\,\hat{h}_{\mu\nu}, \qquad \sum_{c\in\mathscr{C}} \Pi^{\langle c\rangle} = \mathbf{1}, \tag{11.70}$$

so that $\hat{h}_{\mu\nu} = \sum_{a,c} \hat{h}_{\mu\nu}^{(a,\langle c\rangle)}$. When one wishes to display the interaction-sourced form explicitly, this becomes

$$\hat{h}_{\mu\nu}^{(a,\langle c\rangle)}(x) = \Pi^{\langle c\rangle}\Pi^{(a)}\left(\mathcal{P}^{(2)}\left[\int d^dx'\,\mathcal{U}_{\Phi\Theta}^{(a)}(x,x')\cdot\delta\hat{\boldsymbol{\Theta}}(x')\right]\cdot\mathbb{E}_{\mu\nu}^{\dagger}\right). \tag{11.71}$$

which is equivalent by commutativity to first projecting $\hat{h}$ and then expanding in modes (Definition 11.19 and eq. (11.34)).

Step 3: Physical interpretation and support

Each $\hat{h}_{\mu\nu}^{(a,\langle c\rangle)}$ captures the typed TT response in sector a through coupling channel $\langle c\rangle$. For example, the correlational channel encodes long-range, coherence-induced curvature; it vanishes if $\mathcal{U}_{\Phi\Theta}^{(\mathrm{corr})} \equiv 0$. On the certified plateau $\mathfrak{P}$,

$$P_x(\lambda_{\mathrm{UV}})\,K_{\mathrm{IR}}^{(\ell)}\,\hat{h}_{\mu\nu}^{(a,\langle c\rangle)} = \hat{h}_{\mu\nu}^{(a,\langle c\rangle)},$$

so band support is preserved and microcausality follows from the typed Peierls kernel after projection (Propositions 11.14 and 11.38).

Definition: Correlational Graviton

Definition 11.42 (Sectoral graviton fields via commuting triadic projection)**.** Let the typed graviton carrier be $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu} \equiv \mathcal{P}^{(2)}[\delta\hat{\boldsymbol{\Phi}}]\cdot\mathbb{E}_{\mu\nu}^{\dagger}$ (Definitions 11.23 and 11.28 and eq. (11.49)). Let $\{\Pi^{(a)}\}_{a\in\{\mathrm{corr,vac,spec}\}}$ be the sector projectors that resolve the identity and commute with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ on the certified plateau $\mathfrak{P}$ (Definitions 6.280, 9.10 and 11.24). The *sectoral graviton fields* are defined purely by commuting projections:

$$\hat{h}_{\mu\nu}^{(a)}(x) := \Pi^{(a)}\,\hat{h}_{\mu\nu}(x) = \Pi^{(a)}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}(x), \qquad \sum_a \Pi^{(a)} = \mathbf{1}, \quad \Pi^{(a)}\Pi^{(b)} = \delta_{ab}\Pi^{(a)}. \tag{11.72}$$

In particular, the *Correlational Graviton* is

$$\boxed{\hat{h}^{(\mathrm{corr})}_{\mu\nu}(x) := \Pi^{(\mathrm{corr})}\,\hat{h}_{\mu\nu}(x).} \tag{11.73}$$

When one wishes to display the interaction-sourced form explicitly (cf. Sections 10.19.6 and 11.3), this is equivalent—by commutativity of the projectors on $\mathfrak{P}$—to

$$\boxed{\hat{h}^{(\mathrm{corr})}_{\mu\nu}(x) \;\equiv\; \mathcal{P}^{(2)}\Big[\int d^dx'\,\mathcal{U}^{(\mathrm{corr})}_{\Phi\Theta}(x,x')\cdot\delta\hat{\boldsymbol{\Theta}}(x')\Big]\cdot\mathbb{E}^{\dagger}_{\mu\nu},} \tag{11.74}$$

which is a notational convenience; the *defining* construction in this chapter is the typed/sector projector definition (11.72). The temporal/coherence fluctuation $\hat{\tau}_{\mu\nu}$ is TT-null (Chapter 11) and cannot contribute to any $\hat{h}^{(a)}_{\mu\nu}$.

Definition: Vacuum Graviton Field

Definition 11.43 (Vacuum graviton (typed sectoral projection))**.** The *vacuum graviton field* is the vacuum-sector projection of the typed carrier:

$$\boxed{\hat{h}^{(\mathrm{vac})}_{\mu\nu}(x) \;:=\; \Pi^{(\mathrm{vac})}\,\hat{h}_{\mu\nu}(x) \;=\; \Pi^{(\mathrm{vac})}\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}(x).} \tag{11.75}$$

When the interaction-kernel representation is preferred for exposition, $\hat{h}^{(\mathrm{vac})}_{\mu\nu}$ admits the equivalent form $\mathcal{P}^{(2)}\big[\int\mathcal{U}^{(\mathrm{vac})}_{\Phi\Theta}\cdot\delta\hat{\boldsymbol{\Theta}}\big]\cdot\mathbb{E}^{\dagger}_{\mu\nu}$ (cf. Section 10.19.6); physically it captures curvature sourced by vacuum structure $\bar{\Theta}$ and the symmetry content of $\mathcal{M}_{\mathrm{vac}}$ (Section 9.18.6).

Physical Interpretation

- $\hat{h}^{(\mathrm{vac})}_{\mu\nu}$ encodes quasi-static or slowly varying TT curvature arising from vacuum expectation structure rather than long-range entanglement; it is dominant when $\mathcal{M}_{\mathrm{vac}}$ carries nontrivial order (e.g. SSB regimes).
- On $\mathfrak{P}$, band support is preserved: $P_x(\lambda_{\mathrm{UV}})K^{(\ell)}_{\mathrm{IR}}\hat{h}^{(a)}_{\mu\nu} = \hat{h}^{(a)}_{\mu\nu}$, and microcausality follows from the typed Peierls kernel after projection (Propositions 11.14 and 11.38).

Definition: Spectral Graviton Field

Definition 11.44 (Spectral graviton (typed sectoral projection))**.** The *spectral graviton field* is the spectral-sector projection of the typed carrier:

$$\boxed{\hat{h}^{(\mathrm{spec})}_{\mu\nu}(x) \;:=\; \Pi^{(\mathrm{spec})}\,\hat{h}_{\mu\nu}(x) \;=\; \Pi^{(\mathrm{spec})}\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}(x).} \tag{11.76}$$

Equivalently (for display only), one may write $\hat{h}^{(\mathrm{spec})}_{\mu\nu} \equiv \mathcal{P}^{(2)}\big[\int\mathcal{U}^{(\mathrm{spec})}_{\Phi\Theta}\cdot\delta\hat{\boldsymbol{\Theta}}\big]\cdot\mathbb{E}^{\dagger}_{\mu\nu}$ to emphasize sourcing by localized/high-frequency matter dynamics (Section 10.19.6).

Physical Interpretation

- *Spectral sector (typed TT).* The field $\hat{h}^{(\mathrm{spec})}_{\mu\nu}(x) := \Pi^{(\mathrm{spec})}\hat{h}_{\mu\nu}(x)$ (Definition 11.44) captures TT curvature sourced by the *local spectral content* of the Tantrakyma field, i.e. high-frequency or localized excitations pulled back through the spectral component of the interaction kernel $\mathcal{U}^{(\mathrm{spec})}_{\Phi\Theta}$ (Section 10.19.6).
- *Dominant regime and causal control.* This contribution dominates when the matter spectral density is large—e.g., in scattering processes or sharply localized wavepackets—and it is the natural arena for the typed propagator and amplitude constructions (Sections 11.2 and 11.3.4). Microcausality is preserved after sector projection because the channel/sector projectors commute with the typed Peierls kernel (Propositions 11.14 and 11.38).
- *Complementarity within the triad.* $\hat{h}^{(\mathrm{spec})}$ complements the *correlational* and *vacuum* gravitons—$\hat{h}^{(\mathrm{corr})}$ (Definition 11.42 and eq. (11.74)) encodes long-range, coherence-driven curvature; $\hat{h}^{(\mathrm{vac})}$ (Definition 11.43) encodes vacuum-structure responses (e.g., SSB backgrounds). Their relative weights are quantified by the triadic residue vector $\vec{Z}$ (Definition 11.21) and can be further refined per coupling channel via the channel-resolved visibilities (Definition 11.39). On the certified plateau $\mathfrak{P}$ the band tags preserve support and factorization across sectors (Definitions 6.280 and 9.10 and Proposition 11.20).

Graviton Mode	Source Channel	Dominant Regime	Interpretative Notes
$\hat{h}^{(\mathrm{corr})}_{\mu\nu}(x)$	Quantum-informational structure; long-range entanglement	**Pre-geometric / coherence-dominated to mesoscopic**	Geometry-as-entanglement response; suppressed when coherence meters vanish.
$\hat{h}^{(\mathrm{vac})}_{\mu\nu}(x)$	Symmetry/ordering of the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$	**Background-dominated / symmetry-broken phases**	Quasi-static TT curvature from vacuum alignment and order parameters (SSB).
$\hat{h}^{(\mathrm{spec})}_{\mu\nu}(x)$	Localized energy–momentum / high-frequency spectral content	**Microscopic to high-energy / short-wavelength**	Scattering and localized wavepacket regime; approaches classical GR limit for coarse-grained stress–energy.

Table 11.1: Dominance regimes of the triad-resolved graviton contributions.

11.1.4 Triadic Decomposition of the Graviton Field

We have established that the quantum graviton field $\hat{h}_{\mu\nu}(x)$ is the typed, transverse–traceless (TT) projection of the metric fluctuation (equivalently, the spin–2 projection of the Gaiamiti fluctuation) via a geometric embedding (Definitions 11.23 and 11.28 and eq. (11.49)). A central feature of the IQR formalism is that the fluctuation field is not monolithic: it admits a decomposition into three orthogonal components reflecting distinct relational origins—*correlational*, *vacuum*, and *spectral*. Because $\mathcal{P}^{(2)}$ (equivalently $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$) is linear and commutes with the sector projectors on the certified plateau $\mathfrak{P}$ (Definitions 6.280, 9.10 and 11.24), the typed graviton inherits a natural triadic decomposition.

1. Mathematical basis of the decomposition

Let $\delta\hat{\mathbf{\Phi}}(x) \in \Gamma[\mathrm{End}(T_{|\Omega(x)\rangle}\mathcal{M}_{\mathrm{vac}})]$ admit the triadic split

$$\delta\hat{\mathbf{\Phi}}(x) = \delta\hat{\mathbf{\Phi}}^{(\mathrm{corr})}(x) + \delta\hat{\mathbf{\Phi}}^{(\mathrm{vac})}(x) + \delta\hat{\mathbf{\Phi}}^{(\mathrm{spec})}(x),$$

as induced by the commuting sector projectors $\{\Pi^{(a)}\}_{a\in\{\mathrm{corr,vac,spec}\}}$ and the triadic interaction channels (cf. Definition 11.24 and Sections 10.19.6 and 11.3). Applying the spin–2 projection and the dual embedding $\mathbb{E}^{\dagger}_{\mu\nu}$ (Definition 11.19), we obtain:

Definition 11.45 (Triadic decomposition of the typed graviton)**.** Let the typed graviton be $\hat{h}_{\mu\nu}(x) := \mathcal{P}^{(2)}[\delta\hat{\mathbf{\Phi}}](x) \cdot \mathbb{E}^{\dagger}_{\mu\nu}$ (eq. (11.49)). Its *triadic decomposition* is

$$\boxed{\hat{h}_{\mu\nu}(x) = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{h}^{(a)}_{\mu\nu}(x), \qquad \hat{h}^{(a)}_{\mu\nu}(x) := \mathcal{P}^{(2)}\Big[\delta\hat{\mathbf{\Phi}}^{(a)}(x)\Big] \cdot \mathbb{E}^{\dagger}_{\mu\nu} \equiv \Pi^{(a)}\hat{h}_{\mu\nu}(x),} \tag{11.77}$$

where the last equality uses $[\Pi^{(a)}, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}] = 0$ (Definition 11.24).

Each $\hat{h}^{(a)}_{\mu\nu}(x)$ is a symmetric, traceless $(0,2)$-tensor on $(\mathcal{X}_q, \bar{\Sigma})$ and transforms covariantly; $\hat{\tau}_{\mu\nu}$ is TT-null and does not contribute (Chapter 11).

2. Mode algebra and Fock factorization

Combine the definition (11.77) with the triad-resolved TT mode expansion (Definition 11.19 and eq. (11.34)):

$$\hat{h}^{(a)}_{\mu\nu}(x) = \sum_{\lambda=1}^{d_g} \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}} \Big[e^{(a,\lambda)}_{\mu\nu}(k;x)\, \hat{a}_{a,\lambda}(\mathbf{k})\, e^{-ik\cdot x} + e^{(a,\lambda)}_{\mu\nu}(k;x)^*\, \hat{a}^{\dagger}_{a,\lambda}(\mathbf{k})\, e^{+ik\cdot x} \Big],$$

with TT polarizations orthonormal in the $\bar{\Sigma}$-inner product (Section 11.1.3). The only nonvanishing commutators are (Proposition 11.20)

$$\boxed{\Big[\hat{a}_{a,\lambda}(\mathbf{k}),\, \hat{a}^{\dagger}_{b,\lambda'}(\mathbf{k}')\Big] = \delta_{ab}\,\delta_{\lambda\lambda'}\,(2\pi)^{d-1}\,2\omega_a(\mathbf{k})\,\delta^{(d-1)}(\mathbf{k}-\mathbf{k}'), \qquad \text{all others } = 0.} \tag{11.78}$$

Corollary 11.46 (Fock factorization across the triad)**.** *The graviton Fock space factorizes as the completed tensor product of sector Fock spaces,*

$$\boxed{\mathscr{F}_\Phi \;\simeq\; \mathscr{F}_\Phi^{(\mathrm{corr})} \,\widehat{\otimes}\, \mathscr{F}_\Phi^{(\mathrm{vac})} \,\widehat{\otimes}\, \mathscr{F}_\Phi^{(\mathrm{spec})},} \tag{11.79}$$

with commuting creation/annihilation operators labeled by the sector index a as in (11.78) *(cf. Proposition 11.20).*

3. Spectral diagnostics and support

On the physical Hilbert space $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ (Chapter 8), each sector's two-point admits a Källén–Lehmann representation with nonnegative residue and density; collecting the residues defines the triadic *residue vector* $\vec{Z} = (Z_{\mathrm{corr}}, Z_{\mathrm{vac}}, Z_{\mathrm{spec}})$ (Definition 11.21). Band tags commute with the sector and typed projectors, hence preserve support and causal properties:

$$P_x(\lambda_{\mathrm{UV}})\, K_{\mathrm{IR}}^{(\ell)}\, \hat{h}_{\mu\nu}^{(a)} = \hat{h}_{\mu\nu}^{(a)}, \tag{11.80}$$

and microcausality follows from the typed Peierls kernel (*Propositions* 11.14*and* 11.38). (11.81)

This triad-resolved structure underlies the channel projections (Section 11.1.3), the propagator (Section 11.2), and scattering amplitudes (Section 11.3.4), with typed Parasymmetric TLO readouts assembled per sector (Chapter 9).

2. Physical Interpretation of the Graviton Species

Each component $\hat{h}_{\mu\nu}^{(a)}(x)$ in the triadic decomposition (11.77) corresponds to a physically distinct graviton contribution, selected by the commuting sector projectors $\Pi^{(a)}$ and compatible with the typed TT carrier $\hat{h}_{\mu\nu}$ (Definitions 11.24, 11.28 and 11.45). The sector labels track relational sources—correlational, vacuum, and spectral—and they propagate through the mode algebra and Fock factorization (Definition 11.19, eq. (11.34), and Corollary 11.46).

- **Correlational Gravitons** $\hat{h}_{\mu\nu}^{(\mathrm{corr})}(x)$. Defined by the sectoral projection $\hat{h}_{\mu\nu}^{(\mathrm{corr})} := \Pi^{(\mathrm{corr})}\hat{h}_{\mu\nu}$ (Definition 11.42), these quanta encode TT curvature sourced by long-range coherence and entanglement structure, optionally represented via the interaction-kernel form (11.74) (see also channel projectors in Definition 11.36). They realize the principle that *information shapes geometry*, resonant with the ER=EPR perspective [520], holographic tensor-network intuition [1], and modular-flow constructions [521, 522]. In the typed ledger, their strength is captured by sectoral residues in the triadic Källén–Lehmann representation ($\vec{Z}$; Definition 11.21) and by the Parasymmetric TLO visibilities (Chapter 8); the contribution vanishes when coherence meters collapse on the certified plateau $\mathfrak{P}$ (Definitions 6.280 and 9.10).

- **Vacuum Gravitons** $\hat{h}_{\mu\nu}^{(\mathrm{vac})}(x)$. Given by $\hat{h}_{\mu\nu}^{(\mathrm{vac})} := \Pi^{(\mathrm{vac})}\hat{h}_{\mu\nu}$ (Definition 11.43 and Section 11.1.3), these excitations arise from the structure of the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ (Sections 6.1.8 and 9.18.6) and behave as typed Goldstone modes when geometric symmetries are spontaneously broken (Proposition 11.29). Their masslessness corresponds

to the vanishing of the TT-projected mass operator $\mathcal{M}^{[\mathrm{TT}]}$ (Definition 11.33), while small explicit breakings generate $m^2_{\mathrm{TT}} = \mathcal{O}(\epsilon)$ with plateau bounds (Corollary 11.30). These modes capture quasi-static TT curvature from vacuum alignment and order parameters; they also furnish the background against which the typed propagator and Ward identities are evaluated (Section 11.2 and eq. (11.25)). Related vacuum transitions and tunneling phenomena are encompassed in the standard picture of false-vacuum decay [523].

- **Spectral Gravitons** $\hat{h}^{(\mathrm{spec})}_{\mu\nu}(x)$. Defined by $\hat{h}^{(\mathrm{spec})}_{\mu\nu} := \Pi^{(\mathrm{spec})}\hat{h}_{\mu\nu}$ (Definition 11.44 and Section 11.1.3) and optionally by the spectral piece of the interaction kernel $\mathcal{U}^{(\mathrm{spec})}_{\Phi\Theta}$ (Section 10.19.6), these carry energy–momentum–dominated TT curvature. They govern high-frequency, localized, or high-energy regimes and interface directly with the typed propagator and scattering constructions (Sections 11.2, 11.2.2 and 11.3.4). In the semiclassical limit they reduce to helicity-2 perturbations of linearized GR [245], with microcausality ensured by the typed Peierls kernel and band-stable support (Propositions 11.14 and 11.38 and Definitions 6.280 and 9.10).

3. Consequences and Theoretical Significance

The triadic decomposition $\hat{h}_{\mu\nu} = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{h}^{(a)}_{\mu\nu}$ (Definition 11.45 and eq. (11.77)) reveals the fundamentally *composite* character of gravitational excitation in the IQR framework. Because the sector projectors $\Pi^{(a)}$ commute with the typed TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ on the certified plateau $\mathfrak{P}$ (Definitions 6.280, 9.10 and 11.24), each contribution propagates as a well-defined typed channel compatible with microcausality (Proposition 11.14) and with the mode/Fock infrastructure (Definition 11.19, eq. (11.34), and Corollary 11.46). This leads to the following implications:

- **Multi-channel gravitational interaction.** The sector (and optional coupling-channel) resolution (Section 11.1.3 and Definition 11.36) organizes propagation and interactions into independently readable blocks. In the sector/channel basis, the typed two-point and propagator inherit a block-diagonal structure compatible with the mode expansion and background geometry (Sections 11.2, 11.2.2 and 11.2.3). Dynamical couplings descend from the TT-linearized parent vertex (Section 11.3) and can be monitored via the typed Parasymmetric TLO readouts: law and state visibilities (Definitions 11.6 and 11.39), with positivity/dispersion constraints evaluated per block (Section 11.3.6). Renormalization and gauge-parameter independence are assessed on $\mathfrak{P}$ (Nielsen-flatness; Chapter 8).

- **New phenomenological pathways.** Contexts such as early-universe phases with strong vacuum alignment, near-vacuum decoherence, or topological transitions can be dominated by $\hat{h}^{(\mathrm{vac})}$ or $\hat{h}^{(\mathrm{corr})}$, not by $\hat{h}^{(\mathrm{spec})}$ (Definitions 11.42 and 11.43). Typed SSB protects masslessness in the TT sector (Proposition 11.29), while small explicit breakings obey the GMOR-style bound $m^2_{\mathrm{TT}} = \mathcal{O}(\epsilon)$ (Corollary 11.30) through the TT mass block $\mathcal{M}^{[\mathrm{TT}]}$ (Definition 11.33). Hence, observable geometric dynamics may arise without classical stress–energy dominance, and they remain consistent with causality via the typed Peierls bracket (eq. (11.25)).

- **A composite quantum graviton.** In IQR the graviton is not elementary but a sector-resolved superposition of typed TT excitations with distinct relational origins—entanglement/coherence, vacuum geometry, and spectral content (Definitions 11.42 to 11.44). This composition is quantitatively captured by the triadic residue vector $\vec{Z} = (Z_{\text{corr}}, Z_{\text{vac}}, Z_{\text{spec}})$ (Definition 11.21), realized in the KL representation on $\mathcal{H}_{\text{phys}}$ (Chapter 8), and supported by the Fock factorization across sectors (Corollary 11.46).

This reformulation places the gravitational field at the confluence of quantum information, vacuum structure, and energy–momentum dynamics—unifying these sources within a single typed, BRST-healthy, sector- and channel-aware pipeline (Definitions 11.6 and 11.24 and Sections 11.1.3, 11.2 and 11.3).

Graviton Type	Source of Geometry	Related Paradigm
Correlational	Entanglement and quantum coherence structure (sector projector $\Pi^{(\text{corr})}$)	ER=EPR; holographic tensor networks; modular flow
Vacuum	Moduli space and symmetry structure of $\mathcal{M}_{\text{vac}}$ (sector projector $\Pi^{(\text{vac})}$)	Goldstone modes; vacuum topology; phase transitions (SSB/GMOR)
Spectral	Local spectral/energy–momentum content (sector projector $\Pi^{(\text{spec})}$)	Linearized GR; GW phenomenology; semiclassical gravity

Table 11.2: The triadic nature of gravitational quanta and their conceptual anchors.

This triadic picture extends the physical meaning of gravitational phenomena beyond stress–energy sourcing, while preserving causality, positivity, and typed consistency on $\mathfrak{P}$ (Chapter 8). It enriches the ontology of quantum gravity and enables novel, nonlocal and symmetry-based interactions to be formulated and tested within a unified, sector-resolved framework.

11.1.5 Graviton Fock Space and Multi-Particle States

With the linearized, quantized TT modes identified (Definition 11.19 and eq. (11.34)) and the triad-resolved structure established (Definition 11.45 and eq. (11.77)), we now construct the *typed, triad-resolved* Fock space for geometric excitations. All constructions are performed on a certified plateau $\mathfrak{P}$ with BRST-closed band tags commuting with the typed and sector projectors (Definitions 6.280, 9.10 and 11.24), and all physical states are implicitly taken in the BRST cohomology $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$ (Chapter 8).

The Graviton Vacuum State

Definition 11.47 (Graviton vacuum (typed/triad, BRST-closed))**.** Let $|0\rangle_\Phi$ denote a vacuum vector annihilated by all TT graviton annihilation operators $\hat{a}_{a,\lambda}(\mathbf{k})$ appearing in the triad-

resolved mode expansion (Section 11.1.3 and Definition 11.19):

$$\boxed{\hat{a}_{a,\lambda}(\mathbf{k})\,|0\rangle_\Phi = 0, \qquad \forall\, a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\},\ \lambda,\ \mathbf{k}.} \tag{11.82}$$

The *physical* vacuum is its BRST cohomology class $[\,|0\rangle_\Phi\,] \in \mathcal{H}_{\mathrm{phys}}$, satisfying $\hat{Q}_{\mathrm{BRST}}|0\rangle_\Phi = 0$ (Chapter 8).

The Graviton Fock Space

Definition 11.48 (Typed, triad-resolved graviton Fock space)**.** Let $\mathcal{H}_\Phi^{(1)}$ be the one-particle TT Hilbert space spanned by $\hat{a}^\dagger_{a,\lambda}(\mathbf{k})|0\rangle_\Phi$. The (bosonic) Fock space is

$$\boxed{\mathscr{F}_\Phi := \mathbb{C}\,|0\rangle_\Phi \ \oplus \bigoplus_{n\geq 1} \mathrm{Sym}\left[\underbrace{\mathcal{H}_\Phi^{(1)} \otimes \cdots \otimes \mathcal{H}_\Phi^{(1)}}_{n\ \text{times}}\right],} \tag{11.83}$$

and its *physical* subspace is the BRST cohomology $\mathscr{F}_\Phi^{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}}; \mathscr{F}_\Phi)$ (Chapter 8). The creation/annihilation algebra is sector-diagonal as in (11.78), ensuring independence of the triadic sectors.

Multi-Particle States and Triadic Decomposition

Definition 11.49 (Triadic-labeled creation/annihilation and basis)**.** For each sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ and polarization λ, the operators $\hat{a}_{a,\lambda}(\mathbf{k})$, $\hat{a}^\dagger_{a,\lambda}(\mathbf{k})$ obey the mode algebra (11.78). A convenient *typed, triad-resolved* basis for the n-particle sector is

$$\boxed{\left|\mathbf{k}_1, \lambda_1, a_1; \ldots; \mathbf{k}_n, \lambda_n, a_n\right\rangle := \frac{1}{\sqrt{n!}}\, \hat{a}^\dagger_{a_1,\lambda_1}(\mathbf{k}_1) \cdots \hat{a}^\dagger_{a_n,\lambda_n}(\mathbf{k}_n)\,|0\rangle_\Phi,} \tag{11.84}$$

implicitly symmetrized under permutations. States are understood modulo BRST-exact vectors; hence we identify their cohomology classes in $\mathscr{F}_\Phi^{\mathrm{phys}} \subset \mathcal{H}_{\mathrm{phys}}$.

Proposition 11.50 (Fock factorization across the triad)**.** *With the sector-diagonal algebra* (11.78)*, the Fock space factorizes as*

$$\boxed{\mathscr{F}_\Phi \ \simeq\ \mathscr{F}_\Phi^{(\mathrm{corr})} \,\widehat{\otimes}\, \mathscr{F}_\Phi^{(\mathrm{vac})} \,\widehat{\otimes}\, \mathscr{F}_\Phi^{(\mathrm{spec})},} \tag{11.85}$$

and the same holds for the physical subspace $\mathscr{F}_\Phi^{\mathrm{phys}}$ (cf. Corollary 11.46).

Remarks (typed certification and visibilities). (i) The *TT state visibility* $\Lambda^{[\mathrm{TT}]}_{\mathrm{state}}$ used in the Parasymmetric TLO readout (Chapter 9) is computed from the TT two-point Källén–Lehmann content—namely, the sectoral residues and spectral densities $\{Z_a, \rho_a^{(2)}\}_{a=\mathrm{corr,vac,spec}}$ (Definitions 11.21 and 11.39). On the certified plateau $\mathfrak{P}$ these readouts are Nielsen-flat and

band-stable (Definitions 6.280 and 9.10). (ii) All multiparticle observables inherit microcausality from the typed Peierls kernel after projection (Proposition 11.14), and their sectoral decomposition is preserved by the commuting projectors $\Pi^{(a)}$ (Definition 11.24). (iii) When channel projectors $\Pi^{\langle c\rangle}$ are used (Definition 11.36), the basis (11.84) refines by including a channel label $\langle c\rangle$, and the factorization extends accordingly.

11.2 The Graviton Propagator

With the typed, triad-resolved graviton field and Fock construction in hand (Definitions 11.45 and 11.48, eq. (11.77), and Corollary 11.46), we now define and analyze the *graviton propagator*. Throughout, causality and equal-time limits are controlled by the typed Peierls structure (eq. (11.25)) on the chronogeometric background $(\mathcal{X}_q, \bar{\Sigma})$ (Section 5.2.6). Time ordering is taken with respect to the $\bar{\Sigma}$-induced foliation (Section 11.2.1). All statements are certified on the plateau $\mathfrak{P}$ with BRST-closed band tags commuting with the typed and sector projectors (Definitions 6.280, 9.10 and 11.24).

We recall the triadic split of the typed graviton (Definition 11.45):

$$\hat{h}_{\mu\nu}(x) = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{h}^{(a)}_{\mu\nu}(x), \qquad \hat{h}^{(a)}_{\mu\nu} = \Pi^{(a)}\hat{h}_{\mu\nu}.$$

Orthogonality of the sector projectors and their commutation with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ imply a diagonal free two-point structure; hence the full propagator decomposes into a sum of sector blocks with no cross terms at the free level:

$$\boxed{G^{\mathrm{grav}}_{\mu\nu}{}^{\rho\sigma}(x,x') = \sum_{a\in\{\mathrm{corr,vac,spec}\}} G^{(a)}_{\mu\nu}{}^{\rho\sigma}(x,x').} \tag{11.86}$$

Definition 11.51 (Triad-resolved typed graviton propagator)**.** For a given sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, the **(typed) Feynman two-point function** (graviton propagator) is defined on the physical vacuum (Definition 11.47) by:

$$\boxed{G^{(a)}_{\mu\nu}{}^{\rho\sigma}(x,x') \;:=\; {}_{\Phi}\!\left\langle 0\right| T_{\bar{\Sigma}}\!\left\{\hat{h}^{(a)}_{\mu\nu}(x)\,\hat{h}^{(a)\,\rho\sigma}(x')\right\}\left|0\right\rangle_{\Phi},} \tag{11.87}$$

where $T_{\bar{\Sigma}}$ is the time-ordering operator with respect to the causal time of $\bar{\Sigma}$ (Section 11.2.1). Equivalently, $G^{(a)}$ is the TT-typed Peierls/Feynman kernel of the sectoral wave operator (cf. Section 11.1.2).

1. Relation to mode expansion

Using the triad-resolved TT mode expansion (Definition 11.19 and eq. (11.34)) and Wick's theorem, one finds an operator–polarization representation. In momentum space on a locally stationary patch (or in Riemann normal coordinates), this reads

$$\boxed{G^{(a)}_{\mu\nu}{}^{\rho\sigma}(k) = \frac{-i}{k^2 - m^2_{a,\mathrm{TT}} + i\epsilon}\,\Pi^{[\mathrm{TT}](a)}_{\mu\nu}{}^{\rho\sigma}(k;\bar{\Sigma}),} \tag{11.88}$$

where $\Pi^{[\mathrm{TT}](a)}$ is the TT polarization projector assembled from the orthonormal TT tensors $e^{(a,\lambda)}_{\mu\nu}(k)$ (Section 11.1.3). In the spontaneously-broken, typed limit (Proposition 11.29) one has $m^2_{a,\mathrm{TT}} = 0$; small explicit breakings yield a GMOR-style shift $m^2_{a,\mathrm{TT}} = \mathcal{O}(\epsilon)$ (Corollary 11.30 and Definition 11.33).

2. Propagator as typed Green's function

Let $K^{[\mathrm{TT}]}$ denote the TT-projected Lichnerowicz-type wave operator on $(\mathcal{X}_q, \bar{\Sigma})$, augmented by the TT mass/mixing block. For each sector a,

$$\boxed{K^{[\mathrm{TT}](a)}_{\mu\nu}{}^{\alpha\beta}(x)\,\hat{h}^{(a)}_{\alpha\beta}(x) = 0, \qquad K^{[\mathrm{TT}](a)} := \mathcal{L}^{[\mathrm{TT}]} - \mathcal{M}^{[\mathrm{TT}](a)},} \tag{11.89}$$

with $\mathcal{M}^{[\mathrm{TT}](a)} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\mathcal{M}^{(a)}\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 11.33). The Feynman propagator is the Green's function of $K^{[\mathrm{TT}](a)}$:

$$\boxed{K^{[\mathrm{TT}](a)}_{\mu\nu}{}^{\alpha\beta}(x)\,G^{(a)}_{\alpha\beta}{}^{\rho\sigma}(x,x') = i\,\Pi^{[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(\bar{\Sigma})\,\delta^{(d)}(x-x'),} \tag{11.90}$$

so that the causal difference of retarded/advanced solutions reproduces the typed Peierls kernel $\Delta^{[\mathrm{TT}]}$ (Section 11.1.2). Microcausality and band support follow from $\operatorname{supp}\Delta^{[\mathrm{TT}]} \subseteq$ the $\bar{\Sigma}$-null cone and the commutation of band tags with the projectors (Propositions 11.14 and 11.38 and Definitions 6.280 and 9.10).

3. Triadic Källén–Lehmann representation

On $\mathcal{H}_{\mathrm{phys}}$ the TT two-point admits a sector-resolved KL form (Definition 11.21):

$$\boxed{\Delta^{(2),a}(q) = \frac{Z_a}{q^2 + i\epsilon} + \int_0^\infty d\mu^2\,\frac{\rho^{(2)}_a(\mu^2)}{q^2 - \mu^2 + i\epsilon}, \qquad Z_a \geq 0,\ \rho^{(2)}_a(\mu^2) \geq 0,} \tag{11.91}$$

with residue vector $\vec{Z} = (Z_{\mathrm{corr}}, Z_{\mathrm{vac}}, Z_{\mathrm{spec}})$. In the exact SSB, TT-typed limit one has $Z_a > 0$ and $\operatorname{Spec}\mathcal{M}^{[\mathrm{TT}]} = \{0\}$ (Proposition 11.29 and Definition 11.33); explicit breakings deform the spectral threshold by $\mathcal{O}(\epsilon)$ (Corollary 11.30). These spectral data feed the TT state-visibility meters in the typed Parasymmetric TLO (Chapter 9).

4. Background-covariant refinements

In general backgrounds one must use bitensors and $\bar{\Sigma}$-parallel transporters; polarization projectors become point-split and the momentum-space formulas give way to Hadamard/Schwinger–DeWitt constructions. These refinements are presented in Section 11.2.3, and the operator-basis viewpoint in Section 11.2.2. The time-ordering and Feynman prescriptions are summarized in Section 11.2.1.

Summary. The typed, triad-resolved graviton propagator is the Green's function of the TT wave operator, diagonal in the triadic basis at the free level, with a sector-wise KL representation that is positive on $\mathcal{H}_{\mathrm{phys}}$ and Nielsen-flat on $\mathfrak{P}$. It furnishes the universal building block for the interaction analysis in Section 11.3.

11.2.1 The Time-Ordering Operator and the Feynman Propagator

In the relational IQR framework, chronological ordering is defined by the causal cone of the chronogeometric background $(\mathcal{X}_q, \bar{\Sigma})$ (Section 5.2.6). Accordingly, all time-ordering and Feynman prescriptions are *background-covariant* with respect to $\bar{\Sigma}_{\mu\nu}$ and are applied after the typed TT selection (Section 11.1.3 and eq. (11.49)). Band tags commute with the projectors and preserve causal support on the certified plateau $\mathfrak{P}$ (Definitions 6.280, 9.10 and 11.24).

Definition 11.52 (TT time–ordering (TLO) ledgers)**.** On the certified plateau $\mathfrak{P}$, the $\bar{\Sigma}$–time–ordering operator $T_{\bar{\Sigma}}$ (Definition 11.53) and the transverse–traceless and triadic projectors satisfy the bookkeeping ("ledgers") below:

(a) **Commutation with projectors.** $[\,T_{\bar{\Sigma}},\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,] = 0$ and $[\,T_{\bar{\Sigma}},\, \Pi^{(a)}\,] = 0$ for $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$; moreover the band tag commutes as well: $[\,\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell},\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,] = [\,\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell},\, \Pi^{(a)}\,] = 0$ (Definition 9.10 and Proposition 11.25).

(b) **TT visibility / Ward residual.** For conserved external insertions, longitudinal pieces are contact terms that drop out under TT projection; diagrammatically, contracting external legs with the TT Ward identity leaves only TT exchange (Lemma 11.92).

(c) **Causal compatibility.** $T_{\bar{\Sigma}}$, $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and the IR window $K^{(\ell)}_{\mathrm{IR}}$ preserve $\bar{\Sigma}$–causal support, so TT–projected retarded/advanced and Feynman kernels are well defined (Sections 11.2.1 and 11.2.3).

These ledgers justify using only TT, triad-resolved internal lines $G^{\mathrm{F},[\mathrm{TT}],(a)}$ and typed vertices in amplitudes (Section 11.3.4).

Definition 11.53 (Time ordering with respect to $\bar{\Sigma}$)**.** Let $J^{\pm}_{\bar{\Sigma}}(x)$ denote the future/past causal sets defined by the $\bar{\Sigma}$-null cone, and let $\Theta_{\bar{\Sigma}}(x \succeq y) := \mathbf{1}_{x \in J^{+}_{\bar{\Sigma}}(y)}$. For bosonic operators $\hat{A}(x), \hat{B}(y)$ we define the $\bar{\Sigma}$-*time-ordering operator* by

$$\boxed{T_{\bar{\Sigma}}\Big\{\hat{A}(x)\hat{B}(y)\Big\} := \Theta_{\bar{\Sigma}}(x \succeq y)\,\hat{A}(x)\hat{B}(y) + \Theta_{\bar{\Sigma}}(y \succeq x)\,\hat{B}(y)\hat{A}(x),} \tag{11.92}$$

with the equal-time limit defined by symmetric point-splitting consistent with the typed Peierls bracket (eq. (11.25)) and reproducing the typed ETCR on a Cauchy slice (Definition 11.8 and Proposition 11.4).

Definition 11.54 (Typed TT Feynman propagator)**.** For the typed graviton $\hat{h}_{\mu\nu}$ (Definition 11.28), the *Feynman two-point function* (TT-projected) is

$$\boxed{i\,G^{\mathrm{F},[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(x,y) := {}_{\Phi}\langle 0|\, T_{\bar{\Sigma}}\Big\{\hat{h}_{\mu\nu}(x)\,\hat{h}^{\rho\sigma}(y)\Big\}\,|0\rangle_{\Phi}, \qquad |0\rangle_{\Phi} \text{ as in } \textit{Definition } 11.47.} \tag{11.93}$$

Equivalently, since $\hat{h}$ is TT-typed by construction, $G^{\mathrm{F},[\mathrm{TT}]}$ is the TT block of the full Feynman kernel.

Proposition 11.55 (Retarded/advanced representation and Green identity)**.** *Let $G^{\mathrm{ret/adv},[\mathrm{TT}]}$ be the TT-projected retarded/advanced Green operators of the TT wave operator $K^{[\mathrm{TT}]}$ (Section 11.1.2 and eq. (11.89)). Then*

$$\boxed{G^{\mathrm{F},[\mathrm{TT}]}(x,y) = \Theta_{\bar{\Sigma}}(x \succeq y)\, G^{\mathrm{ret},[\mathrm{TT}]}(x,y) + \Theta_{\bar{\Sigma}}(y \succeq x)\, G^{\mathrm{adv},[\mathrm{TT}]}(x,y),} \tag{11.94}$$

and $G^{\mathrm{F},[\mathrm{TT}]}$ solves the TT Green equation with the Feynman $i\epsilon$ prescription:

$$\boxed{K^{[\mathrm{TT}]}_{\mu\nu}{}^{\alpha\beta}(x)\, G^{\mathrm{F},[\mathrm{TT}]}_{\alpha\beta}{}^{\rho\sigma}(x,y) = i\,\Pi^{[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(\bar{\Sigma})\,\delta^{(d)}(x-y).} \tag{11.95}$$

Consequently, the causal difference reproduces the typed Peierls kernel $\Delta^{[\mathrm{TT}]} = G^{\mathrm{ret},[\mathrm{TT}]} - G^{\mathrm{adv},[\mathrm{TT}]}$ (Section 11.1.2).

Corollary 11.56 (Triadic block-diagonality and microcausality)**.** *With sector projectors $\Pi^{(a)}$ commuting with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definition 11.24), the Feynman kernel is block-diagonal:*

$$\boxed{G^{\mathrm{F},[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma} = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \Pi^{(a)}_{\mu\nu}{}^{\alpha\beta}\, G^{\mathrm{F},[\mathrm{TT}]}_{\alpha\beta}{}^{\gamma\delta}\, \Pi^{(a)}_{\gamma\delta}{}^{\rho\sigma},} \tag{11.96}$$

and microcausality holds: the commutator kernel has support only on the $\bar{\Sigma}$-null cone ($\mathrm{supp}\,\Delta^{[\mathrm{TT}]} \subseteq \partial J^{\pm}_{\bar{\Sigma}}$) (Proposition 11.14).

IR/UV band stability. On $\mathfrak{P}$, inserting the band tags as a sandwich, $G^{\mathrm{F},[\mathrm{TT}]}_{\mathfrak{B}} := K^{(\ell)}_{\mathrm{IR}}\, P_x(\lambda_{\mathrm{UV}})\, G^{\mathrm{F},[\mathrm{TT}]}\, P_x(\lambda_{\mathrm{UV}})\, K^{(\ell)}_{\mathrm{IR}}$, preserves typed support and microcausality because the tags commute with the typed/sector projectors and do not enlarge causal cones (Definitions 6.280 and 9.10 and Proposition 11.38). Equal-time limits of (11.93) reproduce the typed ETCR on a Cauchy slice (Definition 11.8 and Proposition 11.4), while momentum-space forms reduce to the polarization-projector representation (eq. (11.88)).

Canonical role in perturbative gravity. The $\bar{\Sigma}$-time-ordered product $T_{\bar{\Sigma}}\{\cdot\}$ (Definition 11.53) defines the typed Feynman kernel $G^{\mathrm{F},[\mathrm{TT}]}$ (Definition 11.54), which enters every term of the Dyson expansion for scattering on $(\mathcal{X}_q, \bar{\Sigma})$. Concretely, $i\,G^{\mathrm{F},[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(x,y) = {}_{\Phi}\langle 0|\, T_{\bar{\Sigma}}\{\hat{h}_{\mu\nu}(x)\hat{h}^{\rho\sigma}(y)\}\,|0\rangle_{\Phi}$ provides the covariant, causal amplitude for a TT graviton created at y to be annihilated at x, with forward/backward propagation in $\bar{\Sigma}$-time encoded by eqs. (11.94) and (11.95). Equal-time limits are taken by $\bar{\Sigma}$-covariant point-splitting compatible with the typed Peierls bracket, so that $\lim_{x^0\to y^0} G^{\mathrm{F},[\mathrm{TT}]}$ reproduces the typed ETCR (eq. (11.25), Definition 11.8, and Proposition 11.4). We assume a Hadamard physical state on $\mathcal{H}_{\mathrm{phys}}$ so the two-point function has the standard short-distance form on curved backgrounds. This typed construction is the cornerstone for building covariant S-matrix elements in perturbative QFT, here adapted to the IQR setting ([82, 155, 403, 502]).

Field-theoretic and diagrammatic interpretation. The operator $T_{\bar{\Sigma}}$ enforces causal consistency of virtual exchanges with respect to the $\bar{\Sigma}$-null cone, and the causal difference reproduces the typed Peierls kernel (eq. (11.25) and Proposition 11.14). Hence each internal graviton line is a *TT-projected* Feynman propagator. On the certified plateau $\mathfrak{P}$, the band tags $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ are chosen $\bar{\Sigma}$-covariantly (e.g. as functions of the TT d'Alembertian) and commute with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$, $\Pi^{(a)}$, and (optionally) channel projectors $\Pi^{\langle c\rangle}$ (Definitions 6.280, 9.10, 11.24 and 11.36), so band-sandwiching *does not enlarge causal cones* (Proposition 11.38) and preserves equal-time limits. In the triadic basis, free internal lines are block-diagonal by sector (Definitions 11.45 and 11.51), with polarization structure captured by the TT projector assembled from orthonormal spin-2 tensors (Section 11.1.3); this mirrors the standard treatment of gauge bosons in perturbation theory ([82, 403, 502]). *Beyond tree level*, triadic blocks can mix via self-energies Σ_{ab} unless symmetry forbids it; our free-level statements and plateau diagnostics apply blockwise.

Physical interpretation of the triadic graviton propagator. As established in Section 11.1.4, Definition 11.51, and eq. (11.86), the sector-resolved kernel $G^{(a)}_{\mu\nu}{}^{\rho\sigma}(x,x')$ acts as the *quantum mediation kernel* for sector a:

- *Kernel.* $G^{(a)}$ is the typed Green function of the TT wave operator with sectoral TT mass/mixing block (eqs. (11.89) and (11.90)); as a convolution kernel it determines the linear response of $\hat{h}^{(a)}$ to localized sources with $\bar{\Sigma}$-causal support.
- *Quantum.* $G^{(a)}$ encodes off-shell propagation of virtual spin-2 quanta. Its KL spectral content—sectoral residues and densities—governs measurable amplitudes and dispersion/positivity constraints per sector (eq. (11.91) and Section 11.3.6). The massless TT pole is protected by the *typed Ward identity* associated with SSB in the Gaiamiti sector (Proposition 11.29); small explicit breaking yields a GMOR-style shift $m^2_{\mathrm{TT}} = \mathcal{O}(\epsilon)$ within plateau bounds (Definition 11.33 and Corollary 11.30). In the semiclassical limit of the spectral sector, $G^{(\mathrm{spec})}$ reproduces the standard helicity-2 propagator of linearized GR ([245, 502]).

Taken together, the typed, triad-resolved Feynman kernels furnish a covariant and causal foundation for perturbative gravity in IQR, unifying informational, vacuum, and energetic sources within a single propagator framework and staging the interaction analysis in Section 11.3.

11.2.2 Mode Expansion and the Operator Basis of the Propagator

The typed graviton Feynman kernel $G^{\mathrm{F},[\mathrm{TT}]}$ admits an explicit mode-sum representation obtained by inserting the triad-resolved TT mode expansion (Section 11.1.3 and eq. (11.34)) into the $\bar{\Sigma}$-time-ordered two-point (Definition 11.54). This builds a bridge between the operator (creation– annihilation) picture and the wave/Green-function picture familiar from perturbative QFT ([82, 524]).

1. Triad-resolved relativistic mode expansion (typed TT)

For each triadic sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ and orthonormal TT polarization basis $e^{(a,\lambda)}_{\mu\nu}(k)$ (Section 11.1.3), the typed graviton field expands as

$$\boxed{\hat{h}^{(a)}_{\mu\nu}(x) = \sum_{\lambda=1}^{d_g} \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}} \frac{1}{\sqrt{2\omega_{\mathbf{k}}}} \Big[\hat{a}_{a,\lambda}(\mathbf{k})\, e^{(a,\lambda)}_{\mu\nu}(k)\, e^{-ikx} + \hat{a}^{\dagger}_{a,\lambda}(\mathbf{k})\, e^{(a,\lambda)*}_{\mu\nu}(k)\, e^{+ikx} \Big],} \tag{11.97}$$

with $\omega_{\mathbf{k}} = \sqrt{\mathbf{k}^2 + m^2_{a,\mathrm{TT}}}$ and $[\hat{a}_{a,\lambda}(\mathbf{k}), \hat{a}^{\dagger}_{b,\lambda'}(\mathbf{k}')] = \delta_{ab}\delta_{\lambda\lambda'}(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{k}')$ (Definition 11.24 and Corollary 11.46).

2. Wightman kernels and $\bar{\Sigma}$-time ordering

Define the positive/negative-frequency Wightman kernels by vacuum contractions of (11.97):

$$G^{(a)>}_{\mu\nu}{}^{\rho\sigma}(x,y) := {}_{\Phi}\langle 0|\, \hat{h}^{(a)}_{\mu\nu}(x)\, \hat{h}^{(a)\,\rho\sigma}(y)\, |0\rangle_{\Phi}, \tag{11.98}$$

$$G^{(a)<}_{\mu\nu}{}^{\rho\sigma}(x,y) := {}_{\Phi}\langle 0|\, \hat{h}^{(a)}_{\mu\nu}(y)\, \hat{h}^{(a)\,\rho\sigma}(x)\, |0\rangle_{\Phi}. \tag{11.99}$$

Using the canonical algebra one obtains the standard mode sums,

$$\boxed{\begin{aligned} G^{(a)>}_{\mu\nu}{}^{\rho\sigma}(x,y) &= \sum_{\lambda=1}^{d_g} \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}} \frac{1}{2\omega_{\mathbf{k}}}\, e^{(a,\lambda)}_{\mu\nu}(k)\, e^{(a,\lambda)*\,\rho\sigma}(k)\, e^{-ik(x-y)}, \\ G^{(a)<}(x,y) &= G^{(a)>}(y,x). \end{aligned}} \tag{11.100}$$

The triad-resolved typed Feynman kernel then follows from $\bar{\Sigma}$-time ordering (Definition 11.53):

$$\boxed{G^{\mathrm{F},[\mathrm{TT}],(a)}_{\mu\nu}{}^{\rho\sigma}(x,y) = \Theta_{\bar{\Sigma}}(x \succeq y)\, G^{(a)>}_{\mu\nu}{}^{\rho\sigma}(x,y) + \Theta_{\bar{\Sigma}}(y \succeq x)\, G^{(a)<}_{\mu\nu}{}^{\rho\sigma}(x,y),} \tag{11.101}$$

where $\Theta_{\bar{\Sigma}}$ encodes the causal order in the $\bar{\Sigma}$-cone (Definition 11.53). Equal-time limits are taken by $\bar{\Sigma}$-covariant point-splitting compatible with the typed Peierls bracket, reproducing the typed ETCR on a Cauchy slice (eq. (11.25), Definition 11.8, and Proposition 11.4).

Remark 11.57 (What "foliation" means and why it matters)**.** An $\bar{\Sigma}$*–foliation* is a smooth time function $t : \mathcal{X}_q \to \mathbb{R}$ whose level sets $\Sigma_t := \{x \in \mathcal{X}_q \,|\, t(x) = \mathrm{const}\}$ are spacelike Cauchy hypersurfaces for the background Lorentzian structure $\bar{g}^{\mathrm{Lor}}$ (equivalently, for the causal cones of the unified background $\bar{\Sigma}$ used in this chapter). Writing n^μ for the future–pointing unit normal to Σ_t and $h_{\mu\nu}$ for the induced spatial projector (so that $h_{\mu\nu}n^\nu = 0$ and $\bar{\Sigma}_{\mu\nu} = -n_\mu n_\nu + h_{\mu\nu}$ in the usual signature convention), the foliation provides the "equal–time" notion required by the canonical construction. In Chapter 12 it serves four roles:

1. **Canonical (equal–time) quantization.** The typed equal–time commutation relations (ETCR) are imposed on Cauchy slices Σ_t selected by the foliation (the *band–regularized* canonical algebra in the TT carrier); see Definition 11.8 and Proposition 11.4 and its covariant counterpart via the typed Peierls bracket eq. (11.25). On the certified plateau $\mathfrak{P}$, Chapter 12 proves canonical $\leftrightarrow$ Peierls equivalence, so physical predictions do not depend on the particular admissible choice of t.

2. $\bar{\Sigma}$**–time ordering and propagators.** The foliation (equivalently, the $\bar{\Sigma}$ causal order) underlies the time–ordering operator $\Theta_{\bar{\Sigma}}$ used to assemble the TT Feynman kernel from the Wightman kernels:

$$G^{\mathrm{F},[\mathrm{TT}],(a)}(x,y) = \Theta_{\bar{\Sigma}}(x \succeq y)\, G^{(a)>}(x,y) + \Theta_{\bar{\Sigma}}(y \succeq x)\, G^{(a)<}(x,y),$$

cf. Definition 11.53 and eqs. (11.100) and (11.101). Equal–time limits are taken by $\bar{\Sigma}$–covariant point–splitting compatible with the typed Peierls bracket, reproducing the ETCR on Σ_t.

3. **Mode expansion and polarization basis.** Given a foliation, the TT graviton admits a mode expansion on Σ_t with frequencies $\omega_{\mathbf{k}}$ and TT polarization tensors $e^{(a,\lambda)}_{\mu\nu}(k)$, leading to the standard Wightman mode sums in eq. (11.100). The "$>/<$" kernels are the unordered vacuum two–point functions with positive/negative–frequency support relative to the chosen foliation/state, which the time–ordering then recombines.

4. **Compatibility with the weave/triad structure.** The foliation is required to be *admissible* (compatible with the unified cones of $\bar{\Sigma}$ and the band regularization). Within this admissible class, the TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and the weave triad $\{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ commute with the bookkeeping and do not depend on the particular slicings used to impose ETCR—hence the triad–resolved Fock factorization and diagnostics are foliation–independent on $\mathfrak{P}$ (see the TT quantization and triad factorization statements in Chapter 12).

In short, a $\bar{\Sigma}$–foliation supplies the "equal time" needed to state the canonical algebra and to define $\bar{\Sigma}$–time ordering, while the Peierls formulation guarantees that (on the certified plateau) observable TT physics does not depend on which admissible slicing one uses to implement those steps.

Remark 11.58 (Meaning of $G^{>}$, $G^{<}$ and $\bar{\Sigma}$–time ordering)**.** The kernels $G^{(a)>}$ and $G^{(a)<}$ in (11.100) are the *Wightman* two–point functions (also called "greater/lesser" functions): they are vacuum expectation values of the *unordered* operator products,

$$G^{(a)>}_{\mu\nu}{}^{\rho\sigma}(x,y) = {}_{\Phi}\langle 0|\, \hat{h}^{(a)}_{\mu\nu}(x)\, \hat{h}^{(a)\,\rho\sigma}(y)\, |0\rangle_{\Phi}, \qquad G^{(a)<}(x,y) = G^{(a)>}(y,x),$$

so that "$>$" places the operator at x to the left (positive–frequency part in the mode expansion), while "$<$" places it to the right (negative–frequency part) [255, 230, 82]. In curved backgrounds, the split into positive/negative frequency is defined relative to the chosen $\bar{\Sigma}$–foliation/state and is standard in the algebraic/Hadamard framework [245, 10, 13].

The *Feynman* (time–ordered) TT kernel in (11.101) is obtained by ordering with the $\bar{\Sigma}$–causal step function $\Theta_{\bar{\Sigma}}$ (cf. Definition 11.53), giving the familiar decomposition

$$G^{\mathrm{F},[\mathrm{TT}],(a)}(x,y) = \Theta_{\bar{\Sigma}}(x \succeq y)\, G^{(a)>}(x,y) + \Theta_{\bar{\Sigma}}(y \succeq x)\, G^{(a)<}(x,y),$$

exactly as in flat–space QFT with the usual Heaviside functions [82, Sec. 4]; in curved spacetime this formula is valid once a global time function (or, more generally, the causal order) associated with $\bar{\Sigma}$ is specified [245, 10, 13]. Equal–time limits are taken by $\bar{\Sigma}$–covariant point–splitting and reproduce the typed ETCR on a Cauchy slice (cf. eq. (11.25)),

Definition 11.8, and Proposition 11.4); distributionally, $G^{>} - G^{<}$ yields the Pauli–Jordan commutator function that implements the canonical algebra [255, 230, 384]. For the graviton TT polarization basis and the sum over helicities d_g used in (11.100), see standard constructions in gravitational–wave quantization [502].

3. Momentum-space / polarization-projector form

Fourier transforming (11.101) on a locally stationary patch (or in Riemann normal coordinates) yields the familiar momentum-space representation:

$$\boxed{G^{\mathrm{F},[\mathrm{TT}],(a)\ \rho\sigma}_{\mu\nu}(k) = \frac{i}{k^2 - m^2_{a,\mathrm{TT}} + i\epsilon}\, \Pi^{[\mathrm{TT}](a)\ \rho\sigma}_{\mu\nu}(k;\bar{\Sigma}),} \tag{11.102}$$

with the TT polarization projector assembled from the orthonormal basis, $\Pi^{[\mathrm{TT}](a)\ \rho\sigma}_{\mu\nu}(k) := \sum_\lambda e^{(a,\lambda)}_{\mu\nu}(k)\, e^{(a,\lambda)*\,\rho\sigma}(k)$ (Section 11.1.3). In the exact SSB/typed limit one has $m^2_{a,\mathrm{TT}} = 0$ with a protected massless pole; explicit breaking induces a GMOR-style shift $m^2_{a,\mathrm{TT}} = \mathcal{O}(\epsilon)$ (Proposition 11.29, Definition 11.33, and Corollary 11.30).

Remark 11.59 (KL positivity and band-stable causality)**.** On the physical Hilbert space $\mathcal{H}_{\mathrm{phys}}$ the sector-resolved TT two-point admits a Källén–Lehmann representation with non-negative residue and spectral density (eq. (11.91)); this *KL positivity* ensures that the polarization projector contributes positive weight to observable amplitudes. On the certified plateau $\mathfrak{P}$, band tags $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ are chosen $\bar{\Sigma}$-covariantly (e.g. as functions of the TT d'Alembertian) and commute with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and $\Pi^{(a)}$ (Definitions 6.280, 9.10 and 11.24), so band-sandwiching preserves microcausal support and does not enlarge cones (Proposition 11.38).

Operator-basis viewpoint. Equations (11.100)–(11.102) show that $G^{\mathrm{F},[\mathrm{TT}]}$ is built from the same orthonormal operator basis $\{\hat{a}_{a,\lambda}(\mathbf{k}), \hat{a}^\dagger_{a,\lambda}(\mathbf{k})\}$ that spans the triad-resolved Fock space (Definition 11.48 and Corollary 11.46), thereby making explicit the link between the particle (creation/annihilation) and wave (Green function) descriptions ([82, 524]).

The Propagator as a Virtual Exchange Amplitude The triad-resolved, typed momentum-space form in eq. (11.102) is the central result for perturbative gravity in the IQR. Its interpretation is multi-layered:

- **Covariance.** As a TT-typed bi-kernel on $(\mathcal{X}_q, \bar{\Sigma})$, $G^{\mathrm{F},[\mathrm{TT}],(a)\ \rho\sigma}_{\mu\nu}(x,y)$ transforms as a rank-$(0,4)$ bitensor (a section of $\mathrm{TT}^2 \otimes \mathrm{TT}^2$) under background diffeomorphisms generated by $\bar{\Sigma}$ (Definitions 11.53 and 11.54). The momentum-space representation with $\Pi^{[\mathrm{TT}](a)\ \rho\sigma}_{\mu\nu}(k;\bar{\Sigma})$ is valid in a locally stationary patch (or Riemann normal coordinates) and is related to the position-space bitensor by the usual Fourier map.
- **Typed gauge/BRST invariance.** The explicit TT projector ensures that only the physical, transverse-traceless spin-2 polarizations propagate; pure-gauge components are removed at the outset. On the certified plateau $\mathfrak{P}$, the kernel is BRST-closed and gauge-parameter independent (Nielsen-flat) and thus constitutes the correct physical

propagator for perturbation theory (Section 11.1.2 and Definitions 6.280 and 9.10; cf. [155, 245, 403, 502]).

- **KL positivity and SSB protection.** On $\mathcal{H}_{\mathrm{phys}}$ the TT two-point function admits a Källén–Lehmann representation with non-negative residues and spectral densities (eq. (11.91)), so the spectral weight is positive in each sector. In the exact SSB limit the typed Ward identity protects the massless TT pole, while small explicit breaking induces the GMOR-type shift $m^2_{a,\mathrm{TT}} = \mathcal{O}(\epsilon)$ (Proposition 11.29, Definition 11.33, and Corollary 11.30).

- **Virtual graviton exchange.** Physically, $G^{\mathrm{F},[\mathrm{TT}],(a)}$ is the amplitude for *virtual* TT spin-2 exchange in sector a. In the Dyson expansion, every internal wavy line is a TT-projected triadic propagator, and it connects typed interaction vertices obtained by reducing the Chapter 11 bi-local parent coupling to the linearized form in this chapter (Sections 11.3 and 11.3.3). This is the standard field-theoretic picture of exchange, here implemented with the $\bar{\Sigma}$-time ordering and typed projectors ([82, 403, 502]).

11.2.3 Graviton Propagator in Background Geometry

On the emergent chronogeometric background $(\mathcal{X}_q, \bar{\Sigma}_{\mu\nu})$, the TT-typed graviton $\hat{h}^{(a)}_{\mu\nu}(x)$ (sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$) propagates according to a *project-then-solve* prescription: first apply the background-covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (York-type, Chapter 11), then define all dynamical operators and Green kernels on the TT image (Sections 11.1.2 and 11.1.3 and Definition 11.28).

TT Lichnerowicz-type wave operator.

Definition 11.60 (TT Lichnerowicz–type wave operator (sector–resolved))**.** Let $\mathbb{L}^{(2)}_{\bar{\Sigma}}$ denote the spin–2 Lichnerowicz–type operator acting on symmetric rank–2 tensors over $(\mathcal{X}_q, \bar{\Sigma})$, with principal part $-\bar{\nabla}^\lambda\bar{\nabla}_\lambda\,\delta^\mu{}_\alpha\delta^\nu{}_\beta$ and curvature couplings built from $\bar{R}_{\mu\nu\rho\sigma}[\bar{\Sigma}]$. For each triad sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Definition 10.2), the *typed, sector–resolved* wave operator is the TT–sandwiched operator

$$\boxed{K^{[\mathrm{TT}],(a)\alpha\beta}_{\mu\nu}(x) := \Big[\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \circ \Big(\,\mathbb{L}^{(2)}_{\bar{\Sigma}} - \mathcal{M}^{(a)}{}_{\cdot\cdot}{}^{\cdot\cdot}(x)\,\Big) \circ \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Big]_{\mu\nu}{}^{\alpha\beta},} \tag{11.103}$$

where $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ is the background–covariant York–Lichnerowicz TT projector (eq. (10.4) and Definition 10.3) and $\mathcal{M}^{(a)}$ is the sectoral mass/mixing tensor projected to the TT block (Definition 11.33 and Proposition 11.32). The following properties hold on a certified plateau $\mathfrak{P}$:

1. **Typed equations of motion.** The typed graviton carrier $\hat{h}^{(a)}_{\mu\nu} := \Pi^{(a)}\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu}$ (Definition 11.3 and Proposition 10.9) obeys $K^{[\mathrm{TT}],(a)\alpha\beta}_{\mu\nu}\,\hat{h}^{(a)}_{\alpha\beta} = 0$ (up to sources), which fixes the normalization and dynamics sector–by–sector.

2. **Green operators and typed propagator.** The retarded/advanced Green operators $G^{\mathrm{ret/adv},[\mathrm{TT}],(a)}$ solve the Green equations for $K^{[\mathrm{TT}],(a)}$, and the typed Feynman propagator $G^{\mathrm{F},[\mathrm{TT}],(a)}$ is the corresponding Feynman Green function (Definition 11.54). The Pauli–Jordan kernel $\Delta^{[\mathrm{TT}]} := G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]}$ determines the covariant commutator and the Peierls bracket (eqs. (11.25) and (11.26)).
3. **Hyperbolicity and microcausality.** The principal symbol of $K^{[\mathrm{TT}],(a)}$ is inherited from $\mathbb{L}^{(2)}_{\bar\Sigma}$ and is $\bar\Sigma$–hyperbolic, so $\operatorname{supp} G^{\mathrm{ret/adv},[\mathrm{TT}],(a)}$ lies on the $\bar\Sigma$–causal cones; hence $\operatorname{supp}\Delta^{[\mathrm{TT}]} \subset J^+_{\bar\Sigma} \cup J^-_{\bar\Sigma}$, which implies typed microcausality for the Peierls bracket (Proposition 11.14 and Remark 9.83).
4. **Compatibility with the realized weave configuration (plateau safety).** On $\mathfrak{P}$ the TT and triad projectors commute with the band tags and are BRST–closed; therefore $K^{[\mathrm{TT}],(a)}$ is regulator–safe and gauge–parameter independent (Nielsen–flat) in all constructions that use it—propagators, Peierls bracket, and diagnostics (Definitions 6.280 and 9.10, Propositions 7.3 and 10.9, and Corollary 11.5).

Central role of the typed Lichnerowicz–type operator. The wave operator $K^{[\mathrm{TT}],(a)\alpha\beta}_{\mu\nu}$ defined by the TT sandwiching of the spin–2 Lichnerowicz operator together with the sectoral mass/mixing tensor (cf. eq. (11.103)) is the kinetic operator for the typed graviton in each triad sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Definitions 10.2 and 11.3). After TT projection, the carrier $\hat h^{(a)}_{\mu\nu}$ obeys the typed field equation $K^{[\mathrm{TT}],(a)\alpha\beta}_{\mu\nu}\,\hat h^{(a)}_{\alpha\beta} = 0$, and the *typed Feynman propagator* $G^{\mathrm{F},[\mathrm{TT}],(a)}{}_{\mu\nu}{}^{\rho\sigma}$ is by definition the Green's function of the same $K^{[\mathrm{TT}],(a)}$ (see Definition 11.54). This identification fixes the normalization of modes, determines the on–shell content sector–by–sector, and ensures that the propagator is strictly TT, i.e. it maps the TT subspace into itself and vanishes on its orthogonal complement (use Definition 11.18 and eq. (11.33)).

The same operator generates the *covariant* algebra via the Peierls construction. The typed Peierls bracket

$$\{F,G\}_{\mathrm{P}} = \Big\langle \frac{\delta F}{\delta h_{\mu\nu}},\ \Delta^{[\mathrm{TT}]\,\mu\nu}{}_{\rho\sigma}\ \frac{\delta G}{\delta h_{\rho\sigma}} \Big\rangle, \qquad \Delta^{[\mathrm{TT}]} := G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]},$$

(eq. (11.25)) is built from the retarded/advanced Green operators of the very same typed wave operator $K_{[\mathrm{TT}]}$. Consequently, $K_{[\mathrm{TT}]}$ (ultimately sourced by $\mathbb{L}^{(2)}_{\bar\Sigma}$) controls the covariant commutator $[\,\hat h(x), \hat h(x')\,] = i\,\Delta^{[\mathrm{TT}]}(x,x')$ and, upon restriction to a Cauchy slice, reproduces the equal–time algebra of the typed canonical pair (eq. (11.26) and Proposition 11.4).

Typed microcausality follows from the $\bar\Sigma$–hyperbolic nature of $K_{[\mathrm{TT}]}$: the retarded/advanced TT Green operators are supported on the $\bar\Sigma$–causal cones, whence the Pauli–Jordan kernel $\Delta^{[\mathrm{TT}]}$ has support only on $J^{\pm}_{\bar\Sigma}$ and the Peierls bracket vanishes for $\bar\Sigma$–spacelike separations (Proposition 11.14). The IR window $K^{(\ell)}_{\mathrm{IR}}$ is cone–preserving, and the band realized weave configuration commutes with the TT projector, so these causal properties are regulator–safe on a certified plateau $\mathfrak{P}$ (Definition 6.280, Remark 9.83, and Proposition 10.9).

In momentum space the typed propagator is the inverse of $K_{[\mathrm{TT}]}$ on the TT subspace and projects onto TT polarizations, carrying in each sector the typed mass parameter $m^2_{a,\mathrm{TT}}$. In the spontaneously broken limit, the TT Goldstone direction forces $m^2_{a,\mathrm{TT}} = 0$ and yields a

massless pole with positive residue (Proposition 11.29); a small explicit breaking shifts the pole according to the GMOR–style estimate $m_{\mathrm{TT}}^2 = \mathcal{O}(\epsilon)$ with a plateau bound (Corollary 11.30). These spectral statements are read directly from the structure of $K_{[\mathrm{TT}]}$ and its TT inverse (cf. the triad–resolved Källén–Lehmann form in Definition 11.21).

Finally, the operator is intrinsically compatible with the typed realized weave configuration: it is sandwiched by the commuting TT and triad projectors and respects the band/tag hygiene on $\mathfrak{P}$, so covariance, causality, and gauge–parameter independence (Nielsen flatness) propagate to all derived objects—propagator, Peierls bracket, and law/state diagnostics (Definition 9.10, Propositions 7.3 and 10.9, and Corollary 11.5). This is why tree–level exchange amplitudes are expressed as contractions of typed vertices with the typed propagator—the Green's function of $K^{[\mathrm{TT}]}$—so scattering and linear response depend precisely on the Lichnerowicz–type operator through its TT projection (Definitions 11.54 and 11.67).

Typed linear dynamics (project then solve).

Definition 11.61 (Typed TT equation of motion (project then solve))**.** Let $K_{\mu\nu}^{[\mathrm{TT}],(a)\alpha\beta}(x)$ be the sector–resolved TT wave operator of Definition 11.60 and let $\hat{h}_{\mu\nu}^{(a)} := \Pi^{(a)}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ be the typed graviton carrier in triad sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Definitions 10.2 and 11.3). The *typed TT equation of motion* is

$$\boxed{K_{\mu\nu}^{[\mathrm{TT}],(a)\alpha\beta}(x)\,\hat{h}_{\alpha\beta}^{(a)}(x) = \hat{J}_{\mu\nu}^{[\mathrm{TT}],(a)}(x), \qquad \hat{J}^{[\mathrm{TT}],(a)} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\hat{J}^{(a)},} \tag{11.104}$$

where $\hat{J}^{(a)} := \Pi^{(a)}\hat{J}$ is the triad–filtered source induced by the bi–local matter–geometry interaction (Section 11.3 and Definition 11.24). On a certified plateau $\mathfrak{P}$, the realized weave configuration commutations imply $\Pi^{(a)}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{(a)}$ (Proposition 10.9), so either ordering yields the same typed source.

Remark 11.62. (i) Retarded/advanced Green operators of $K^{[\mathrm{TT}],(a)}$ produce covariant solutions with cone support, and their causal difference $\Delta^{[\mathrm{TT}]}$ generates the Peierls bracket and covariant commutator (Definition 11.60, Proposition 11.14, and eqs. (11.25) and (11.26)). (ii) The Feynman Green function of $K^{[\mathrm{TT}],(a)}$ is the typed propagator that enters tree–level exchange amplitudes (Definitions 11.54 and 11.67). (iii) Formulating (11.104) inside the TT, triad–resolved subspace enforces purity and prevents leakage into non–TT or off–sector channels (cf. Definition 11.7).

Explanation (typed linear dynamics: project then solve). The operator $K_{\mu\nu}^{[\mathrm{TT}],(a)\alpha\beta}(x)$ is the sector–resolved, TT–sandwiched Lichnerowicz–type wave operator of Definition 11.60. The typed graviton carrier in sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ is $\hat{h}_{\mu\nu}^{(a)} := \Pi^{(a)}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ (Definitions 10.2 and 11.3), where the commuting property of the realized weave configuration on the certified plateau $\mathfrak{P}$ ensures $\Pi^{(a)}\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Pi^{(a)}$ (Proposition 10.9). The typed source $\hat{J}^{[\mathrm{TT}],(a)} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{J}^{(a)}$ is obtained by projecting the triad–filtered interaction current $\hat{J}^{(a)}$ that arises from the bi–local matter–geometry coupling in the interaction action (Section 11.3 and Definition 11.24). Writing the equation of motion,

$$K_{\mu\nu}^{[\mathrm{TT}],(a)\alpha\beta}(x)\,\hat{h}_{\alpha\beta}^{(a)}(x) = \hat{J}_{\mu\nu}^{[\mathrm{TT}],(a)}(x),$$

implements the principle "project, then solve": the dynamics is enforced *within* the TT, sector–resolved subspace, so no longitudinal/trace components or cross–triad leaks can appear in the solution (cf. TT purity/leak diagnostics in Definition 11.7).

Green representation, causality, and algebra. Let ${G^{\mathrm{ret/adv},[\mathrm{TT}],(a)}}_{\mu\nu}{}^{\rho\sigma}(x,y)$ be the retarded/advanced Green operators of $K^{[\mathrm{TT}],(a)}$ ($\bar{\Sigma}$–hyperbolic; Definition 11.60). The causal support statement $\operatorname{supp} G^{\mathrm{ret/adv},[\mathrm{TT}]} \subset J^{\pm}_{\bar{\Sigma}}$ implies the retarded solution

$$\hat{h}^{(a)}_{\mu\nu}(x) = \int d\mu_{\bar{\Sigma}}(y)\; {G^{\mathrm{ret},[\mathrm{TT}],(a)}}_{\mu\nu}{}^{\rho\sigma}(x,y)\; \hat{J}^{[\mathrm{TT}],(a)}_{\rho\sigma}(y),$$

which is manifestly covariant and microcausal (Proposition 11.14). The Feynman propagator $G^{\mathrm{F},[\mathrm{TT}],(a)}$ used in time–ordered exchange amplitudes is the corresponding Feynman Green function of $K^{[\mathrm{TT}],(a)}$ (Definitions 11.54 and 11.67). The Pauli–Jordan kernel $\Delta^{[\mathrm{TT}]} := G^{\mathrm{ret}}_{[\mathrm{TT}]} - G^{\mathrm{adv}}_{[\mathrm{TT}]}$ generated by the same operator controls the Peierls bracket and the covariant commutator, whose equal–time limit reproduces the typed canonical algebra (eqs. (11.25) and (11.26) and Proposition 11.4). Gauge–parameter independence of these statements on $\mathfrak{P}$ follows from BRST/Nielsen safety (Proposition 7.3 and Corollary 11.5), and regulator stability from cone–preserving band tags (Definition 6.280 and Remark 9.83).

Typed Green kernels and causal support. Define the retarded/advanced TT Green kernels as the bi-tensors $G^{\mathrm{ret/adv},[\mathrm{TT}],(a)}_{\mu\nu}{}^{\rho\sigma}(x,y)$ solving

$$\boxed{K^{[\mathrm{TT}],(a)}_{\mu\nu}{}^{\alpha\beta}(x)\, G^{\mathrm{ret/adv},[\mathrm{TT}],(a)}_{\alpha\beta}{}^{\rho\sigma}(x,y) = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}\,\mu\nu}{}^{\rho\sigma}\,\delta^{(d)}(x-y),} \tag{11.105}$$

with supports $\operatorname{supp} G^{\mathrm{ret}} \subset J^{+}_{\bar{\Sigma}}(y)$ and $\operatorname{supp} G^{\mathrm{adv}} \subset J^{-}_{\bar{\Sigma}}(y)$. The causal (Pauli–Jordan) kernel and the typed Feynman kernel are then

$$\Delta^{[\mathrm{TT}],(a)} := G^{\mathrm{ret},[\mathrm{TT}],(a)} - G^{\mathrm{adv},[\mathrm{TT}],(a)}, \qquad \operatorname{supp}\Delta^{[\mathrm{TT}],(a)} \subset J^{+}_{\bar{\Sigma}}(y) \cup J^{-}_{\bar{\Sigma}}(y), \tag{11.106}$$

$$i\, G^{\mathrm{F},[\mathrm{TT}],(a)}_{\mu\nu}{}^{\rho\sigma}(x,y) = {}_{\Phi}\langle 0|\, T_{\bar{\Sigma}}\Big\{\hat{h}^{(a)}_{\mu\nu}(x)\hat{h}^{(a)\,\rho\sigma}(y)\Big\}\,|0\rangle_{\Phi}, \quad \text{with } K^{[\mathrm{TT}],(a)} \circ G^{\mathrm{F},[\mathrm{TT}],(a)} = i\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\delta^{(d)}(\cdot), \tag{11.107}$$

(Definitions 11.53 and 11.54, eq. (11.102), and Proposition 11.14).

Composition convention. For bi-tensors A, B of type $(0,4)$ we write

$$(A\circ B)_{\mu\nu}{}^{\rho\sigma}(x,y) := \int_{\mathcal{X}_q} d\mu_{\bar{\Sigma}}(z)\, A_{\mu\nu}{}^{\alpha\beta}(x,z)\, B_{\alpha\beta}{}^{\rho\sigma}(z,y),$$

with $d\mu_{\bar{\Sigma}}$ the background-covariant measure.

Hyperbolicity and Nielsen flatness (plateau tests). The principal symbol of $K^{[\mathrm{TT}],(a)}$ is $\sigma\big(K^{[\mathrm{TT}],(a)}\big)(x,\xi) = \bar{\Sigma}^{\lambda\kappa}(x)\,\xi_\lambda\xi_\kappa\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}(x)$, so $K^{[\mathrm{TT}],(a)}$ is normally hyperbolic on $(\mathcal{X}_q,\bar{\Sigma})$; hence retarded/advanced solutions exist and have $\bar{\Sigma}$-causal support. On the certified plateau $\mathfrak{P}$, observables built from $G^{\mathrm{ret/adv/F},[\mathrm{TT}],(a)}$ are gauge-parameter independent (*Nielsen-flat*) and stable under admissible band deformations; band tags commute with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and do not enlarge causal cones (Definitions 6.280 and 9.10 and Proposition 11.38).

Remark 11.63 (Equivalence with mode-sum representations)**.** In a locally stationary patch (or via covariant Fourier–Hadamard techniques), the kernels in (11.107) coincide with the triad-resolved mode sums and the momentum-space projector form (Section 11.2.2 and eq. (11.102)), ensuring both manifest locality (Green-function picture) and spectral completeness (operator picture) within the IQR formalism.

11.2.4 Triadic Structure and Interpretation of the Graviton Propagator

By construction, the free graviton two-point function is *typed* (TT-projected) and *triad-resolved*. The full kernel is the orthogonal sum of sectoral contributions (Definition 11.51 and eq. (11.86)):

$$\boxed{G^{\mathrm{grav}}_{\mu\nu}{}^{\rho\sigma}(x,x') = \sum_{a\in\{\mathrm{corr,vac,spec}\}} G^{(a)}_{\mu\nu}{}^{\rho\sigma}(x,x'), \qquad [\Pi^{(a)},\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}] = 0,} \tag{11.108}$$

so that, at the free level on the certified plateau $\mathfrak{P}$, the internal lines of Feynman graphs are block-diagonal by sector and TT-pure (Section 11.1.4 and Definition 11.54). This makes explicit that the apparent single "gravitational interaction" is, in IQR, a composite phenomenon mediated by three virtual spin-2 channels with distinct relational origins.

The Three Channels of Gravitational Interaction

Correlational channel: geometry from quantum information

The correlational propagator $G^{(\mathrm{corr})}$ captures TT fluctuations sourced by the information-theoretic structure of the state—coherence and entanglement—in the sense of the correlational distance d_{corr} (Section 4.9.1 and Definition 11.24). Its field operator $\hat{h}^{(\mathrm{corr})}_{\mu\nu}$ is the TT projection of the correlational component of the Gaiamiti fluctuation (Definition 11.42 and eq. (11.74)). As a mediator, this channel is sensitive to gradients of modular/entanglement data rather than classical stress–energy, providing a dynamical avatar of the "information builds geometry" motif ([520, 1]; cf. Section 11.1.3 for the TT basis).

Vacuum channel: geometry from symmetry breaking

The vacuum propagator $G^{(\mathrm{vac})}$ describes TT excitations tied to the response of the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ (Section 6.1.8). In the exact SSB limit, the typed Ward identity enforces a protected massless TT pole in this channel (Proposition 11.29); small explicit breaking produces a

GMOR-type shift consistent with the TT-projected mass operator (Definition 11.33 and Corollary 11.30). The corresponding field, $\hat{h}^{(\mathrm{vac})}_{\mu\nu}$, is defined in Definition 11.43 and eq. (11.75) and mediates long-range geometric responses to shifts within $\mathcal{M}_{\mathrm{vac}}$.

Spectral channel: geometry from energy–momentum

The spectral propagator $G^{(\mathrm{spec})}$ is driven by local spectral content (energetic/momentum scales) as encoded by the spectral distance d_{spec} (Section 4.9.6) and the sectoral source defined by the interaction kernel (Section 10.19.6 and Definition 11.44). In the semiclassical regime, $G^{(\mathrm{spec})}$ reduces to the familiar helicity-2 kernel of linearized GR with TT polarization projector (Section 11.2.2 and eq. (11.102); [245, 502]), thus governing the classical phenomena sourced by stress–energy.

Remarks. (i) Each $G^{(a)}$ is defined by first projecting the Lichnerowicz-type operator onto the TT subspace and then solving for the sectoral Green kernel (Section 11.2.3 and eqs. (11.103) and (11.107)). (ii) KL positivity holds on the physical Hilbert space for each sectoral two-point (eq. (11.91)); Nielsen flatness and hyperbolicity are plateau tests ensuring gauge-parameter independence and causal support (Proposition 11.14). (iii) Beyond tree level, radiative corrections can induce sectoral self-energies Σ_{ab} consistent with the typed projectors; the resulting dispersion/positivity bounds are assessed triadwise (Section 11.3.6).

11.2.5 A Composite Gravitational Force and its Predictions

In the IQR framework the *typed, triad-resolved* propagators add coherently at the free level (eq. (11.108)), so the net gravitational interaction is a superposition of three TT spin–2 exchange channels with distinct relational origins (correlational, vacuum, spectral; cf. Section 11.1.4 and Definition 11.51). Beyond tree level, sectoral self-energies Σ_{ab} compatible with the typed projectors may induce controlled mixing among channels (triadic transmutation), still certified on the plateau $\mathfrak{P}$ by TT law/state visibilities ($\Lambda^{[\mathrm{TT}]}_{\mathrm{law}}, \Lambda^{[\mathrm{TT}]}_{\mathrm{state}}$; Definition 11.52 and Proposition 11.14).

Unique predictions of the triadic model. The novelty arises from the correlational and vacuum channels, absent in single-metric treatments ([156, 10]). In addition to the familiar *spectral* (stress–energy) graviton, the theory predicts:

- *Correlational gravitons* $\hat{h}^{(\mathrm{corr})}_{\mu\nu}$ mediating geometry sourced by quantum informational structure (coherence/entanglement), in line with the "information builds geometry" paradigm (Definition 11.42; [1, 525, 520]).
- *Vacuum gravitons* $\hat{h}^{(\mathrm{vac})}_{\mu\nu}$ tied to the structure of the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ and its spontaneously broken symmetries; in the exact SSB limit they exhibit a protected massless TT pole, with a GMOR-type shift under small explicit breaking (Proposition 11.29 and Definition 11.33; [526]).

Consequently, the framework admits *gravity without traditional stress–energy sources*: highly entangled yet low-energy configurations can source correlational curvature, and vacuum

rearrangements can source TT waves during phase transitions (Section 11.1.4; [1, 525]). This challenges the strong reading of universality in GR while remaining testable against precision constraints ([479]).

Falsifiable aspects and observational handles. The triadic structure leads to concrete, potentially observable deviations from GR that can be certified on $\mathfrak{P}$ via TT visibilities and positivity/dispersion checks (Section 11.3.6):

1. **Apparent non-universality of Newton's constant.** Because exchange amplitudes add channelwise (eq. (11.108)), the effective coupling measured between two sources can depend on their triadic composition. Denote by G_{eff} the empirically inferred coupling in a given setup; then G_{eff} is a functional of the sector weights (the TT KL residue vector $\vec{Z}$, eq. (11.91)) and may differ for sources with equal stress–energy but different coherence/vacuum structure. A targeted null test compares the attraction between two samples with matched mass–energy but sharply different internal quantum coherence (highly entangled vs. decohered), while controlling for environmental decoherence and vacuum alignment ([527, 528]; cf. Definition 11.52).

2. **Directional or frequency response tied to chronogeometry.** Propagation is governed by the TT Lichnerowicz-type operator built from $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Section 11.2.3 and eq. (11.103)). In regions where $\bar{t}_{\mu\nu}$ is sizable, the *chronogeometric* cone can differ from that inferred by probes coupling only to $\bar{g}_{\mu\nu}$, opening the door to apparent anisotropy/dispersion of TT waves relative to standard matter clocks. Precision bounds on Lorentz-violating dispersion therefore constrain the allowed $\bar{t}$-backdrop and sectoral self-energies ([529, 514]); any confirmed direction- or frequency-dependence beyond GR expectations would be evidence for the chronogeometric structure posited here.

3. **Primordial imprints in cosmology.** During high-coherence, high-energy epochs, correlational and vacuum channels can be non-negligible, modifying the tensor power spectrum, its polarization, and the stochastic GW background. One expects non-standard tensor consistency relations or mixed-polarization signatures seeded by triadic mixing and SSB-protected modes (Section 11.1.4 and Proposition 11.29). CMB B-modes and direct searches for stochastic backgrounds thus provide incisive tests ([439, 530, 512]).

Certification protocol. For any proposed deviation, the TT law visibility $\Lambda^{[\mathrm{TT}]}_{\text{law}}$ and state visibility $\Lambda^{[\mathrm{TT}]}_{\text{state}}$ must be near unity on a certified plateau (Definition 11.52), KL positivity must hold sectorwise (eq. (11.91)), and microcausality with respect to the $\bar{\Sigma}$-cone must be maintained (Proposition 11.14 and Definition 11.53). This ensures that any phenomenological inference is *typed, causal, and gauge-robust* before being confronted with data.

11.3 Graviton-Mediated Scattering

With the typed, TT-projected graviton field $\hat{h}_{\mu\nu} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\hat{g}_{\mu\nu}$ (Section 11.1.3) and the triad-resolved propagators in hand (Definitions 11.51 and 11.54, eq. (11.86), and Section 11.2.2), we

now formulate graviton–mediated scattering on the certified plateau $\mathfrak{P}$ (band tags commuting with $\Pi^{(a)}$ and $\Pi^{[\mathrm{TT}]}_{\bar\Sigma}$; Definitions 6.280 and 9.10 and Proposition 11.14). All couplings below are understood as the TT-typed *shadow* of the bi-local matter–geometry interaction introduced in Chapter 11 (the $\Phi\Phi \leftrightarrow \Theta\Theta$ block), and inherit Hermiticity, $\bar\Sigma$-cone support, and TT-preservation by the weave algebra and the TT-nullity of the τ-typed leg (Section 11.1.3).

Definition 11.64 (Graviton–Tantrakyma vertex operator (typed, triad-resolved))**.** Let $S_{\mathrm{int}}[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}]$ denote the bi-local parent interaction (Chapter 11). Its TT-typed, linearized reduction around $(\mathcal{X}_q, \bar\Sigma)$ is defined by

$$\boxed{\hat V^{\mu\nu}(x) := \left(\Pi^{[\mathrm{TT}]}_{\bar\Sigma}\right)^{\mu\nu}{}_{\alpha\beta} \left.\frac{\delta S_{\mathrm{int}}[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}]}{\delta \hat h_{\alpha\beta}(x)}\right|_{\mathfrak{P}}, \qquad \hat V^{\mu\nu} = \hat V^{\nu\mu}, \quad \bar\Sigma_{\mu\nu}\hat V^{\mu\nu} = 0.} \tag{11.109}$$

and decomposes orthogonally into the triadic channels $\hat V^{\mu\nu} = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat V^{(a)\mu\nu}$ with $\hat V^{(a)\mu\nu} := \Pi^{(a)}\hat V^{\mu\nu}$ and $[\Pi^{(a)}, \Pi^{[\mathrm{TT}]}_{\bar\Sigma}] = 0$ (Definition 11.24).

Remark 11.65 (Decomposition and practical reading of eq. (11.109))**. What each piece means.**

- $\left(\Pi^{[\mathrm{TT}]}_{\bar\Sigma}\right)^{\mu\nu}{}_{\alpha\beta}$. This is the *background–covariant transverse–traceless (TT) projector* for rank-2 symmetric tensors on the certified plateau determined by $\bar\Sigma_{\mu\nu}$ (see the TT calculus from Ch. 11). As a map it sends a two–tensor $X^{\alpha\beta}$ to its TT part,

  $$X^{\mu\nu}_{[\mathrm{TT}]} = \left(\Pi^{[\mathrm{TT}]}_{\bar\Sigma}\right)^{\mu\nu}{}_{\alpha\beta} X^{\alpha\beta},$$

  enforcing symmetry, tracelessness w.r.t. $\bar\Sigma$, and—when inserted in the dynamics—transversality w.r.t. $\bar\nabla$.
- $\dfrac{\delta S_{\mathrm{int}}[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}]}{\delta \hat h_{\alpha\beta}(x)}$. The *functional derivative* of the (bi–local) interaction action with respect to the graviton field $\hat h_{\alpha\beta}(x)$. Before typing, this is the "raw'' vertex tensor with two free indices $(\alpha\beta)$.
- $\big|_{\mathfrak{P}}$. *Evaluation on the certified plateau* $\mathfrak{P}$ (Ch. 8): band tags are fixed, BRST cohomology has been taken, and all quantities are *Nielsen–flat* (gauge–parameter independent). Operationally: take the derivative, then restrict to the physical, regulator–clean arena.
- *Left–hand side* $\hat V^{\mu\nu}(x)$. The *typed (TT) vertex operator* that couples to the typed graviton $\hat h_{\mu\nu}$. It is *by construction*

  $$\hat V^{\mu\nu} = \hat V^{\nu\mu}, \qquad \bar\Sigma_{\mu\nu}\hat V^{\mu\nu} = 0,$$

  i.e. symmetric and $\bar\Sigma$–traceless (TT). Transversality is then enforced via the TT Ward identity in the covariant Peierls framework; see Section 11.1.2 and the vertex discussion in Section 11.3.2.

Why we project. We *project after differentiating* so that only the *physical*, TT–propagating part of the vertex survives. This aligns the right leg of the vertex with the *typed graviton carrier*

$$\hat{h}_{\mu\nu} = \left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\right)_{\mu\nu}{}^{\rho\sigma}\, \delta\hat{g}_{\rho\sigma} \quad \text{(cf. Section 11.1.3)},$$

guarantees TT–purity on all graviton lines, and makes TT Ward checks straightforward on $\mathfrak{P}$.

Common pitfalls (and the tiny typo).

- The argument of $S_{\mathrm{int}}[\cdots]$ must be closed: use $S_{\mathrm{int}}[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}]$.
- Index placement matters: $\left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\right)^{\mu\nu}{}_{\alpha\beta}$ maps lower–index $\hat{h}_{\alpha\beta}$ to upper–index $\hat{V}^{\mu\nu}$; raise/lower with $\bar{\Sigma}$.

Equivalent "expanded" reading. For a compact, index–free view, read

$$\hat{V}_{[\mathrm{TT}]} \;=\; \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\left(\frac{\delta S_{\mathrm{int}}}{\delta \hat{h}}\right)\Bigg|_{\mathfrak{P}},$$

i.e. "*take the vertex = TT–project (the functional derivative of the interaction) on the plateau.*" This is precisely the typed bi–local → linearized reduction in Section 11.3.2, and it is the object that contracts with TT propagators in amplitudes (Section 11.3.7).

11.3.1 Linearized Interaction Action

The typed, linear coupling of the TT graviton to Tantrakyma degrees of freedom is

Definition 11.66 (Graviton–Tantrakyma interaction (typed, linearized))**.** To first order in $\hat{h}$, the interaction action on $\mathfrak{P}$ reads

$$\boxed{S_{\mathrm{int}}^{(1)}[\hat{h}, \hat{\mathbf{\Theta}}] := \int d\mu_{\bar{\Sigma}}(x)\ \mathrm{Tr}\Big[\hat{h}_{\mu\nu}(x)\, \hat{V}^{\mu\nu}(x)\Big] = \sum_a \int d\mu_{\bar{\Sigma}}(x)\ \mathrm{Tr}\Big[\hat{h}^{(a)}_{\mu\nu}(x)\, \hat{V}^{(a)\mu\nu}(x)\Big]\,,} \tag{11.110}$$

with $d\mu_{\bar{\Sigma}}(x)$ the covariant volume density, and "Tr" the fiber trace over the local operator bundle (Section 11.1.3).

11.3.2 Structure of the Vertex from the Interaction Kernel

Let $\mathcal{U}_{\Phi\Theta}(x, x')$ be the bi-local interaction kernel of Chapter 11 and $\mathcal{U}^{(a)}_{\Phi\Theta}$ its triadic components (Section 10.19.6). The typed vertex admits the representation

$$\boxed{\hat{V}^{(a)\mu\nu}(x) = \Pi^{[\mathrm{TT}]\mu\nu}{}_{\alpha\beta} \int d\mu_{\bar{\Sigma}}(x')\, \hat{\mathcal{K}}^{(a)\alpha\beta}{}_{A}(x, x')\, \delta\hat{\mathbf{\Theta}}^{A}(x'), \qquad a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\},}$$

(11.111)

for some operator-valued kernel $\hat{\mathcal{K}}^{(a)}$ determined by the variation of the parent action. Hermiticity and $\bar{\Sigma}$-causal support follow from the parent bilinear structure; TT-preservation follows from the projector and the TT-nullity of $\hat{\tau}$ (Section 11.1.3).

11.3.3 Graviton Coupling Channels (modal decomposition)

Expanding on the TT polarization basis $e^{(s,a)}_{\mu\nu}(k)$ (Section 11.1.3), the vertex admits a modal decomposition

$$\boxed{\hat{V}^{(a)\mu\nu}(x) = \sum_{s=1}^{d_g} \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}} \Big[\hat{\mathcal{J}}^{(s,a)}(\mathbf{k};x)\, e^{(s,a)\mu\nu}(k)\, e^{-ikx} + \text{h.c.} \Big], \quad [\hat{\mathcal{J}}^{(s,a)}, \hat{\mathcal{J}}^{(s',b)\dagger}] \propto \delta^{ss'}\delta^{ab},} \tag{11.112}$$

so that sector labels commute and the triadic Fock spaces factorize (Sections 11.1.4 and 11.1.5).

11.3.4 Scattering Amplitudes from Graviton Exchange

Setup and external states. Consider $2 \to 2$ scattering of Tantrakyma excitations with external one–particle states $|\Theta_1(p_1)\rangle, |\Theta_2(p_2)\rangle \to |\Theta_3(p_3)\rangle, |\Theta_4(p_4)\rangle$, LSZ–amputated and normalized in the standard relativistic convention. We write expectation values in these external states as matrix elements, e.g. $\langle \hat{V}^{(a)}_{\mu\nu}(x)\rangle := \langle \Theta_3|\hat{V}^{(a)}_{\mu\nu}(x)|\Theta_1\rangle$ and $\langle \hat{V}^{(a)\rho\sigma}(y)\rangle := \langle \Theta_4|\hat{V}^{(a)\rho\sigma}(y)|\Theta_2\rangle$. Integration uses the $\bar{\Sigma}$–invariant measure $d\mu_{\bar{\Sigma}}(x)$ on $\mathcal{X}_q$. Time ordering is with respect to the $\bar{\Sigma}$ causal structure (Section 11.2.1).

Definition 11.67 (Tree–level TT, triad–resolved exchange amplitude)**.** At tree level, the TT–typed exchange amplitude between two Tantrakyma sources is the $\bar{\Sigma}$–time–ordered contraction of two vertices with the typed propagator (Definition 11.54):

$$\boxed{\mathcal{A}_{12\to 34} = \sum_{a\in\{\text{corr,vac,spec}\}} \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y) \left\langle \hat{V}^{(a)}_{\mu\nu}(x) \right\rangle i\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(x,y) \left\langle \hat{V}^{(a)\rho\sigma}(y) \right\rangle.} \tag{11.113}$$

What each factor is:

- $i\, G^{\mathrm{F},[\mathrm{TT}],(a)}_{\mu\nu}{}^{\rho\sigma}(x,y)$ is the sector–a TT Feynman kernel (typed two–point) defined in Definition 11.54 and eq. (11.107); it solves the typed wave equation with Feynman boundary conditions and has support consistent with the $\bar{\Sigma}$ causal cone.
- $\hat{V}^{(a)}_{\mu\nu}(x)$ is the sector–resolved vertex operator (right leg), obtained by projecting the bi–local parent via $\Pi^{(a)}$; equivalently, its explicitly typed version $\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu} := \Pi^{[\mathrm{TT}]\,\alpha\beta}_{\bar{\Sigma}\,\mu\nu}\Pi^{(a)}\hat{V}_{\alpha\beta}$ may be used. On the certified plateau $\mathfrak{P}$, TT/triadic projectors commute and the two forms are interchangeable (cf. Lemma 11.92 and eq. (11.109)).
- The sum over a implements the triadic decomposition of the exchange channel (Section 11.1.4 and Definition 11.51).

Momentum–space form and currents. Fourier transforming the vertex matrix elements defines the *sector currents*

$$\tilde{\mathcal{J}}^{(a)}_{\mu\nu}(k) := \int d\mu_{\bar{\Sigma}}(x)\; e^{+ikx}\,\langle\Theta_3|\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu}(x)|\Theta_1\rangle,$$
$$\tilde{\mathcal{J}}^{(a)\rho\sigma}(-k) := \int d\mu_{\bar{\Sigma}}(y)\; e^{-iky}\,\langle\Theta_4|\hat{V}^{[\mathrm{TT}],(a)\rho\sigma}(y)|\Theta_2\rangle,$$

where k is the momentum flowing through the exchanged graviton (e.g. in the t–channel $k = p_1 - p_3$, in the s–channel $k = p_1 + p_2$, etc.). Using the TT polarization sum $\Pi^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma}(k) := \sum_s e^{(s)\mu\nu}(k)\, e^{(s)}_{\rho\sigma}(k)^*$ (Section 11.1.3), the amplitude becomes

$$\boxed{\mathcal{A}_{12\to34} = \sum_a \int \frac{d^dk}{(2\pi)^d}\; \tilde{\mathcal{J}}^{(a)}_{\mu\nu}(k)\; \frac{i\,\Pi^{[\mathrm{TT}]\mu\nu}{}_{\rho\sigma}(k)}{k^2 - m_a^2 + i\epsilon}\; \tilde{\mathcal{J}}^{(a)\rho\sigma}(-k)\; (2\pi)^d\delta^{(d)}(p_1+p_2-p_3-p_4).}$$

(11.114)

Here m_a^2 is the sector–dependent effective mass parameter inherited from the typed wave operator (Section 11.2.3); in the massless TT limit $m_a^2 = 0$ and the $i\epsilon$ prescription implements the Feynman contour.

Causality/positivity. On $\mathfrak{P}$, the TT projector preserves microcausality with respect to the $\bar{\Sigma}$ cone and ensures Källén–Lehmann positivity per sector; hence the typed kernel obeys the triadic spectral representation with non–negative spectral weights and the standard convexity bounds in the forward limit (eq. (11.91), Proposition 11.14, and Section 11.3.6).

11.3.5 Effective Graviton-Mediated Propagation

Integrating out the TT graviton at quadratic order yields a causal, nonlocal effective action for Tantrakyma fields, block-diagonal in the triad:

$$\boxed{S^{(\Theta)}_{\mathrm{eff}} = \frac{1}{2}\sum_a \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y)\; \mathrm{Tr}\Big[\hat{V}^{(a)}_{\mu\nu}(x)\, i\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(x,y)\, \hat{V}^{(a)\rho\sigma}(y)\Big] + \cdots,}$$

(11.115)

where "$\cdots$" indicates higher-point and radiative corrections consistent with the typed projectors. This representation makes manifest the sector-resolved mediation and is the starting point for dispersion/positivity analyses (Section 11.3.6).

Derivation (integrating out the TT graviton). Work channel–wise on the certified plateau $\mathfrak{P}$, where the TT and triadic projectors commute (Lemma 11.92). Keep terms up to quadratic order in the graviton fluctuation and linear order in the matter–gravity coupling:

$$S[\hat{\boldsymbol{\Theta}}, h] = S_\Theta[\hat{\boldsymbol{\Theta}}] + \frac{1}{2}\sum_a \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y)\, h^{(a)}_{\mu\nu}(x)\, K^{[\mathrm{TT}],(a)\,\mu\nu}{}_{\alpha\beta}(x)\, \delta^{(d)}(x-y)\, h^{(a)\,\alpha\beta}(y)$$
$$+ \sum_a \int d\mu_{\bar{\Sigma}}(x)\, h^{(a)}_{\mu\nu}(x)\, J^{(a)\,\mu\nu}(x).$$

where $h^{(a)} := \Pi^{[\mathrm{TT}]}\Pi^{(a)}\delta\hat{g}$ is TT & sectoral, $K^{[\mathrm{TT}],(a)}$ is the typed wave operator (Section 11.2.3), and $J^{(a)\,\mu\nu}(x) := \mathrm{Tr}\,\hat{V}^{[\mathrm{TT}],(a)\,\mu\nu}(x)$ is the (typed) source current built from the vertex (eq. (11.109) and Section 11.3.2). In compact notation,

$$S = S_\Theta + \frac{1}{2}\sum_a \langle h^{(a)}, K^{[\mathrm{TT}],(a)} h^{(a)}\rangle + \sum_a \langle h^{(a)}, J^{(a)}\rangle.$$

Complete the square in each sector a:

$$\frac{1}{2}\langle h, Kh\rangle + \langle h, J\rangle = \frac{1}{2}\langle h + K^{-1}J,\ K\,(h + K^{-1}J)\rangle - \frac{1}{2}\langle J,\ K^{-1}J\rangle.$$

Gaussian path integral. The in–out generating functional (Feynman $i\epsilon$) factorizes over a and over TT modes,

$$\int \mathcal{D}h\ \exp\Big\{ i\Big[\tfrac{1}{2}\langle h, Kh\rangle + \langle h, J\rangle\Big]\Big\} = \mathcal{N}\ \exp\Big\{ -\frac{i}{2}\,\langle J,\ K^{-1}J\rangle\Big\},$$

where $\mathcal{N}$ contains the (channel–wise) functional determinants $\left(\det K^{[\mathrm{TT}],(a)}\right)^{-1/2}$ (one-loop vacuum bubbles; they are absorbed into the "$\cdots$" in (11.115)).

Relate K^{-1} to the typed Feynman kernel. By definition (eq. (11.107)), the TT Feynman kernel satisfies $K^{[\mathrm{TT}],(a)} \circ G^{\mathrm{F},[\mathrm{TT}],(a)} = i\,\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\delta^{(d)}$, so on the TT subspace $K^{-1} = (1/i)\,G^{\mathrm{F},[\mathrm{TT}],(a)}$. Hence

$$-\frac{i}{2}\,\langle J,\ K^{-1}J\rangle = -\frac{i}{2}\left\langle J,\ \frac{1}{i}G^{\mathrm{F},[\mathrm{TT}]}J\right\rangle = \frac{i}{2}\,\langle J,\ G^{\mathrm{F},[\mathrm{TT}]}J\rangle = \frac{1}{2}\,\langle J,\ i\,G^{\mathrm{F},[\mathrm{TT}]}J\rangle.$$

Putting it together. Summing over sectors and restoring indices gives the nonlocal, triad–block–diagonal effective action for Tantrakyma fields:

$$\boxed{S^{(\Theta)}_{\mathrm{eff}} = S_\Theta + \frac{1}{2}\sum_a \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y)\ \mathrm{Tr}\Big[\hat{V}^{(a)}_{\mu\nu}(x)\, i\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(x,y)\,\hat{V}^{(a)\rho\sigma}(y)\Big] + \cdots}$$

(11.116)

where the ellipsis denotes higher–point/radiative terms (including $\log\det K$) consistent with the typed projectors. Orthogonality $\Pi^{(a)}\Pi^{(b)} = \delta_{ab}\Pi^{(a)}$ implies no cross–sector mixing at this order.

In–in (causal) variant. For causal response or expectation values, the Schwinger–Keldysh integration replaces $i\,G^{\mathrm{F},[\mathrm{TT}]}$ by the retarded TT kernel $G^{\mathrm{ret},[\mathrm{TT}]}$ (eq. (11.105)), yielding a manifestly causal nonlocal term with support inside the $\bar{\Sigma}$ cone.

11.3.6 Positivity and Dispersion Bounds for Triadic Exchange

On $\mathfrak{P}$, each sectoral two-point admits a KL representation with non-negative residue and spectral density on $\mathcal{H}_{\mathrm{phys}}$ (eq. (11.91)). Consequently, forward-limit amplitudes built from (11.114) satisfy standard analyticity/positivity constraints triadwise; the typed construction is Nielsen-flat and gauge-robust (Proposition 11.14). The TT TLO ledgers $(\Lambda^{[\mathrm{TT}]}_{\mathrm{law}}, \Lambda^{[\mathrm{TT}]}_{\mathrm{state}})$ serve as the certification layer for any claimed channel-selective deviation from GR (Definition 11.52).

11.3.7 Graviton-Mediated Tantrakyma Scattering

Definition 11.68 (Graviton–mediated S-matrix (typed, connected))**.** Let $|\Theta_{\rm in}\rangle$ and $|\Theta_{\rm out}\rangle$ be asymptotic Tantrakyma multiparticle states on the certified plateau $\mathfrak{P}$. The *graviton-mediated* scattering amplitude is the connected part of the $\bar{\Sigma}$-time-ordered matrix element

$$\boxed{\mathcal{A}_{\rm grav}[\Theta_{\rm in}\to\Theta_{\rm out}] := \Big\langle \Theta_{\rm out}\Big|\, T_{\bar{\Sigma}} \exp\Big(i\, S^{(1)}_{\rm int}[\hat{h},\hat{\mathbf{\Theta}}]\Big)\,\Big|\Theta_{\rm in}\Big\rangle_{\rm conn},} \tag{11.117}$$

where $T_{\bar{\Sigma}}\{\cdot\}$ is the $\bar{\Sigma}$-time-ordering operator (Definition 11.53) and $S^{(1)}_{\rm int}$ is the typed, linearized interaction $S^{(1)}_{\rm int} = \int d\mu_{\bar{\Sigma}}\,\mathrm{Tr}\big[\hat{h}_{\mu\nu}\hat{V}^{\mu\nu}\big]$ with $\hat{V}^{\mu\nu}$ the TT vertex (Definitions 11.64 and 11.66). The TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and the triad projectors $\Pi^{(a)}$ commute, and all band tags commute with both (Definitions 9.10 and 11.24).

Lemma 11.69 (Tree-level TT graviton exchange (triad-resolved))**.** *Expanding* (11.117) *to second order in the Dyson series and keeping the connected contribution gives the single-exchange amplitude*

$$\boxed{\begin{aligned}\mathcal{A}^{(2)}_{\rm grav} = -\frac{1}{2}\sum_{a\in\{\rm corr,vac,spec\}}\int d\mu_{\bar{\Sigma}}(x)\,d\mu_{\bar{\Sigma}}(y)\,\Big\langle\Theta_{\rm out}\Big|\,T_{\bar{\Sigma}}\Big\{\hat{V}^{(a)}_{\mu\nu}(x)\,\hat{V}^{(a)}_{\rho\sigma}(y)\Big\}\,\Big|\Theta_{\rm in}\Big\rangle\\ \times\, i\,G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu\,\rho\sigma}(x,y),\end{aligned}} \tag{11.118}$$

where $G^{\mathrm{F},[\mathrm{TT}],(a)}$ is the typed Feynman propagator in sector a (Definitions 11.51 and 11.54), and $\hat{V}^{(a)}_{\mu\nu} := \Pi^{(a)}\hat{V}_{\mu\nu}$ (Sections 11.1.4 and 11.3.3). In momentum space this reduces to the block-diagonal form of eq. (11.114).

11.3.8 Effective Graviton-Mediated Propagation

The leading graviton-induced dressing of the Tantrakyma two-point function arises from emission and reabsorption of a virtual TT graviton. Summing over triadic channels yields a causal, nonlocal contribution that respects the $\bar{\Sigma}$-cone and KL positivity on $\mathcal{H}_{\rm phys}$ (eq. (11.91) and Proposition 11.14):

Definition 11.70 (Gravitational dressing of the Tantrakyma propagator (typed, triad-summed))**.** The graviton-exchange correction to the Tantrakyma two-point kernel $\hat{G}_{\Theta\Theta}(x,x')$ is

$$\boxed{\begin{aligned}\Delta\hat{G}_{\Theta\Theta}(x,x') = \sum_a\int d\mu_{\bar{\Sigma}}(z)\,d\mu_{\bar{\Sigma}}(z')\,\Big\langle 0\Big|\,T_{\bar{\Sigma}}\Big\{\hat{\mathbf{\Theta}}(x)\,\hat{V}^{(a)}_{\mu\nu}(z)\,i\,G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(z,z')\\ \hat{V}^{(a)\rho\sigma}(z')\,\hat{\mathbf{\Theta}}(x')\Big\}\,\Big|0\Big\rangle_{\rm conn}.\end{aligned}} \tag{11.119}$$

with $i\,G^{\mathrm{F},[\mathrm{TT}],(a)}$ the TT Feynman kernel (Definition 11.54) and $\hat{V}^{(a)}$ as in Definition 11.64. On $\mathfrak{P}$, band tags $K^{(\ell)}_{\rm IR}$ do not enlarge causal cones and the result is Nielsen-flat and gauge robust (Definition 6.280 and Proposition 11.14).

Explanation of Definitions 11.70 and 11.71. Both formulas compute the *gravitational dressing* (self–energy insertion) of the Tantrakyma two–point kernel by exchanging a single typed (TT) graviton between two matter–geometry interaction vertices. The construction is causal and covariant on the background $(\mathcal{X}_q, \bar{\Sigma})$ and is evaluated on a certified plateau $\mathfrak{P}$ so that all realized weave configuration operators commute and are BRST/Nielsen–safe (Definitions 6.280 and 9.10, Propositions 7.3 and 10.9, and Corollary 11.5). The operator $T_{\bar{\Sigma}}$ denotes $\bar{\Sigma}$–time ordering on the foliation determined by the chronogeometric background, the measures $d\mu_{\bar{\Sigma}}$ are the relational volume elements, and the subscript "conn" restricts to the connected contribution (cf. Chapter 10 and Definition 6.7 and eq. (11.115)). The kernel $i\,G^{\mathrm{F},[\mathrm{TT}],(a)}$ is the TT Feynman Green function of the sector–resolved typed wave operator $K^{[\mathrm{TT}],(a)}$ (Definitions 11.54 and 11.60), and $\hat{V}^{(a)}$ is the triad–filtered graviton–Tantrakyma vertex (Definitions 10.2 and 11.64). In this way, (11.119) realizes the standard diagrammatic contraction "vertex–propagator–vertex" summed over triad sectors $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, providing the leading nonlocal, causal correction to $\hat{G}_{\Theta\Theta}$ (compare Definition 11.67).

The explicitly TT–typed form (11.120) inserts the York–Lichnerowicz projector at the vertices, $\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu} := (\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}})_{\mu\nu}{}^{\alpha\beta}\,\Pi^{(a)}\hat{V}_{\alpha\beta}$ (eq. (11.109) and Definition 10.3). This makes manifest that only transverse–traceless polarizations propagate and couple. The two definitions are *equivalent* on $\mathfrak{P}$: by projector commutations and block–diagonality, $\Pi^{(a)}\,G^{\mathrm{F},[\mathrm{TT}]}(k)\,\Pi^{(b)} = \delta_{ab}\,G^{\mathrm{F},[\mathrm{TT}],(a)}(k)$ and $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{V} = \hat{V}^{[\mathrm{TT}]}$ (Propositions 10.9, 11.20 and 11.77 and eq. (11.33)). Moreover, the TT Ward identities $k_\mu \hat{V}^{[\mathrm{TT}],(a)\mu\nu} = 0$ and $\bar{\Sigma}_{\mu\nu}\hat{V}^{[\mathrm{TT}],(a)\mu\nu} = 0$ ensure that any non–TT or τ–typed insertion is TT–null (eq. (11.128) and Corollary 11.73), so inserting $\Pi^{[\mathrm{TT}]}$ at the vertices does not alter the value of the contraction but clarifies its typed content. Causality and gauge robustness follow from the support of the typed causal kernel $\Delta^{[\mathrm{TT}]}$ and the cone–preserving band window $K^{(\ell)}_{\mathrm{IR}}$ (Proposition 11.14 and Remark 9.83). In summary, (11.119) and (11.120) are two notationally different but cohomologically identical realizations of the same TT, triad–resolved graviton dressing of the Tantrakyma propagator.

Definition 11.71 (TT-typed gravitational dressing of the Tantrakyma propagator)**.** On the certified plateau $\mathfrak{P}$, the TT–projected, sector–resolved graviton dressing of the Tantrakyma two–point function is

$$\boxed{\begin{aligned}\Delta\hat{G}^{[\mathrm{TT}]}_{\Theta\Theta}(x,x') \equiv \sum_{a\in\{\mathrm{corr,vac,spec}\}} \int d\mu_{\bar{\Sigma}}(z)\,d\mu_{\bar{\Sigma}}(z')\,\Big\langle 0\Big|\,T_{\bar{\Sigma}}\Big\{ \\ \hat{\boldsymbol{\Theta}}(x)\,\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu}(z)\,i\,G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(z,z') \\ \hat{V}^{[\mathrm{TT}],(a)\,\rho\sigma}(z')\,\hat{\boldsymbol{\Theta}}(x')\Big\}\,\Big|0\Big\rangle_{\mathrm{conn}}.\end{aligned}} \tag{11.120}$$

Here $i\,G^{\mathrm{F},[\mathrm{TT}],(a)}$ is the typed Feynman kernel (Definition 11.54 and eq. (11.107)) and

$$\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu}(z) := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}\,\mu\nu}{}^{\alpha\beta}\,\Pi^{(a)}\,\hat{V}_{\alpha\beta}(z)$$

is the typed, sectoral vertex (eq. (11.109) and Section 11.3.2).

Proposition 11.72 (TT-typed linearized vertex from the bi-local parent)**.** *Let $S_{\mathrm{int}}[\hat{\boldsymbol{\Phi}}, \hat{\boldsymbol{\Theta}}]$ be the bi-local interaction action of Chapter 11 (Definition 10.223 and Section 10.19.4), and let*

the typed graviton be defined by the background-covariant TT projector

$$\hat{h}_{\mu\nu}(x) := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}(x) \quad \textit{(symmetric, traceless, transverse on } (\mathcal{X}_q, \bar{\Sigma})\textit{; cf. Section 11.1.3).}$$

Then the linearized*, TT-typed reduction of the interaction is*

$$\boxed{S_{\mathrm{int}}^{(1)}[\hat{h}, \hat{\boldsymbol{\Theta}}] = \int d\mu_{\bar{\Sigma}}(x)\ \mathrm{Tr}\Big[\hat{h}_{\mu\nu}(x)\,\hat{V}^{\mu\nu}(x; \hat{\boldsymbol{\Theta}})\Big]\,,} \tag{11.121}$$

with the typed vertex operator

$$\boxed{\begin{aligned}\hat{V}^{\mu\nu}(x; \hat{\boldsymbol{\Theta}}) &:= \Big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big)^{\mu\nu}{}_{\alpha\beta}\ \frac{\delta S_{\mathrm{int}}\Big[\hat{\boldsymbol{\Phi}}, \hat{\boldsymbol{\Theta}}\Big]}{\delta g_{\alpha\beta}(x)}\bigg|_{\hat{\boldsymbol{\Phi}}\to\bar{\boldsymbol{\Phi}}} \\ &\equiv \Big(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\Big)^{\mu\nu}{}_{\alpha\beta}\int d\mu_{\bar{\Sigma}}(x')\,\frac{\delta\mathcal{U}_{\Phi\Theta}(x, x')}{\delta g_{\alpha\beta}(x)}\,\hat{\boldsymbol{\Theta}}(x').\end{aligned}} \tag{11.122}$$

where $\mathcal{U}_{\Phi\Theta}$ is the bi-local interaction kernel of Chapter 11 (Definition 4.9 and Section 10.19.4). On the certified plateau $\mathfrak{P}$ the band tags commute with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definitions 6.280 and 9.10), and with the triad projectors $\Pi^{(a)}$ (Proposition 11.93), so the sector-resolved vertex $\hat{V}^{(a)\mu\nu} := \Pi^{(a)}\hat{V}^{\mu\nu}$ is well defined and $[\,\Pi^{(a)}, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,] = 0$.

Proof sketch. Start from the bi-local parent

$$S_{\mathrm{int}} = \int d\mu_{\bar{\Sigma}}(x)\,d\mu_{\bar{\Sigma}}(x')\,\mathrm{Tr}\Big[\hat{\boldsymbol{\Phi}}^{\dagger}(x)\,\mathcal{U}_{\Phi\Theta}(x, x')\,\hat{\boldsymbol{\Theta}}(x')\Big]$$

(Section 10.19.4). Linearize around $\bar{\Phi}$ and vary with respect to the metric to first order in $\delta g_{\alpha\beta}$, then project with $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ to extract the radiative spin–2 part, obtaining (11.122). Inserting $\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$ gives (11.121). Commutation with band/triad projectors follows from Definition 9.10 and Proposition 11.93. □

Corollary 11.73 (TT preservation and τ-null right leg)**.** *Let $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ denote temporal/-coherence fluctuations (Chapter 11). On the weave, $\hat{\tau}$ is TT-null (no radiative spin–2; Section 11.1.3). Consequently, any right-leg insertion that is τ-typed produces no TT vertex:*

$$\boxed{\Pi^{[\mathrm{TT}]\,\mu\nu}{}_{\alpha\beta}\,\hat{V}^{\alpha\beta}\Big(x; \hat{\boldsymbol{\Theta}} \mapsto \hat{\tau}\Big) = 0, \qquad \Rightarrow \qquad S_{\mathrm{int}}^{(1)}[\hat{h}, \hat{\tau}] = 0.} \tag{11.123}$$

Hence τ cannot radiate spin–2, and the linearized vertex preserves the TT type.

Remark 11.74 (Sectoral (triadic) reduction of the vertex)**.** Using $\Pi^{(a)}$ (Section 11.1.4) and the commuting relations, define $\hat{V}^{(a)\mu\nu} := \Pi^{(a)}\hat{V}^{\mu\nu}$ and $\hat{h}^{(a)}_{\mu\nu} := \Pi^{(a)}\hat{h}_{\mu\nu}$. Then

$$S_{\mathrm{int}}^{(1)} = \sum_{a\in\{\mathrm{corr,vac,spec}\}}\int d\mu_{\bar{\Sigma}}(x)\,\mathrm{Tr}\Big[\hat{h}^{(a)}_{\mu\nu}(x)\,\hat{V}^{(a)\mu\nu}(x; \hat{\boldsymbol{\Theta}})\Big]\,,$$

which is block-diagonal in the triad and compatible with the typed Feynman rules (Definitions 11.51 and 11.54).

11.3.9 Graviton Coupling Channels

To analyze scattering and mediation processes it is convenient to decompose the graviton–Tantrakyma vertex into *typed* (TT) and *triadic* components, and then into a polarization/-momentum basis compatible with the TT mode expansion of Section 11.1.3.

Definition 11.75 (Triadic decomposition of the typed vertex)**.** Let the typed graviton field be $\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ and the linearized vertex be defined by (11.121)–(11.122) (Section 11.3.2). Using the commuting triad projectors $\{\Pi^{(a)}\}_{a\in\{\mathrm{corr,vac,spec}\}}$ (Section 11.1.4) and the band tags on the certified plateau $\mathfrak{P}$ (Definitions 6.280 and 9.10), define

$$\boxed{\hat{V}^{\mu\nu}(x;\hat{\boldsymbol{\Theta}}) = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{V}^{(a)\mu\nu}(x;\hat{\boldsymbol{\Theta}}), \qquad \hat{V}^{(a)\mu\nu} := \Pi^{(a)}\,\hat{V}^{\mu\nu}, \qquad \left[\Pi^{(a)}, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\right] = 0.} \tag{11.124}$$

The *typed, triad-resolved* vertex blocks are $\hat{V}^{[\mathrm{TT}],(a)\mu\nu} := \Pi^{[\mathrm{TT}]\,\mu\nu}{}_{\rho\sigma}\,\hat{V}^{(a)\rho\sigma}$, and the linearized action is block-diagonal,

$$S_{\mathrm{int}}^{(1)} = \sum_a \int d\mu_{\bar{\Sigma}}(x)\,\mathrm{Tr}\Big[\hat{h}^{(a)}_{\mu\nu}(x)\,\hat{V}^{[\mathrm{TT}],(a)\mu\nu}(x;\hat{\boldsymbol{\Theta}})\Big], \tag{11.125}$$

$$\text{where} \quad \hat{h}^{(a)}_{\mu\nu} := \Pi^{(a)}\hat{h}_{\mu\nu}. \tag{11.126}$$

Remark 11.76 (Polarization/momentum (operator) basis)**.** Let $\{e^{(s,a)}_{\mu\nu}(k)\}_{s=1}^{d_g}$ be an orthonormal TT polarization basis in sector a (Section 11.1.3), and let $\mathcal{K}^{\mu\nu}(x,x')$ denote the effective response kernel in Proposition 11.72. The *modal vertex amplitudes* are defined by

$$\boxed{\begin{aligned} \mathcal{V}^{(s,a)}(k;x) &:= \int d^dx'\; \mathcal{K}^{\mu\nu}(x,x')\,e^{(s,a)}_{\mu\nu}(k)\,e^{-ik\cdot x'}, \\ \hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu}(x) &= \sum_s \int \frac{d^dk}{(2\pi)^d}\; e^{(s,a)}_{\mu\nu}(k)\,\mathcal{V}^{(s,a)}(k;x) \;+\; \mathrm{h.c.}, \end{aligned}} \tag{11.127}$$

which is compatible with the sector-resolved TT mode expansion of $\hat{h}^{(a)}_{\mu\nu}$ (eq. (11.97)) and the triadic propagators (Definition 11.51 and eq. (11.86)).

In the *typed, triad-resolved* expansion of eq. (11.127) one should read:

- $\mathcal{V}^{(s,a)}(k;x)$ is the *modal vertex amplitude* in triadic sector $a \in \{\mathrm{corr,vac,spec}\}$, a scalar function of the spacetime point x and momentum k, encoding the strength/structure of the coupling between a Tantrakyma excitation and the s-th TT polarization of the sector-a graviton. It is evaluated on the certified plateau $\mathfrak{P}$ with BRST-closed band tags, so that readings are Nielsen-flat (Definitions 6.280 and 9.10).
- The polarization contraction $e^{(s,a)\mu\nu}(k)\,\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu}(x)$ isolates the contribution of each independent TT spin-2 mode to the vertex in sector a (Section 11.1.3 and Definition 11.75). Commutation $[\Pi^{(a)}, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}] = 0$ ensures the contraction is well-defined in type (eq. (11.124)).

- The structure of $\mathcal{V}^{(s,a)}(k;x)$ follows by Fourier-transforming the effective response kernel $\mathcal{K}^{\mu\nu}(x,x')$ (Proposition 11.72):

$$\mathcal{V}^{(s,a)}(k;x) := \int d^d x'\; \mathcal{K}^{\mu\nu}(x,x')\, e^{(s,a)}_{\mu\nu}(k)\, e^{-ikx'}.$$

- This modal basis allows the interaction action and the resulting amplitudes to be written entirely in terms of TT-projected, sector-resolved propagators and momentum-dependent vertex factors (Definition 11.51 and eq. (11.86)), as used in Section 11.3.7.

Proposition 11.77 (TT Ward identity and sectoral preservation)**.** *On the plateau $\mathfrak{P}$ the typed vertex satisfies the TT Ward identities*

$$\boxed{k_\mu\, \hat{V}^{[\mathrm{TT}],(a)\mu\nu}(k) = 0, \qquad \bar{\Sigma}_{\mu\nu}\, \hat{V}^{[\mathrm{TT}],(a)\mu\nu}(k) = 0, \quad \forall a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\},} \tag{11.128}$$

and τ-typed insertions are TT-null (Corollary 11.73). Consequently, internal graviton lines in typed Feynman graphs are TT-propagators contracted with TT vertices in the same *triadic block, i.e. the coupling is block-diagonal by a at the linearized level.*

Proof. Typed vertex and projectors. On the certified plateau $\mathfrak{P}$, the TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and the triad projectors $\{\Pi^{(a)}\}_{a\in\{\mathrm{corr,vac,spec}\}}$ commute with each other and with the band realized weave configuration (tag hygiene) (Proposition 10.9 and Definitions 6.280 and 9.10). Define the typed vertex in momentum space by left–projecting the rank–2 vertex kernel,

$$\hat{V}^{[\mathrm{TT}],(a)}_{\mu\nu}(k) := \left(\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\Pi^{(a)}\right)_{\mu\nu}{}^{\rho\sigma}\, \hat{V}_{\rho\sigma}(k), \tag{11.129}$$

so that it couples only to TT, sector–a carriers (Definitions 10.2, 10.3 and 11.3).

TT Ward identities. By construction, the image of $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ consists of symmetric, traceless, and transverse tensors (York–Lichnerowicz TT calculus: eq. (10.4) and Definition 10.3). Equivalently, using the typed polarization basis $\{e^{(a,\lambda)}_{\mu\nu}(k;x)\}$ of Definition 11.18, one has for each $(k;x)$:

$$\bar{g}^{\mu\nu}(x) e^{(a,\lambda)}_{\mu\nu}(k;x) = 0, \qquad k^\mu e^{(a,\lambda)}_{\mu\nu}(k;x) = 0 \quad (\text{eqs. (11.30) and (11.31)}). \tag{11.130}$$

Since $\hat{V}^{[\mathrm{TT}],(a)}$ is valued in the TT image,

$$k_\mu\, \hat{V}^{[\mathrm{TT}],(a)\mu\nu}(k) = 0, \qquad \bar{\Sigma}_{\mu\nu}\, \hat{V}^{[\mathrm{TT}],(a)\mu\nu}(k) = 0, \tag{11.131}$$

which is precisely eq. (11.128). Moreover, the coherence/temporal (τ) insertions are TT–null by the TT calculus and the projector properties, giving Corollary 11.73.

Sectoral preservation (block–diagonality in a). Let $G^{\mathrm{F},[\mathrm{TT}],(a)}{}_{\mu\nu}{}^{\rho\sigma}(k)$ be the typed Feynman propagator, the Green function of $K^{[\mathrm{TT}],(a)}$ (Definitions 11.54 and 11.60). Using projector commutations and orthogonality of the triad projectors ($\Pi^{(a)}\Pi^{(b)} = \delta_{ab}\Pi^{(a)}$; Definition 10.2 and Proposition 10.9), one finds the block structure

$$\Pi^{(a)}\, G^{\mathrm{F},[\mathrm{TT}]}(k)\, \Pi^{(b)} = \delta_{ab}\, G^{\mathrm{F},[\mathrm{TT}],(a)}(k), \qquad \Pi^{(a)}\, \hat{V}^{[\mathrm{TT}]}(k) = \hat{V}^{[\mathrm{TT}],(a)}(k), \tag{11.132}$$

so internal graviton lines in typed Feynman graphs are TT propagators contracted with TT vertices in the *same* triadic block. In particular, a mixed contraction with $a \neq b$ contains $\Pi^{(a)} G^{\mathrm{F},[\mathrm{TT}]}(k) \Pi^{(b)} = 0$ and vanishes. This block–diagonality is consistent with the triad–resolved mode expansion and the orthogonality/completeness relations of the TT polarization basis (Definitions 11.18 and 11.19 and eq. (11.33)), and is reflected in the factorized CCR/Fock structure (Proposition 11.20).

Causality and plateau/Nielsen safety. Typed microcausality and the Peierls bracket are generated by the same TT operator (Proposition 11.14 and eq. (11.25)); since all realized weave configuration operators are BRST–closed and Nielsen–flat on $\mathfrak{P}$, the Ward identities and the block–diagonal coupling are gauge–parameter independent and regulator–safe (Proposition 7.3, Corollary 11.5, and Remark 9.83).

Altogether, eq. (11.128) holds, τ-typed insertions are TT–null, and internal lines couple TT propagators to TT vertices *within* the same triad sector, as claimed. □

Remark 11.78 (Typed TLO law residual from diagrammatic contractions)**.** Let $\mathbf{R}^{[\mathrm{TT}]}$ and $\Lambda^{[\mathrm{TT}]}_{\mathrm{law}}$ denote the TT law residual and visibility (Chapter 9; cf. the TT TLO overlay introduced in Section 11.1.3). In momentum space, a practical estimator on $\mathfrak{P}$ is obtained by contracting the TT Ward identity with external polarization legs and inserting the typed propagator $G^{\mathrm{F},[\mathrm{TT}],(a)}$ (Definitions 11.51 and 11.54):

$$\boxed{\begin{aligned}\mathscr{R}^{(s,a)}(k) &:= e^{(s,a)}_{\mu\nu}(k)\left[K^{\mu\nu}_{[\mathrm{TT}]\rho\sigma}(k)\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\rho\sigma}{}_{\alpha\beta}(k) - \mathbf{1}^{\mu\nu}{}_{\alpha\beta}\right] e^{(s,a)\,\alpha\beta}(k),\\ &\Lambda^{[\mathrm{TT}]}_{\mathrm{law}} \to 1 \text{ as } \mathscr{R}^{(s,a)}(k) \to 0,\end{aligned}} \tag{11.133}$$

where $K_{[\mathrm{TT}]}$ is the TT Lichnerowicz-type operator on $(\mathcal{X}_q, \bar{\Sigma})$ (Section 11.2.3). By Proposition 11.77 and typed microcausality (Proposition 11.14), $\mathscr{R}^{(s,a)}(k)$ vanishes on-shell and remains Nielsen-flat under admissible band deformations on $\mathfrak{P}$.

Notation check ($\mathscr{R}$ vs. $\mathbf{R}^{[\mathrm{TT}]}$). The symbol $\mathscr{R}$ is introduced only in the diagrammatic estimator $\mathscr{R}^{(s,a)}(k)$ of eq. (11.133). Everywhere else the *TT law residual* is denoted by the bold operator-valued symbol $\mathbf{R}^{[\mathrm{TT}]}$ and its visibility by $\Lambda^{[\mathrm{TT}]}_{\mathrm{law}}$ (Definition 11.6). Thus the notation is consistent provided that:

$$\boxed{\mathscr{R}^{(s,a)}(k) \text{ is a } \textit{momentum–space estimator}; \quad \mathbf{R}^{[\mathrm{TT}]} \text{ is the } \textit{exact} \text{ TT law residual.}}$$

Here $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ is the triad label (Definition 10.2) and s indexes TT polarizations (Definition 11.18). The superscript $^{(s,a)}$ should always appear as an ordered pair in parentheses, and the argument k should be present when working in momentum space. No other variants of $\mathscr{R}$ (e.g. $\mathcal{R}$, $\mathscr{R}_a$, or $\mathscr{R}^{a,s}$) have been introduced.

Definition 11.79 (Diagrammatic TT law–residual estimator)**.** Given TT polarization tensors $e^{(s,a)}_{\mu\nu}(k)$ (Definition 11.18), the TT Lichnerowicz–type operator $K_{[\mathrm{TT}]}$ (Definition 11.60), and the typed Feynman propagator $G^{\mathrm{F},[\mathrm{TT}],(a)}$ (Definition 11.54), define

$$\boxed{\mathscr{R}^{(s,a)}(k) := e^{(s,a)}_{\mu\nu}(k)\left[K^{\mu\nu}_{[\mathrm{TT}]\rho\sigma}(k)\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\rho\sigma}{}_{\alpha\beta}(k) - \mathbf{1}^{\mu\nu}{}_{\alpha\beta}\right] e^{(s,a)\,\alpha\beta}(k).} \tag{11.134}$$

This *estimator* is a scalar function of k on the certified plateau $\mathfrak{P}$, and it vanishes on–shell by the typed Ward identity (Propositions 11.14 and 11.77). Its smallness correlates with the law visibility $\Lambda_{\mathrm{law}}^{[\mathrm{TT}]}$ of Definition 11.6, but it does not replace the exact residual $\mathbf{R}^{[\mathrm{TT}]}$.

This decomposition underpins several foundational aspects of the perturbative framework:

1. **Momentum-space Feynman rules (typed and triad-resolved).** The expansion (11.127) expresses $\hat{V}_{\mu\nu}^{[\mathrm{TT}],(a)}(x)$ in plane-wave TT modes and polarization tensors $e_{\mu\nu}^{(s,a)}(k)$, which are the standard building blocks for Feynman rules. Energy–momentum conservation and the TT propagator structure are manifest in loop and tree graphs, with internal lines carrying the sector label a and using $G^{\mathrm{F},[\mathrm{TT}],(a)}$ (Definition 11.54 and Sections 11.2.2 and 11.3.7). Band tags commute with the projectors, so causal cones are not enlarged on $\mathfrak{P}$ (Proposition 11.14).

2. **Polarization selection rules and dynamical couplings.** Working in the TT polarization basis isolates helicity-2 couplings. The modal amplitudes $\mathcal{V}^{(s,a)}(k;x)$ reveal selection rules and constraints (helicity flow, parity/time-reversal where applicable) sector by sector, controlled by the TT Ward identities (11.128) and the typed projection $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Section 11.1.3 and Definition 11.75).

3. **Background covariance and gauge (type) invariance of observables.** Because $e_{\mu\nu}^{(s,a)}(k)$ are TT with respect to $(\mathcal{X}_q, \bar{\Sigma})$ (transverse $k^\mu e_{\mu\nu}^{(s,a)} = 0$, traceless $\bar{\Sigma}^{\mu\nu} e_{\mu\nu}^{(s,a)} = 0$), amplitudes built from (11.127) are manifestly background-covariant and invariant under linearized diffeomorphisms in the TT type. Diagrammatically, contracting external TT legs with (11.128) provides a typed TLO law check; the corresponding residual $\mathscr{R}^{(s,a)}(k)$ of eq. (11.133) controls the law-visibility $\Lambda_{\mathrm{law}}^{[\mathrm{TT}]}$ on $\mathfrak{P}$.

11.3.10 Scattering Amplitudes from Graviton Exchange

With the typed graviton operator, vertex, and propagators in hand (Section 11.1.3, eq. (11.109), and Definition 11.54), we now assemble tree–level scattering amplitudes for Tantrakyma excitations mediated by virtual gravitons. All statements below are evaluated on a certified plateau $\mathfrak{P}$, with band tags commuting with the sector and TT projectors (Definitions 6.280 and 9.10 and Section 11.1.3).

Definition 11.80 (Triad-resolved, TT-projected tree amplitude)**.** Let $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ denote a triadic sector and $\hat{V}^{\mu\nu}(x)$ the typed vertex (eq. (11.109)). The tree-level graviton-exchange amplitude between asymptotic Tantrakyma states $|\mathbf{T}_1\rangle, |\mathbf{T}_2\rangle \to |\mathbf{T}_3\rangle, |\mathbf{T}_4\rangle$ is, in position space,

$$\boxed{\mathcal{A}_{\mathrm{grav}}^{(a)} = \int d\mu(x)\, d\mu(x')\, \left\langle \mathbf{T}_3 \middle| \hat{V}_{(a)}^{\mu\nu}(x) \middle| \mathbf{T}_1 \right\rangle \left(i\, G_{\mu\nu}^{\mathrm{F},[\mathrm{TT}],(a)\quad \rho\sigma}(x,x') \right) \left\langle \mathbf{T}_4 \middle| \hat{V}_{(a)\,\rho\sigma}(x') \middle| \mathbf{T}_2 \right\rangle,} \tag{11.135}$$

where $d\mu(x) = \sqrt{-\det \bar{\Sigma}(x)}\, d^d x$ and $G^{\mathrm{F},[\mathrm{TT}],(a)}$ is the TT-projected, sector-a Feynman propagator (Definitions 11.51 and 11.54). The full tree amplitude is the block-diagonal sum

$$\boxed{\mathcal{A}_{\mathrm{grav}} = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \mathcal{A}^{(a)}_{\mathrm{grav}}.} \tag{11.136}$$

Remark 11.81 (Momentum-space representation)**.** Define the sector-resolved, TT vertex form factors $\tilde{J}^{(a)}_{\mu\nu}(q) := \int d\mu(x)\, e^{iq\cdot x}\, \langle \mathbf{T}_3 | \hat{V}^{(a)}_{\mu\nu}(x) | \mathbf{T}_1 \rangle$ and similarly for the second leg. Using $i\, G^{\mathrm{F},[\mathrm{TT}],(a)}_{\mu\nu}{}^{\rho\sigma}(q)$ (Sections 11.2.2 and 11.2.3), we obtain

$$\boxed{\mathcal{A}^{(a)}_{\mathrm{grav}} = \int \frac{d^d q}{(2\pi)^d}\, \tilde{J}^{(a)}_{\mu\nu}(-q) \left(i\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(q) \right) \tilde{J}^{(a)\,\rho\sigma}(q).} \tag{11.137}$$

Lemma 11.82 (Block diagonality and TT purity)**.** *On $\mathfrak{P}$, the sector projectors $\Pi^{(a)}$ commute with the background-covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Section 11.1.3). Consequently, internal graviton lines are TT-projected and block-diagonal in the triad label a: there are no cross-channel propagators at tree level, and $\mathcal{A}_{\mathrm{grav}}$ decomposes as in (11.136). Moreover, insertions that are τ-typed on the right leg are TT-null and cannot radiate spin-2 (Section 11.3.2).*

Remark 11.83 (Causality and gauge safety)**.** Time ordering is taken with respect to the $\bar{\Sigma}$-cone (Definition 11.53), and $G^{\mathrm{F},[\mathrm{TT}]}$ inherits microcausality from the retarded/advanced TT kernels (Section 11.1.2). On $\mathfrak{P}$, band tags do not enlarge cones and ensure Nielsen flatness (Definition 6.280 and Proposition 11.14). The TT projection removes gauge (longitudinal/trace) modes, so only physical spin-2 polarizations propagate internally (Section 11.1.3).

Sidebar: Forward-limit dispersion and triadic KL positivity. In each sector a, the TT two-point function admits a Källén–Lehmann representation with positive residue and spectral density on $\mathcal{H}_{\mathrm{phys}}$ (Section 11.2.2). Analyticity and unitarity then imply forward-limit dispersion relations for $\mathcal{A}^{(a)}_{\mathrm{grav}}(s,t)$ at $t\to 0$, whose subtraction constants and moments are nonnegative functionals of the sectoral spectral densities. These yield triad-resolved positivity/dispersion bounds constraining low-energy Wilson coefficients and contact terms (Section 11.3.6).

Symmetries of the amplitude. The integrands in (11.135) are covariant bitensors on $(\mathcal{X}_q, \bar{\Sigma})$, and the volume element $d\mu(x)$ is diffeomorphism invariant; hence $\mathcal{A}_{\mathrm{grav}}$ is a scalar under background isometries. Gauge invariance at the linearized level is manifest by construction through the TT projection of both the internal propagators and the vertex legs (eq. (11.109) and Definition 11.54).

11.3.11 Effective Graviton-Mediated Propagation

On a certified plateau $\mathfrak{P}$ (band tags fixed, BRST-closed, Nielsen-flat; Definitions 6.280 and 9.10), the typed graviton can be integrated out at quadratic order to yield a nonlocal, *retarded* self-interaction for the Tantrakyma field. Causality is governed by the $\bar{\Sigma}$-null cone throughout (Section 11.1.2).

Definition 11.84 (Retarded TT mediator kernel)**.** Let $G^{\mathrm{ret},[\mathrm{TT}]}_{\mu\nu}{}^{\ \rho\sigma}(x,x')$ be the retarded Green operator of the TT wave operator on $(\mathcal{X}_q,\bar{\Sigma})$ (Section 11.2.3) and let $\hat{V}^{\mu\nu}(x)$ be the typed vertex (eq. (11.109)). The *retarded TT mediator kernel* is

$$\boxed{\mathcal{K}^{\mathrm{ret},[\mathrm{TT}]}(x,x') := \hat{V}^{\mu\nu}(x)\, G^{\mathrm{ret},[\mathrm{TT}]}_{\mu\nu}{}^{\ \rho\sigma}(x,x')\, \hat{V}_{\rho\sigma}(x'), \qquad \operatorname{supp}\mathcal{K}^{\mathrm{ret},[\mathrm{TT}]} \subseteq J^+_{\bar{\Sigma}},} \tag{11.138}$$

where $J^+_{\bar{\Sigma}}$ is the $\bar{\Sigma}$-causal future. Triadically, $\mathcal{K}^{\mathrm{ret},[\mathrm{TT}]} = \sum_a \mathcal{K}^{\mathrm{ret},[\mathrm{TT}],(a)}$ with $\mathcal{K}^{\mathrm{ret},[\mathrm{TT}],(a)}$ built from $G^{\mathrm{ret},[\mathrm{TT}],(a)}$ and $\hat{V}^{(a)}$ (Section 11.3.3).

Proposition 11.85 (Causal influence action for Tantrakyma)**.** *Integrating out the typed graviton at Gaussian order on $\mathfrak{P}$ yields the real-time (in–in) effective action for $\hat{\boldsymbol{\Theta}}$ with a causal nonlocal term*

$$\boxed{S^{\mathrm{eff}}_{\Theta} \;=\; S_{\Theta} + \frac{1}{2}\int d\mu(x)\, d\mu(x')\; \hat{\boldsymbol{\Theta}}(x)\, \mathcal{K}^{\mathrm{ret},[\mathrm{TT}]}(x,x')\, \hat{\boldsymbol{\Theta}}(x'),} \tag{11.139}$$

where $d\mu(x) = \sqrt{-\det\bar{\Sigma}(x)}\, d^d x$. The nonlocal kernel has $\bar{\Sigma}$-retarded support by (11.138); the IR window $K^{(\ell)}_{\mathrm{IR}}$ does not enlarge causal cones (Definition 6.280).

Corollary 11.86 (Dressed, causal equation of motion)**.** *Let $\mathcal{D}_\Theta$ denote the local (bare) Tantrakyma wave operator, so that $\mathcal{D}_\Theta\,\hat{\boldsymbol{\Theta}} = \hat{\mathcal{J}}$ in absence of gravity (Definition 10.208). Variation of (11.139) gives*

$$\boxed{\big(\mathcal{D}_\Theta\,\hat{\boldsymbol{\Theta}}\big)(x) + \int d\mu(x')\, \mathcal{K}^{\mathrm{ret},[\mathrm{TT}]}(x,x')\, \hat{\boldsymbol{\Theta}}(x') = \hat{\mathcal{J}}(x),} \tag{11.140}$$

a manifestly $\bar{\Sigma}$-causal, TT-mediated propagation law. Sectorwise, $\mathcal{K}^{\mathrm{ret},[\mathrm{TT}]} = \sum_a \mathcal{K}^{\mathrm{ret},[\mathrm{TT}],(a)}$.

Proposition 11.87 (Dyson equation for the retarded Tantrakyma propagator)**.** *Let $\Delta^{\mathrm{ret}}_{\Theta,0}$ be the bare retarded Tantrakyma propagator ($\mathcal{D}_\Theta \circ \Delta^{\mathrm{ret}}_{\Theta,0} = \mathbb{I}$) and $\Delta^{\mathrm{ret}}_{\Theta}$ the dressed one. Then on $\mathfrak{P}$*

$$\boxed{\big(\Delta^{\mathrm{ret}}_{\Theta}\big)^{-1} = \big(\Delta^{\mathrm{ret}}_{\Theta,0}\big)^{-1} - \Sigma^{\mathrm{ret}}_{\Theta,\mathrm{grav}}, \qquad \Sigma^{\mathrm{ret}}_{\Theta,\mathrm{grav}} \equiv \mathcal{K}^{\mathrm{ret},[\mathrm{TT}]},} \tag{11.141}$$

with $\Sigma^{\mathrm{ret}}_{\Theta,\mathrm{grav}}$ the retarded *TT self-energy generated by graviton exchange. Triadically, $\Sigma^{\mathrm{ret}}_{\Theta,\mathrm{grav}} = \sum_a \Sigma^{\mathrm{ret},(a)}_{\Theta,\mathrm{grav}}$.*

Remark 11.88 (Relation to time-ordered dressing)**.** The in–out (S-matrix) correction uses the Feynman kernel, $\Sigma^{\mathrm{F}}_{\Theta,\mathrm{grav}} = \hat{V}\, iG^{\mathrm{F},[\mathrm{TT}]}\, \hat{V}$ (Definition 11.54), reproducing the standard self-energy integrand of Definition 11.71. For causal response and propagation on $(\mathcal{X}_q,\bar{\Sigma})$, the appropriate kernel is the retarded one in (11.138); both agree on spectral data (KL densities) on the physical Hilbert space (Section 11.2.2).

Triadic Decomposition of the Self-Energy

A direct consequence of the typed, triad-resolved propagator (Definition 11.54 and eq. (11.86)) is that the gravitational dressing of Tantrakyma propagation splits cleanly by channel on the certified plateau $\mathfrak{P}$:

$$\boxed{\Delta\hat{G}_{\Theta\Theta}(x,x') = \sum_{a\in\{\mathrm{corr},\,\mathrm{vac},\,\mathrm{spec}\}} \Delta\hat{G}^{(a)}_{\Theta\Theta}(x,x').} \tag{11.142}$$

Each sectoral contribution is obtained by contracting the typed vertex (eqs. (11.109) and (11.122)) with the triad-resolved TT Feynman kernel (Definition 11.54 and Section 11.2.2):

$$\boxed{\Delta\hat{G}^{(a)}_{\Theta\Theta}(x,x') = \int d\mu_{\bar{\Sigma}}(z)\, d\mu_{\bar{\Sigma}}(z')\, \Big\langle 0\Big|\, T_{\bar{\Sigma}}\Big\{\hat{\boldsymbol{\Theta}}(x)\, \hat{V}^{\mu\nu}_{(a)}(z)\, \hat{V}^{\rho\sigma}_{(a)}(z')\, \hat{\boldsymbol{\Theta}}(x')\Big\}\, \Big|0\Big\rangle\, i\, G^{\mathrm{F},[\mathrm{TT}],(a)}_{\mu\nu,\rho\sigma}(z,z').} \tag{11.143}$$

Here $T_{\bar{\Sigma}}$ is the $\bar{\Sigma}$-time-ordering (Definition 11.53), and causal support of $G^{\mathrm{F},[\mathrm{TT}],(a)}$ is governed by the $\bar{\Sigma}$-null cone (Section 11.2.3 and Proposition 11.14). Nielsen flatness and hyperbolicity on $\mathfrak{P}$ ensure regulator- and gauge-parameter independence of the decomposition (Ch. 8).

Physical reading of the three terms.

1. *Correlational dressing* $\Delta\hat{G}^{(\mathrm{corr})}_{\Theta\Theta}$: self-energy induced by coupling to the information-theoretic sector (entanglement/coherence), sourced via $\hat{V}^{\mu\nu}_{(\mathrm{corr})}$ (Section 11.3.3).

2. *Vacuum dressing* $\Delta\hat{G}^{(\mathrm{vac})}_{\Theta\Theta}$: self-energy from polarizing the vacuum manifold $\mathcal{M}_{\mathrm{vac}}$ through $\hat{V}^{\mu\nu}_{(\mathrm{vac})}$ (Section 11.1.3).

3. *Spectral dressing* $\Delta\hat{G}^{(\mathrm{spec})}_{\Theta\Theta}$: the familiar energy–momentum–driven contribution via $\hat{V}^{\mu\nu}_{(\mathrm{spec})}$, reproducing the semiclassical limit in the spectral channel (Section 11.2.3).

Thus the observed (dressed) matter propagator acquires channel-wise corrections consistent with the triadic structure of the gravitational mediator (Section 11.2.4).

11.3.12 Graviton-Mediated Tantrakyma Scattering

We compute scattering on $\mathfrak{P}$ with $\bar{\Sigma}$-time ordering (Definition 11.53) and typed vertices (Section 11.3.2).

Definition 11.89 (Graviton–mediated S-matrix element)**.** For asymptotic Tantrakyma states $|\Theta_{\mathrm{in}}\rangle$, $|\Theta_{\mathrm{out}}\rangle$, the connected graviton-mediated amplitude is

$$\boxed{\mathcal{A}_{\mathrm{grav}}\big[\Theta_{\mathrm{in}}\to\Theta_{\mathrm{out}}\big] := \Big\langle\Theta_{\mathrm{out}}\Big|\, T_{\bar{\Sigma}}\exp\Big(i\, S^{(1)}_{\mathrm{int}}[\hat{h},\hat{\boldsymbol{\Theta}}]\Big)\,\Big|\Theta_{\mathrm{in}}\Big\rangle_{\mathrm{conn}},} \tag{11.144}$$

with $S^{(1)}_{\mathrm{int}}$ the linearized, TT-typed interaction (eqs. (11.109) and (11.110)).

Tree-level, single-graviton exchange. Expanding (11.144) to second order and Wick contracting the TT graviton fields yields the tree graph.

Lemma 11.90 (Typed, triad-resolved tree amplitude)**.** *The single-exchange contribution decomposes by triad as*

$$\boxed{\mathcal{A}^{(2)}_{\rm grav} = -\frac{1}{2}\sum_{a\in\{\rm corr,\,vac,\,spec\}}\int d\mu_{\bar\Sigma}(x)\,d\mu_{\bar\Sigma}(y)\;\mathcal{J}^{\mu\nu}_{(a)}(x)\;i\,G^{\mathrm{F},[\mathrm{TT}],(a)}{}_{\mu\nu}{}^{\rho\sigma}(x,y)\;\mathcal{J}^{(a)}_{\rho\sigma}(y),}\tag{11.145}$$

where $\mathcal{J}^{\mu\nu}_{(a)}(x) := \langle\Theta_{\rm out}|\hat V^{\mu\nu}_{(a)}(x)|\Theta_{\rm in}\rangle$ *are typed, sector-resolved matrix elements of the vertex (Section 11.3.3), and* $G^{\mathrm{F},[\mathrm{TT}],(a)}$ *are the TT Feynman kernels in each sector (Definition 11.54 and eq. (11.102)).*

Equation (11.145) is block-diagonal in the triad and manifestly covariant/causal: time ordering is with respect to the $\bar\Sigma$-cone; the IR window and band tags preserve microcausality and commute with the typed projectors (Definitions 6.280 and 9.10 and Proposition 11.14). Gauge-parameter independence (Nielsen flatness) and hyperbolicity of the TT principal symbol are part of plateau certification (Ch. 8).

The Triadic Nature of Gravitational Scattering Because the typed graviton propagator decomposes by sector (eq. (11.86)) and the sector projectors commute with the TT projector on the certified plateau $\mathfrak{P}$ (Sections 11.1.3 and 11.3.3), every graviton–mediated amplitude splits into a block–diagonal sum:

$$\boxed{\mathcal{A}_{\rm grav} = \sum_{a\in\{\rm corr,\,vac,\,spec\}}\mathcal{A}^{(a)}_{\rm grav}.}\tag{11.146}$$

At tree level the sectoral component is the typed TT contraction of currents with the sector–resolved Feynman kernel (Lemma 11.90):

$$\boxed{\mathcal{A}^{(a)}_{\rm grav} = -\frac{1}{2}\int d\mu_{\bar\Sigma}(x)\,d\mu_{\bar\Sigma}(y)\;\mathcal{J}^{\mu\nu}_{(a)}(x)\;i\,G^{\mathrm{F},[\mathrm{TT}],(a)}{}_{\mu\nu}{}^{\rho\sigma}(x,y)\;\mathcal{J}^{(a)}_{\rho\sigma}(y)\;+\;(\text{loops}).}\tag{11.147}$$

Here $\mathcal{J}^{\mu\nu}_{(a)}(x) = \langle\Theta_{\rm out}|\hat V^{\mu\nu}_{(a)}(x)|\Theta_{\rm in}\rangle$ are the typed, triad–resolved vertex matrix elements (Section 11.3.3 and eq. (11.109)), and $G^{\mathrm{F},[\mathrm{TT}],(a)}$ are the $\bar\Sigma$–time–ordered, TT–projected propagators in each sector (Definition 11.54 and Section 11.2.1). Causality and microcausality follow from the $\bar\Sigma$–null support of the typed kernels (Section 11.2.3 and Proposition 11.14), and band/IR operations preserve these cones (Definitions 6.280 and 9.10).

Sectoral interpretation.

- *Correlational channel* (a = corr): exchange of TT quanta sourced by informational structure (entanglement/coherence); see Section 11.2.4.

- *Vacuum channel* ($a = \mathrm{vac}$): exchange of TT Goldstone–like modes tied to the vacuum manifold; masslessness in the SSB limit is ensured by Proposition 11.29.
- *Spectral channel* ($a = \mathrm{spec}$): the energy–momentum–driven exchange reproducing the linearized GR limit (Section 11.2.3).

Coherence and mixing. On $\mathfrak{P}$ the internal graviton lines are block–diagonal in the triad, so there is no cross–channel interference at the free–field (tree) level (Lemma 11.90). Possible mixing can only enter via explicit sector–mixing structures in higher–order vertices or loop corrections, and remains TT–typed by construction (Section 11.3.2).

Generating functional view. The compact expression $\mathcal{A}_{\mathrm{grav}}[\Theta_{\mathrm{in}} \to \Theta_{\mathrm{out}}]$ (eq. (11.144)) is the generating functional for all graviton–exchange processes; expanding the Dyson series yields tree and loop graphs with internal lines $G^{\mathrm{F},[\mathrm{TT}],(a)}$ in each channel. In the forward limit, sector–by–sector Källén–Lehmann positivity of the TT two–point function (Section 11.2.2) supports dispersion relations and sum–rule constraints applied independently to each $\mathcal{A}^{(a)}_{\mathrm{grav}}$.

Lemma 11.91 (Dyson expansion (typed, TT, and triad-resolved))**.** *For $2 \to 2$ Tantrakyma scattering on the certified plateau $\mathfrak{P}$, the leading graviton–mediated contribution arises from the second term of the Dyson series built from the linearized interaction $S^{(1)}_{\mathrm{int}} = \int d\mu_{\bar{\Sigma}}(x)\, \hat{h}_{\mu\nu}(x)\, \hat{V}^{\mu\nu}(x)$ (eqs. (11.109) and (11.110)):*

$$\boxed{\mathcal{A}^{(2)}_{\Theta\Theta\to\Theta\Theta} = \frac{i^2}{2!} \left\langle \Theta_f \middle| T_{\bar{\Sigma}} \left\{ \left(\int d\mu_{\bar{\Sigma}}(x)\, \hat{h}_{\mu\nu}(x)\, \hat{V}^{\mu\nu}(x) \right)^2 \right\} \middle| \Theta_i \right\rangle_{\mathrm{conn}}.} \tag{11.148}$$

Equivalently—after Wick contracting the two graviton fields into the typed Feynman kernel $iG^{\mathrm{F},[\mathrm{TT}]}$ (Definition 11.54 and Section 11.2.1)—the tree-level exchange amplitude is

$$\boxed{\mathcal{A}^{(2)}_{\Theta\Theta\to\Theta\Theta} = -\frac{1}{2} \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y) \left\langle \Theta_f \middle| T_{\bar{\Sigma}} \{ \hat{V}^{\mu\nu}(x)\, \hat{V}^{\rho\sigma}(y) \} \middle| \Theta_i \right\rangle i\, G^{\mathrm{F},[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(x,y).} \tag{11.149}$$

On $\mathfrak{P}$ the triad projectors commute with the TT projector (Sections 11.1.3 and 11.3.3), so the internal line decomposes by sector, $iG^{\mathrm{F},[\mathrm{TT}]} = \sum_a iG^{\mathrm{F},[\mathrm{TT}],(a)}$, yielding $\mathcal{A}^{(2)} = \sum_a \mathcal{A}^{(2),(a)}$ (eq. (11.146)).

Proof via Wick's theorem. Start from the Dyson term (11.148), expand the square to a double integral over x, y, and move the integrals outside the matrix element by linearity of $T_{\bar{\Sigma}}$:

$$\mathcal{A}^{(2)} = \frac{i^2}{2} \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y) \left\langle \Theta_f \middle| T_{\bar{\Sigma}} \{ \hat{h}_{\mu\nu}(x) \hat{V}^{\mu\nu}(x)\, \hat{h}_{\rho\sigma}(y) \hat{V}^{\rho\sigma}(y) \} \middle| \Theta_i \right\rangle_{\mathrm{conn}}.$$

Apply Wick's theorem: since there are no external gravitons, the only non-vanishing connected contraction pairs the two $\hat{h}$'s, producing the typed Feynman propagator $i\, G^{\mathrm{F},[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(x,y) = {}_{\Phi}\langle 0|\, T_{\bar{\Sigma}} \{ \hat{h}_{\mu\nu}(x) \hat{h}^{\rho\sigma}(y) \} |0\rangle_{\Phi}$ (Definition 11.54). The remaining operators reorganize into $T_{\bar{\Sigma}} \{ \hat{V}^{\mu\nu}(x) \hat{V}^{\rho\sigma}(y) \}$. This yields (11.149). On $\mathfrak{P}$, triad projectors commute with $\Pi^{[\mathrm{TT}]}$ and band tags (Section 11.3.3), so $G^{\mathrm{F},[\mathrm{TT}]} = \sum_a G^{\mathrm{F},[\mathrm{TT}],(a)}$ and the amplitude splits as a sectoral sum, as claimed. □

11.3.13 Positivity/Dispersion Bounds for Triadic Graviton Exchange

We derive forward–limit dispersion constraints for elastic $2\to2$ scattering mediated by spin–2 exchange, resolved *triadically* by the commuting sector projectors P_χ with $\chi \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (cf. the sectoral/TT projectors in Section 11.1.3 and the triadic decomposition of the graviton in Section 11.1.4). To avoid a clash with the interferometric overlap $\mathcal{M}$ used elsewhere, we denote the Lorentz–invariant QFT scattering amplitude by $\mathscr{M}$.

Forward dispersion and triadic split. Let $\mathscr{M}^{(2)}_{ab\to ab}(s,t)$ be the crossing–even part of the Lorentz–invariant amplitude in the TT (spin–2) channel isolated by the projector of Definition 11.23, with Mandelstam invariants s,t and forward limit $t\to0$. Inserting the sector projectors into the TT exchange kernel yields a triadic decomposition *at the absorptive level*:

$$\mathscr{M}^{(2)}_{ab\to ab}(s,t) = \sum_\chi \mathscr{M}^{(2),\chi}_{ab\to ab}(s,t), \qquad \mathrm{Im}\,\mathscr{M}^{(2)} = \sum_\chi \mathrm{Im}\,\mathscr{M}^{(2),\chi}, \tag{11.150}$$

with $P_\chi P_{\chi'} = \delta_{\chi\chi'}P_\chi$ and $\sum_\chi P_\chi = \mathbb{I}$ (Section 11.1.3). Unitarity (optical theorem), microcausality (Peierls support on $\bar\Sigma$–null cones), and analyticity/crossing then imply a twice–subtracted forward dispersion relation with a positive spectral integrand for each sector [82, 14, 531, 255, 409]:

$$\boxed{\frac{\partial^2}{\partial s^2}\,\mathrm{Re}\,\mathscr{M}^{(2)}_{ab\to ab}(s,0) \;\geq\; 0, \qquad \rho^{(2)}_{\mathrm{tot}}(\mu^2) = \rho^{(2)}_{\mathrm{corr}}(\mu^2) + \rho^{(2)}_{\mathrm{vac}}(\mu^2) + \rho^{(2)}_{\mathrm{spec}}(\mu^2),} \tag{11.151}$$

where each sectoral TT spectral density obeys the Källén–Lehmann (KL) positivity $\rho^{(2)}_\chi(\mu^2)\geq 0$, being the (typed, TT) two–point density built from the corresponding graviton projector (cf. Definition 11.51 and the typed Feynman kernel in Definition 11.54).

KL representation, residues, and sum rules. In momentum space the typed, TT propagator in sector χ admits a KL form [82, 14]:

$$i\,G^{\mathrm{F},[\mathrm{TT}],\chi}_{\mu\nu}{}^{\rho\sigma}(k) = \int_0^\infty d\mu^2\, \frac{\rho^{(2)}_\chi(\mu^2)}{k^2-\mu^2+i\epsilon}\, \Pi^{[\mathrm{TT}]}_{\mu\nu}{}^{\rho\sigma}(k;\bar\Sigma), \tag{11.152}$$

with $\rho^{(2)}_\chi(\mu^2)\geq0$ and the TT projector $\Pi^{[\mathrm{TT}]}$ built from the orthonormal spin–2 basis (Section 11.1.3). If a narrow pole at $\mu^2=m_\chi^2$ is present, the corresponding residue $Z_\chi \equiv \lim_{k^2\to m_\chi^2}(k^2-m_\chi^2)\,G^{\mathrm{F},[\mathrm{TT}],\chi}$ is non–negative. Triadic completeness implies additivity of both the spectral densities and the pole residues:

$$\boxed{\rho^{(2)}_{\mathrm{tot}} = \sum_\chi \rho^{(2)}_\chi, \qquad Z_{\mathrm{tot}} = \sum_\chi Z_\chi, \qquad Z_\chi \geq 0.} \tag{11.153}$$

Forward–limit positivity (sector–resolved). Combining (11.91) with standard forward dispersion for the crossing–even amplitude gives, for any subtraction point $s_\star$ in the analytic

domain,

$$\boxed{\frac{\partial^2}{\partial s^2}\,\mathrm{Re}\,\mathscr{M}^{(2),\chi}_{ab\to ab}(s_\star,0)=\frac{2}{\pi}\int_{s_{\rm th}}^{\infty}ds'\,\frac{\mathrm{Im}\,\mathscr{M}^{(2),\chi}_{ab\to ab}(s',0)}{(s'-s_\star)^3}\;\geq\;0,}\tag{11.154}$$

with $s_{\rm th}$ the sectoral threshold. The inequality follows from the optical theorem $\mathrm{Im}\,\mathscr{M}^{(2),\chi}\propto\sum_X|\langle X|T^{[\mathrm{TT}],\chi}|ab\rangle|^2\geq 0$ and thus from $\rho^{(2)}_\chi\geq 0$.

Connection to TT state–visibility on $\mathfrak{P}$. On the certified plateau $\mathfrak{P}$ (band tags fixed, BRST cohomology taken, and Nielsen–flatness enforced; cf. Section 11.1.5), the TT *state–visibility* diagnostic is governed by the sectoral KL weights in (11.91). Any loss of positivity (e.g. a negative Z_χ or negative region of $\rho^{(2)}_\chi$) would manifest as a violation of forward–limit bounds (11.154) and thus signal a breakdown of physicality on $\mathfrak{P}$ (microcausality/unitarity).

EFT consequences. Expanding the forward amplitude at low s produces Wilson coefficients in the triad–resolved effective interaction (Section 11.3.4). The inequalities (11.154) then translate into model–independent sign constraints and size bounds on those coefficients, with the sectoral additivity (11.153) correlating the three channels. These results mirror standard EFT positivity arguments adapted to the typed, TT, triad–resolved IQR setting [82, 14, 531].

A. Setup: Forward amplitudes with triadic spin–2 exchange. Work in the TT sector singled out by Definition 11.23; resolve the exchange using the commuting sector projectors P_χ of Section 11.1.3. Consider elastic scattering of identical, neutral Tantrakyma probes (treated as scalars for definiteness) with $s=(p_1+p_2)^2$, $t=(p_1-p_3)^2$, $u=4m^2-s-t$, and define the crossing–even combination $\mathscr{M}_+(s,t)=\frac{1}{2}\big[\mathscr{M}(s,t)+\mathscr{M}(u,t)\big]$ so that $\mathscr{M}_+(s,0)=\mathscr{M}_+(-s,0)$. Stress–tensor Ward identities on the BRST–physical space guarantee analyticity and the optical theorem, furnishing the forward–limit framework used above [82, 14, 531].

Relational regularization and the forward limit. To control IR/UV issues intrinsically in the emergent geometry $(\mathcal{X}_q,\bar\Sigma)$, perform dispersion at fixed state–conditioned band on $\mathfrak{P}$ (coherent, relational regularization), and take the forward limit $t\to 0$ after establishing (11.151). This preserves the typed microcausal structure and ensures each sectoral contribution $\mathscr{M}^{(2),\chi}$ is well–defined in the forward analysis (cf. Section 11.2.1 and Definition 11.54).

Lemma 11.92 (Commutativity of TT and triadic projectors on the physical sector)**.** *Let $\widehat{T}_{\mu\nu}(x)$ be the conserved stress tensor (Ward/BRST identities), and let $W_{\mu\nu;\rho\sigma}(x,y)$ denote its two–point distribution in the BRST/GNS–physical state (Sections 1.4.1 and 12.2). Let $\Pi^{[\mathrm{TT}]\,\alpha\beta}_{\bar\Sigma\,\mu\nu}$ be the transverse–traceless (spin–2) projector (Definition 11.23 and Section 11.1.3), acting on the symmetric tensor indices with respect to the background $\bar\Sigma_{\mu\nu}$, and let $\{P_\chi\}_{\chi\in\{\mathrm{corr,vac,spec}\}}$ be the orthogonal sector projectors from the Unified Inter–Modal Correlator (Definition 6.4), acting on the triadic (internal) fibre. Then, as operator–valued distributions on test data of the form $f^{\mu\nu}(x)\otimes\mathbf{v}$ with $f\in\mathcal{D}(\mathcal{X}_q)$ and $\mathbf{v}$ in the triadic fibre,*

$$\big(\Pi^{[\mathrm{TT}]}_{\bar\Sigma}\otimes\mathbb{I}\big)\big(\mathbb{I}\otimes P_\chi\big)\,W\;=\;\big(\mathbb{I}\otimes P_\chi\big)\big(\Pi^{[\mathrm{TT}]}_{\bar\Sigma}\otimes\mathbb{I}\big)\,W,\tag{11.155}$$

in the sense of distributions modulo contact terms that vanish under (i) smearing with conserved sources and (ii) LSZ amputation in the forward limit. Equivalently, the TT–projected, triadically resolved correlators are well-defined and unique:

$$W^{[\mathrm{TT}],\chi} := \left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes P_\chi\right) W = \left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes \mathbb{I}\right)(\mathbb{I} \otimes P_\chi)\, W = (\mathbb{I} \otimes P_\chi)\left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes \mathbb{I}\right) W. \quad (11.156)$$

Proof. (1) *Tensor–product structure.* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ acts only on space–time tensor indices, whereas P_χ acts only on the finite–dimensional triadic fibre (Definition 6.4). On the algebraic tensor product $\mathcal{D}^{(2)}_{\mathrm{sym}}(\mathcal{X}_q) \,\widehat{\otimes}\, \mathbb{C}^3$ they commute algebraically: $(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes \mathbb{I})(\mathbb{I} \otimes P_\chi) = (\mathbb{I} \otimes P_\chi)(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes \mathbb{I})$.

(2) *Physical sector and BRST closure (plateau $\mathfrak{P}$).* On the BRST/GNS–physical sector (Section 12.2) and on the certified plateau $\mathfrak{P}$ (band tags fixed, Nielsen–flatness), P_χ is BRST–closed and orthogonal ($P_\chi P_{\chi'} = \delta_{\chi\chi'} P_\chi$), so inserting P_χ before or after any operation on space–time indices leaves the triadic block invariant.

(3) *Transversality and contact terms.* Ward identities imply $\bar{\nabla}^\mu W_{\mu\nu;\rho\sigma} = 0$ as a distribution (compatibly with Definitions 11.53 and 11.54). Longitudinal pieces killed by $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ can arise only as contact terms (derivatives of δ), which vanish when smeared against conserved test tensors $f^{\mu\nu}$ ($\bar{\nabla}_\mu f^{\mu\nu} = 0$), and drop out after LSZ amputation in the forward limit used for dispersion. Hence (11.155) holds in the physically relevant distributional sense.

(4) *Domain and continuity.* $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ is a local differential projector (momentum–space multiplier), and P_χ is a bounded idempotent on the triadic fibre; both are continuous endomorphisms of the test space and extend by duality to the space of operator–valued distributions. The commutation therefore extends to W itself. □

Proposition 11.93 (Typed–sectoral projection commuting on the physical band)**.** *On the certified plateau $\mathfrak{P}$, the background–covariant TT projector $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ (Definition 11.23) and the triadic sector projectors $\Pi^{(a)}$ with $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Definitions 6.4 and 11.45)* commute *on operator–valued distributions with conserved insertions, modulo contact terms that vanish when paired with conserved sources and under LSZ amputation. Equivalently, for the TT two–point function W and any local fluctuation $\delta\hat{g}_{\mu\nu}$,*

$$(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes \mathbb{I})\,(\mathbb{I} \otimes \Pi^{(a)})\, W = (\mathbb{I} \otimes \Pi^{(a)})\,(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes \mathbb{I})\, W, \quad (11.157)$$

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \Pi^{(a)}\, \delta\hat{g}_{\mu\nu} = \Pi^{(a)}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}. \quad (11.158)$$

Consequently, channel projection can be performed before or after *TT projection on fields and propagators; in particular,*

$$G^{[\mathrm{TT}],(a)} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \Pi^{(a)}\, G\, \Pi^{(a)}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} = \Pi^{(a)}\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, G\, \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \Pi^{(a)}. \quad (11.159)$$

Proof sketch. Immediate from Lemma 11.92 (TT/triadic commutativity on the physical sector), using BRST closure and orthogonality of $\Pi^{(a)}$, and noting that contact terms drop out for conserved sources. Band tags commute with both projectors on $\mathfrak{P}$ (Definition 9.10 and Proposition 11.25), so there is no leakage across types. □

Corollary 11.94 (Channel–wise TT spectral decomposition)**.** *The TT two–point function admits a Källén–Lehmann representation that is* triadically block–diagonal*:*

$$W^{(2)} = \sum_{\chi \in \{\mathrm{corr},\mathrm{vac},\mathrm{spec}\}} W^{(2),\chi}, \qquad W^{(2),\chi} := \left(\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \otimes P_\chi\right) W,$$

with non–negative sectoral spectral densities by KL positivity on the BRST/GNS–physical sector (Sections 11.1.3 and 11.3.6). Consequently, the channel–wise dispersion relations and positivity bounds derived in Section 11.3.6 apply separately to each $W^{(2),\chi}$.

Remark 11.95 (Gauge–fixing independence)**.** The statement is *gauge–parameter independent*: it is made on the BRST/GNS–physical sector, where longitudinal/gauge contributions are BRST–exact and drop out of W modulo contact terms. The decomposition and positivity are thus properties of physical correlators, not of any particular gauge choice.

B. Universal IR subtraction (massless t–channel pole). In each triadic TT sector $\chi \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, massless spin–2 exchange produces the universal long–range Born singularity for small $|t|$:

$$\mathscr{M}_{+}^{(2),\chi}(s,t) \;=\; \frac{\kappa_\chi^2}{4}\,\frac{s^2}{-t} \;+\; \mathscr{M}_{+,\mathrm{reg}}^{(2),\chi}(s,t), \qquad \lim_{t\to 0} \mathscr{M}_{+,\mathrm{reg}}^{(2),\chi}(s,t) \text{ finite}, \tag{11.160}$$

where the IR–universal coupling κ_χ is fixed by Ward–type identities for the conserved $T_{\mu\nu}$ in sector χ (equivalence–principle normalization), and $\mathscr{M}_{+,\mathrm{reg}}^{(2),\chi}$ is analytic at $t = 0$.[1]
Define IR–subtracted forward amplitudes by removing only the universal Born piece and then taking the forward limit:

$$\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s) \;:=\; \lim_{t\to 0^+}\left[\mathscr{M}_{+}^{(2),\chi}(s,t) \;-\; \frac{\kappa_\chi^2}{4}\,\frac{s^2}{-t}\right], \qquad \widetilde{\mathscr{M}}_{+}^{(2)}(s) \;:=\; \sum_{\chi} \widetilde{\mathscr{M}}_{+}^{(2),\chi}(s). \tag{11.161}$$

This subtraction preserves analyticity in s at fixed $t{=}0$ and is compatible with unitarity and crossing: it removes only the long–range t-channel singularity while leaving the absorptive part (and thus the dispersion kernel) unchanged [82, 14, 531]. In the relational scheme of Sections 4.9.13 and 4.9.15, (11.161) is implemented at fixed state–conditioned IR/UV band, and the limit $t \to 0^+$ is taken after subtraction, ensuring a well–defined forward amplitude sector by sector.

C. Channel–wise dispersion relation and positivity. Analyticity and growth (emergent background). Assume: (A1) microcausality with respect to the effective Lorentzian tensor $\bar{g}_{\mu\nu}^{\mathrm{Lor}}$ (Sections 5.3.4, 5.3.6 and 5.4); (A2) polynomial boundedness after the universal IR subtraction (Sections 4.9.13 and 4.9.15); (A3) BRST/GNS physical states with Hadamard short–distance form (Section 1.4.1); (A4) local, $\bar{\Sigma}$–covariant couplings with Ward identities isolating TT exchange. By Lemma 11.92, TT and triadic projectors commute on the physical two–point, so the decomposition involves no mixing. Then each sector's forward, crossing–even amplitude obeys the twice–subtracted dispersion relation [82, 14, 531]:

$$\begin{aligned}\mathrm{Re}\,\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s) \;=\; &\widetilde{\mathscr{M}}_{+}^{(2),\chi}(0) \;+\; \tfrac{1}{2}\,s^2\,\widetilde{\mathscr{M}}_{+}^{(2),\chi\prime\prime}(0) \\ &+\; \frac{s^4}{\pi}\int_{s_{\mathrm{th}}^{\chi}}^{\infty} \mathrm{d}s'\;\frac{\mathrm{Im}\,\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s')}{s'^4}\left(\frac{1}{s'-s}+\frac{1}{s'+s}\right),\end{aligned} \tag{11.162}$$

[1] If a state–dependent spectral gap $m_{\mathrm{eff}} > 0$ opens (cf. Section 4.9.15), the pole is $s^2/(-t-m_{\mathrm{eff}}^2)$. In (11.161) subtract $s^2/(-t-m_{\mathrm{eff}}^2)$; the massless form (11.160) is recovered as $m_{\mathrm{eff}} \downarrow 0$.

whence the forward convexity (optical theorem):

$$\boxed{\widetilde{\mathscr{M}}_{+}^{(2),\chi\,\prime\prime}(0) \;=\; \frac{2}{\pi}\int_{s_{\mathrm{th}}^{\chi}}^{\infty}\frac{\mathrm{d}s}{s^{3}}\,\mathrm{Im}\,\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s) \;\geq\; 0} \tag{11.163}$$

equivalently, with $\rho_{\chi}^{(2)}(s)=(1/\pi)\,\mathrm{Im}\,\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s)\geq 0$: $\widetilde{\mathscr{M}}_{+}^{(2),\chi\,\prime\prime}(0)=2\int_{s_{\mathrm{th}}^{\chi}}^{\infty}\rho_{\chi}^{(2)}(s)\,s^{-3}\mathrm{d}s\geq 0$.

D. Spectral representation and the triadic sum rule. Let $\Delta^{(2)}(q)$ be the TT propagator (or TT part of the stress–tensor exchange kernel). With $\Pi^{[\mathrm{TT}]}$ from Definition 11.23 and sector projectors P_{χ} from Definition 6.4 (which commute on the BRST/GNS physical two–point), define

$$\Delta^{(2),\chi}(q) \;:=\; \Pi^{[\mathrm{TT}]}\,P_{\chi}\,\Delta^{(2)}(q)\,P_{\chi}\,\Pi^{[\mathrm{TT}]}.$$

Then the triadically resolved Källén–Lehmann representation reads [82, 14]

$$\Delta^{(2),\chi}(q) \;=\; \frac{Z_{\chi}}{q^{2}+i\epsilon} \;+\; \int_{0^{+}}^{\infty}\mathrm{d}\mu^{2}\,\frac{\rho_{\chi}^{(2)}(\mu^{2})}{q^{2}-\mu^{2}+i\epsilon}, \qquad Z_{\chi}\geq 0,\quad \rho_{\chi}^{(2)}(\mu^{2})\geq 0, \tag{11.164}$$

and summing over χ (using $P_{\chi}P_{\chi'}=\delta_{\chi\chi'}P_{\chi}$, $\sum_{\chi}P_{\chi}=\mathbb{I}$) yields the *triadic spectral sum rule*

$$\boxed{\rho_{\mathrm{tot}}^{(2)}(\mu^{2}) \;=\; \rho_{\mathrm{corr}}^{(2)}(\mu^{2}) \;+\; \rho_{\mathrm{vac}}^{(2)}(\mu^{2}) \;+\; \rho_{\mathrm{spec}}^{(2)}(\mu^{2}), \qquad \rho_{\bullet}^{(2)}(\mu^{2})\geq 0\;.} \tag{11.165}$$

Inserting (11.165) into LSZ for the TT channel reproduces the channel–wise convexity bound (11.163) ($\widetilde{\mathscr{M}}_{+}^{(2),\chi\,\prime\prime}(0)\propto\int\rho_{\chi}^{(2)}(s)\,s^{-3}\mathrm{d}s\geq 0$).

E. Low–energy EFT bounds (constraints on triadic Wilson coefficients). Expand the IR–subtracted, forward, crossing–even amplitude in each sector (eq. (11.161)):

$$\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s) \;=\; c_{0}^{(\chi)} \;+\; c_{2}^{(\chi)}\,s^{2} \;+\; c_{4}^{(\chi)}\,s^{4} \;+\cdots, \qquad (\text{even in } s \text{ by crossing}). \tag{11.166}$$

From (11.163) (twice–subtracted dispersion; universal t-channel pole removed) [82, 14, 531],

$$\begin{aligned} c_{2}^{(\chi)} &= \frac{1}{\pi}\int_{s_{\mathrm{th}}^{\chi}}^{\infty}\frac{\mathrm{d}s}{s^{3}}\,\mathrm{Im}\,\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s) \;\geq\; 0,\\ c_{2n}^{(\chi)} &= \frac{(2n-3)!}{\pi}\int_{s_{\mathrm{th}}^{\chi}}^{\infty}\frac{\mathrm{d}s}{s^{2n-1}}\,\mathrm{Im}\,\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s) \;\geq\; 0, \qquad n\geq 2. \end{aligned} \tag{11.167}$$

Matching to EFT. If heavy TT exchange induces the dimension–8 contact

$$\mathcal{L}_{\mathrm{eff}} \;\supset\; \sum_{\chi\in\{\mathrm{corr,vac,spec}\}}\frac{\alpha_{\chi}}{\Lambda^{4}}\left(J_{\mu\nu}^{(\chi)}J_{(\chi)}^{\mu\nu}\right), \tag{11.168}$$

then at tree level $\widetilde{\mathscr{M}}_{+}^{(2),\chi}(s)\;\supset\;\kappa_{\mathrm{EFT}}\,(\alpha_{\chi}/\Lambda^{4})\,s^{2}$ with $\kappa_{\mathrm{EFT}}>0$, and comparing with (11.166)–(11.167) gives

$$\boxed{\alpha_{\chi}\;\geq\;0 \qquad \text{for each}\;\;\chi\in\{\mathrm{corr,vac,spec}\}} \tag{11.169}$$

Proposition (Triadic forward positivity). *Let $\widetilde{\mathcal{M}}_{+}^{(2),\chi}(s)$ be the IR–subtracted, forward, crossing–even $2\to 2$ amplitude mediated by the TT spin–2 sector in channel χ. Assuming microcausality, analyticity, and polynomial boundedness with respect to $\bar{g}_{\mu\nu}^{\mathrm{Lor}}$,*

$$\frac{\partial^2}{\partial s^2}\,\mathrm{Re}\,\widetilde{\mathcal{M}}_{+}^{(2),\chi}(s)\Big|_{s=0} \;=\; \frac{2}{\pi}\int_{s_{\mathrm{th}}^{\chi}}^{\infty}\frac{\mathrm{d}s}{s^3}\,\mathrm{Im}\,\widetilde{\mathcal{M}}_{+}^{(2),\chi}(s) \;\geq\; 0.$$

Corollary (EFT coefficient bounds). *In any low–energy realization of Section 11.3.12, the coefficients multiplying forward s^{2n} contact structures sourced by triadic spin–2 exchange satisfy $c_{2n}^{(\chi)}\geq 0$. In particular, the leading dimension–8 triadic coefficients obey $\alpha_\chi\geq 0$ as in (11.169).*

Remarks. (i) *Universality of the subtraction.* The t–channel pole is fixed by Ward identities; subtracting it removes only the long–range piece and leaves the dispersive kernel unchanged [82, 14]. (ii) *Crossing/odd parts.* For non-identical external states, apply the twice–subtracted dispersion relation to the crossing–even part [531]. (iii) *Relational IR scheme.* Working at fixed state–conditioned IR floor (and coherent UV ceiling) as in Sections 4.9.13 and 4.9.15 yields the same non–negativity; removing regulators at the end commutes with the dispersion integrals by dominated convergence.

Interpretive Summary.

Triadic spectral positivity. By isolating the transverse–traceless (spin–2) exchange and resolving it with the sector projectors P_χ ($\chi=\mathrm{corr},\mathrm{vac},\mathrm{spec}$), the absorptive part in each channel is non-negative and admits a Källén–Lehmann density $\rho_\chi^{(2)}(\mu^2)\geq 0$. The total spectral weight is the sum of the three sectors, $\rho_{\mathrm{tot}}^{(2)}=\sum_\chi\rho_\chi^{(2)}$ (eq. (11.165)). This is precisely the spectral manifestation of unitarity and microcausality for spin–2 exchange [255, 230, 409, 82, 14].

Channel-wise forward convexity. After subtracting the universal long–range t-channel pole (eq. (11.161)), the twice-subtracted, crossing-even dispersion relation with a positive kernel (eq. (11.162)) implies the forward sum rule (eq. (11.163)). Geometrically, the real part of each sector's forward amplitude has non-negative curvature at $s=0$. Any putative negative curvature would contradict at least one S-matrix pillar (unitarity/analyticity/crossing) [82, 14, 531].

IR universality and relational finiteness. The only universal IR singularity is the massless t-channel pole fixed by Ward identities; its subtraction isolates the genuinely model-dependent remainder (eq. (11.161)). Within the relational regularization scheme—working at fixed, state-conditioned IR/UV band and taking the forward limit last—the conclusions are unchanged but the procedure is intrinsically finite (Section 4.9.15).

EFT sign constraints. The low-energy expansion of the IR-subtracted forward amplitude yields $c_{2n}^{(\chi)} \geq 0$ for all $n \geq 1$ (eqs. (11.166) and (11.167)). Matching to the dimension-8 contact $\left(J_{\mu\nu}^{(\chi)}\right)^2/\Lambda^4$ gives $\alpha_\chi \geq 0$ in each sector (eq. (11.169)). Thus any UV completion that induces triadic spin–2 contact terms must respect these sign constraints; a negative α_χ would signal a breakdown of the S-matrix axioms or of the spin–2 projection assumptions.

Bridge to interferometry. The interferometric bounds (Section 3.1.8) assert that coherence is partitioned triadically and cannot exceed an ℓ^2 envelope, while the dispersive bounds assert that absorptive probability is partitioned triadically and cannot be negative. Together they yield an instrument-to-field synthesis: visibility constrains *how* channels interfere; dispersion/positivity constrains *how* they dissipate.

In short, once the universal IR pole is removed, each triadic spin–2 channel carries positive spectral weight and enforces a convex forward amplitude, which in turn imposes *non-negativity* constraints on the corresponding low-energy triadic Wilson coefficients. These conclusions rest only on unitarity, analyticity, crossing, and Ward identities, and are expressed in a form directly usable for EFT matching and phenomenological consistency checks (Section 11.3.6).

11.4 Geometry–matter interface in the typed (TT) formalism.

The graviton is the typed fluctuation of geometry, namely the background–covariant transverse–traceless carrier $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\hat{g}_{\mu\nu}$ (Definition 11.3). Gravitational effects are accessed through their imprint on matter: the Tantrakyma sector provides calibrated probes and sources via the bi–local matter–geometry interaction, producing a triad–filtered vertex $\hat{V}_{\mu\nu}^{(a)}$ that couples linearly to the typed graviton in each sector $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$ (Section 11.3 and Definition 11.24). At the linear level the typed equation of motion is

$$K_{\mu\nu}^{[\mathrm{TT}],(a)\alpha\beta}\, \hat{h}_{\alpha\beta}^{(a)} = \hat{J}_{\mu\nu}^{[\mathrm{TT}],(a)}, \qquad \hat{J}^{[\mathrm{TT}],(a)} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{J}^{(a)},$$

so the geometric carrier $\hat{h}$ is driven by matter currents $\hat{J}^{(a)}$ through the typed Lichnerowicz–type operator $K^{[\mathrm{TT}],(a)}$ (Definitions 11.60 and 11.61). The TT Ward identities guarantee that only physical polarizations couple, $k_\mu\, \hat{V}^{[\mathrm{TT}],(a)\mu\nu} = 0$ and $\bar{\Sigma}_{\mu\nu}\, \hat{V}^{[\mathrm{TT}],(a)\mu\nu} = 0$, and that τ–typed insertions are TT–null (Proposition 11.77 and Corollary 11.73). Hence the Tantrakyma sector necessarily appears whenever the observable imprint of geometry is evaluated.

Two standard computations illustrate this structure. First, tree–level exchange between Tantrakyma sources proceeds through a typed graviton propagator sandwiched between typed vertices, yielding a sector–resolved amplitude that is block–diagonal in a (Definition 11.67 and Propositions 11.20 and 11.77). Second, integrating out the typed graviton at quadratic order produces a causal, nonlocal effective action for Tantrakyma fields,

$$S_{\mathrm{eff}}^{(\Theta)} = \frac{1}{2}\sum_a \int d\mu_{\bar{\Sigma}}(x)\, d\mu_{\bar{\Sigma}}(y)\, \mathrm{Tr}\Big[\hat{V}_{\mu\nu}^{(a)}(x)\, i\, G^{\mathrm{F},[\mathrm{TT}],(a)\,\mu\nu}{}_{\rho\sigma}(x,y)\, \hat{V}^{(a)\rho\sigma}(y)\Big] + \cdots,$$

which underlies the dispersion/positivity analyses (Sections 11.3.5 and 11.3.6 and eq. (11.115)). The same typed Feynman Green function $i\, G^{\mathrm{F},[\mathrm{TT}],(a)}$ governs the Tantrakyma two–point

dressing $\Delta\hat{G}_{\Theta\Theta}$ (Definitions 11.70 and 11.71) and, via its causal difference $\Delta^{[\mathrm{TT}]}$, the Peierls bracket and the covariant commutator (eqs. (11.25) and (11.26) and Proposition 11.14). In summary, the graviton originates in the geometric (Gaiamiti) sector, while its observable content is coupled to and diagnosed by Tantrakyma matter—both as a source in the typed equations of motion and as a probe in amplitudes and propagator dressings—within the BRST–healthy, plateau–stable TT framework (Proposition 7.3 and Corollary 11.5).

Synthesis and alignment with standard expectations. The typed, TT–projected graviton carrier $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ (Definition 11.3) obeys a Lichnerowicz–type wave equation sandwiched by the TT projector (Definition 11.60). Couplings to matter respect the typed Ward identities that enforce transversality and tracelessness (Proposition 11.77). The covariant algebra arises from the Peierls bracket built with the retarded/advanced Green operators of the same typed wave operator (eq. (11.25) and Proposition 11.14). At tree level, exchange and dressing take the familiar "vertex–propagator–vertex'' form, both in position space (Definition 11.67) and in momentum space (eq. (11.137)), and integrating out the typed graviton yields a causal, nonlocal current–current effective action for Tantrakyma fields (Section 11.3.5, eq. (11.115), and Definition 11.71). In this sense, the IQR formulation is fully consonant with linearized gravity and the EFT/QFT-in-curved-spacetime toolkit: physical polarizations are TT, the commutator descends from the causal bi-solution, and amplitudes are controlled by TT projectors and Green kernels [244, 7, 415, 502, 82, 91].

Typed/triadic machinery versus standard minimal gravity. What departs from the minimal textbook setup are the organizational devices introduced by IQR: the triad decomposition $a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$, band tags with certified plateaux, and Nielsen–flat diagnostics together with typed TLO overlays. These structures commute with the TT projector and remain BRST-clean on the certified plateau, so microcausality, the typed Ward identities, and the TT algebra are preserved (Propositions 7.3 and 10.9, Definition 6.280, and Corollary 11.5). They refine bookkeeping and regulator control without altering the physical TT content encoded in Definitions 11.3, 11.60, 11.67 and 11.71.

Masslessness, explicit deformations, and observational status. Within IQR the masslessness of the typed graviton follows from the symmetry/SSB structure in the TT channel (Proposition 11.29). A GMOR–style statement under a controlled explicit breaking produces a small mass deformation (Corollary 11.30), which is a *model* hypothesis akin to massive–gravity deformations rather than a property of vanilla GR. Such deformations must remain consistent with current bounds from gravitational–wave observations that find no deviation from pure-tensor GR radiation; multi–event analyses (GWTC–3) report limits consistent with a strictly massless spin–2 field and the absence of extra polarizations [122, 479]. Ghost–free massive/bimetric frameworks illustrate how tiny graviton masses can be arranged consistently, but they are tightly constrained [113, 481].

Conclusion. Consequently, the typed TT dynamics, Ward identities, Peierls construction, exchange amplitudes, and matter–sector dressings employed here (Definitions 11.3, 11.60, 11.67 and 11.71) are expected and standard in spirit. The triad/band/plateau/Nielsen

apparatus is compatible bookkeeping that preserves the TT physics while improving control over causality, gauge cleanliness, and regulators; any GMOR–type graviton–mass discussion is a permissible deformation rather than a GR prediction and is therefore subject to stringent data-informed bounds [122, 113, 481, 479].

11.4.1 The Feynman Rules for Matter and Geometry

The perturbative dynamics of the IQR, particularly the interactions between matter and geometry, can be systematically organized and calculated using a set of Feynman rules. These rules provide a graphical representation for the terms in the Dyson expansion of the S-matrix (Section 11.3.12). The fundamental components are the propagators for the fields and the vertices describing their interactions.

The Tantrakyma Propagator (Matter)

A matter-like excitation of the Tantrakyma field (of species 'p') propagating from spacetime point x to y is represented by a solid line.

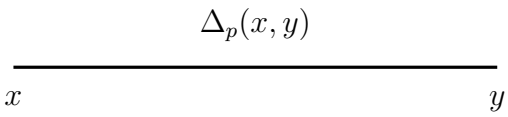

Figure 11.1: Tantrakyma field propagator $\Delta_p(x, y)$, representing matter-like quanta propagating between spacetime points x and y in the emergent configuration space.

- *Diagrammatic Rule:* A solid line connecting points x and y.
- *Mathematical Expression:* This line corresponds to the *Tantrakyma field propagator*, $\Delta_p(x, y)$, which is derived from the matter-sector correlator $\hat{G}_{\Theta\Theta}$ (Definition 10.208).

The Graviton Propagator (Geometry)

A quantum fluctuation of the geometric field propagating from x to y is represented by a wavy line, the standard convention for a mediating gauge boson.

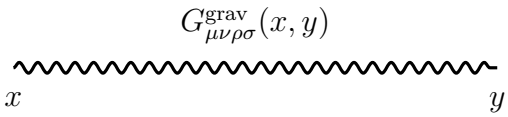

Figure 11.2: Full graviton propagator $G^{\text{grav}}_{\mu\nu\rho\sigma}(x, y)$, encoding quantum fluctuations of the spin-2 geometry field across spacetime.

- *Diagrammatic Rule:* A wavy line connecting points x and y.
- *Mathematical Expression:* This line corresponds to the *full graviton propagator*, $G^{\text{grav}}_{\mu\nu\rho\sigma}(x, y)$ (Section 11.2).

The Triadic Decomposition of the Graviton Propagator

A central prediction of the pqs framework is that the graviton is a composite object with three distinct relational origins. Therefore, any internal graviton line in a Feynman diagram must be treated as the sum of three separate channels.

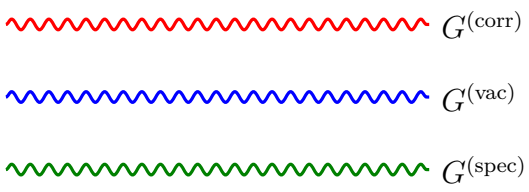

Figure 11.3: Triadic decomposition of the graviton propagator into correlational ($G^{(\text{corr})}$), vacuum ($G^{(\text{vac})}$), and spectral ($G^{(\text{spec})}$) sectors. Each corresponds to a distinct origin mode of geometric excitation.

- *Diagrammatic Rule:* A single wavy graviton line is understood as the sum of three distinct types of propagation, which can be represented by different colors or styles.
- *Mathematical Expression:* The total propagator is the sum of the triadic components (eq. (11.86)):

  $$G^{\text{grav}}_{\mu\nu\rho\sigma}(x,y) = G^{(\text{corr})}_{\mu\nu\rho\sigma}(x,y) + G^{(\text{vac})}_{\mu\nu\rho\sigma}(x,y) + G^{(\text{spec})}_{\mu\nu\rho\sigma}(x,y)$$

  When calculating a scattering amplitude, one must sum over all diagrams involving each of these three distinct internal graviton lines.

The Graviton-Matter Interaction Vertex

The fundamental interaction between matter and geometry is represented by a three-point vertex where two Tantrakyma field lines meet a single graviton line.

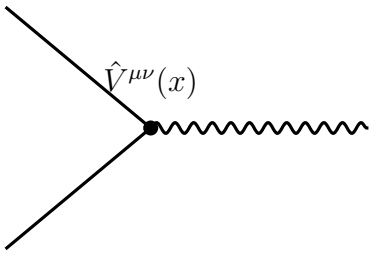

Figure 11.4: Graviton–matter interaction vertex, coupling two Tantrakyma fields (solid lines) to a graviton (wavy line) via the vertex operator $\hat{V}^{\mu\nu}(x)$.

- *Diagrammatic Rule:* A point where two solid lines (Tantrakyma) and one wavy line (graviton) meet.
- *Mathematical Expression:* This vertex corresponds to a factor of $i\hat{V}^{\mu\nu}(x)$, the *graviton-Tantrakyma vertex operator* defined in Definition 11.64. It represents the "gravitational charge" of the matter field.

11.5 The Chronogeometric Gravity

The preceding chapters fix the IQR realized weave configuration and establish how a physical chronogeometry emerges from an operator substrate via diagnostic realized reference configuration (band–limited, BRST–clean) expectations (Definitions 6.280 and 9.10 and Proposition 7.3). The unified geometric carrier is the *Chronogeometric Tensor* (Definition 5.26), defined as the expectation of the operator-valued kernel $\hat{\Sigma}_{\mu\nu}$ in the Quantum Holo-State (Definition 1.27):

$$\bar{\Sigma}_{\mu\nu}(x) := \Big\langle \mathring{\boldsymbol{\Psi}} \Big| \hat{\Sigma}_{\mu\nu}(x) \Big| \mathring{\boldsymbol{\Psi}} \Big\rangle = \bar{g}_{\mu\nu}(x) + \bar{t}_{\mu\nu}(x),$$

the standard background split used throughout (Section 5.2.6). The tensor $\bar{\Sigma}_{\mu\nu}$ determines both the causal cones and the differential geometry on $(\mathcal{X}_q, \bar{\Sigma})$; in particular, it fixes the Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$ (Definition 6.7) and its inverse tensor $\bar{\Sigma}^{\mu\nu}$ used to raise indices (Definition 6.24). The two pieces encode:

- classical distance and causal structure via $\bar{g}_{\mu\nu}$ (background metric block; Section 5.2.6), and
- coherence/phase–flow via the temporal/coherence block $\bar{t}_{\mu\nu}$ (expectation of $\hat{t}_{\mu\nu}$; Definition 5.17).

Unified source (expectation level). Curvature in IQR is sourced by a *unified* stress–energy constructed from geometry (Gaiamiti), matter (Tantrakyma), and their interaction, as organized by the total relational action (Definition 9.357). The operator and scalar (fiber–traced) stress tensors are defined in Section 9.17.9, Definition 9.356, and eq. (9.224), with the interaction piece fixed variationally (eq. (9.237)). On a certified plateau $\mathfrak{P}$ with the physical projector $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\mathrm{BRST}})$ the *expectation–level* total source is (Definition 9.358)

$$\boxed{\bar{T}^{\mu\nu}_{\mathrm{total}}(x) := \Big\langle \mathring{\boldsymbol{\Psi}} \Big| \mathsf{P}_{\mathrm{phys}}\, \mathrm{Tr}\Big\{ \hat{T}^{\mu\nu}_{(\Phi)}(x) + \hat{T}^{\mu\nu}_{(\Theta)}(x) + \hat{T}^{\mu\nu}_{(\mathrm{int})}(x) \Big\} \Big| \mathring{\boldsymbol{\Psi}} \Big\rangle,} \tag{11.170}$$

which is precisely the diagnostic realized reference configuration form emphasized in eqs. (9.230) and (9.238). Concretely,

- $\hat{T}^{\mu\nu}_{(\Phi)}$ is the Gaiamiti Noether tensor (geometry sector) with kernel form given in eq. (9.235);
- $\hat{T}^{\mu\nu}_{(\Theta)}$ is the Tantrakyma Noether tensor (matter sector) as in Definition 9.356 and eq. (9.236);
- $\hat{T}^{\mu\nu}_{(\mathrm{int})}$ follows from the variation of S_{int} with respect to $\bar{\Sigma}_{\mu\nu}$ (eq. (9.237));
- $\big|\mathring{\boldsymbol{\Psi}}\big\rangle$ is the Quantum Holo-State entering all diagnostic realized reference configuration expectations (Definition 1.27).

By linearity of the expectation (diagnostic realized reference configuration semantics), additivity holds as stated in eqs. (9.233) and (9.234).

Self-consistency and conservation. The unified Hilbert variation yields the unique geometric source and the on–shell conservation law (eq. (9.232)):

$$\boxed{\nabla_\mu^{(\mathrm{rel})}\,\bar{T}^{\mu\nu}_{\mathrm{total}}(x)=0,} \tag{11.171}$$

with separate sectoral conservation in the absence of exchange ($\hat{T}^{\mu\nu}_{(\mathrm{int})}=0$), and conservation of the sum otherwise (Section 9.18.12). Thus, the chronogeometric field equations in IQR equate two *emergent* objects on $(\mathcal{X}_q,\bar{\Sigma})$: relational curvature (built from $\bar{\Sigma}$ and $\bar{\nabla}$; Section 5.2.6) and the diagnostic realized reference configuration–projected total source (11.170).

Remark 11.96 (Temporal/coherence curvature as macroscopic quantum structure)**.** The temporal/coherence block $\bar{t}_{\mu\nu}(x)$ is the expectation of a well–defined operator $\hat{t}_{\mu\nu}(x)$ (Definition 5.17), not an ad hoc metric deformation. It encodes how local phase evolution and coherence flow are *curved* by the state, thereby modifying geodesic transport defined by $\bar{\nabla}$ (Definition 6.7). In particular, $\bar{t}_{\mu\nu}$ supports coherence–driven focusing/defocusing and entanglement–induced curvature consistent with the unified source mechanism (Section 9.18.12) and with the additivity/split formulas (eqs. (9.233) and (9.238)).

Instrumentation preamble (diagnostic realized reference configuration, projectors, and readout). All derivations and readouts in this section are performed on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}=(P_x(\lambda_{\mathrm{UV}}),K^{(\ell)}_{\mathrm{IR}})$ that commute with the triad projectors $\Pi^{(\mathrm{corr})},\Pi^{(\mathrm{vac})},\Pi^{(\mathrm{spec})}$ and with the background–covariant TT projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (Definitions 6.280, 9.10, 10.3 and 11.24 and eq. (10.4)). Observables are evaluated on the physical cohomology $\mathcal{H}_{\mathrm{phys}}:=H^0(\hat{Q}_{\mathrm{BRST}})$ (diagnostic realized reference configuration projection $\mathsf{P}_{\mathrm{phys}}$), and all law–channel variations are Nielsen–flat on $\mathfrak{P}$ (Proposition 7.3 and Corollary 11.5). In particular, the Einstein equations are kept verbatim as the central law and will be presented in the BRST/cohomological and band–regular form, with a TT–typed TLO panel attached only for radiative gravity (Definitions 11.6 and 11.106 and eq. (11.191)).

Relational geometry, conservation, and causal support. All connections and curvatures are those of the realized chronogeometry $(\mathcal{X}_q,\bar{\Sigma})$: indices are raised with $\bar{\Sigma}^{\mu\nu}$, and covariant differentiation is by the Relational Levi–Civita connection $\bar{\nabla}\equiv\nabla^{(\mathrm{rel})}$ (Definitions 5.26, 6.7 and 6.24). The unified Bianchi identity $\bar{\nabla}^\mu\bar{G}_{\mu\nu}\equiv 0$ is read on the same background and is matched by the expectation–level conservation law $\bar{\nabla}^{(\mathrm{rel})}_\mu\,\bar{T}^{\mu\nu}_{\mathrm{total}}=0$ (Section 9.18.12 and eq. (9.232)). Linearization employs the TT–sandwiched Lichnerowicz–type operator and its Σ–*causal* advanced/retarded Green kernels, ensuring microcausality on the very cone used elsewhere in the treatise (Definition 11.60, eq. (11.25), and Proposition 11.14). The physical–polarization content is carried by the typed TT graviton, while non–TT "observables'' (e.g. gauge–condition or triad–mixed readouts) are explicitly identified; TT purity and orthogonality follow the Chapter 11 projector calculus and sectoral factorization (Definitions 11.3 and 11.19 and Propositions 11.20 and 11.77).

11.5.1 The Unified Riemann Curvature Tensor

All geometric objects in this section are built from the realized chronogeometric background $(\mathcal{X}_q, \bar{\Sigma})$: indices are raised with $\bar{\Sigma}^{\mu\nu}$ and covariant derivatives are taken with the Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$, which is torsion–free and $\bar{\Sigma}$–compatible (Definitions 5.26, 6.7 and 6.24 and Section 5.2.6). The split $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Section 5.2.6 and Definition 5.17) will be used to exhibit the metric and phase/coherence contributions to curvature.

Definition 11.97 (Riemann tensor of $(\mathcal{X}_q, \bar{\Sigma})$)**.** For any vector field v^λ, the curvature is defined by the commutator

$$\boxed{\left(\bar{\nabla}_\mu \bar{\nabla}_\nu - \bar{\nabla}_\nu \bar{\nabla}_\mu\right) v^\lambda \;=\; \bar{R}^\lambda{}_{\rho\mu\nu}[\bar{\Sigma}]\; v^\rho,} \tag{11.172}$$

equivalently, in a coordinate chart with Christoffel symbols $\Gamma^\lambda{}_{\mu\nu}[\bar{\Sigma}]$ of $\nabla^{(\mathrm{rel})}$ (Definition 6.7),

$$\boxed{\bar{R}^\lambda{}_{\rho\mu\nu}[\bar{\Sigma}] = \partial_\mu \Gamma^\lambda{}_{\nu\rho} - \partial_\nu \Gamma^\lambda{}_{\mu\rho} + \Gamma^\lambda{}_{\mu\alpha}\Gamma^\alpha{}_{\nu\rho} - \Gamma^\lambda{}_{\nu\alpha}\Gamma^\alpha{}_{\mu\rho}.} \tag{11.173}$$

Contractions and Einstein tensor (chronogeometric). The Ricci and scalar curvatures of $\bar{\Sigma}$ are

$$\boxed{\bar{R}_{\mu\nu}[\bar{\Sigma}] := \bar{R}^\rho{}_{\mu\rho\nu}[\bar{\Sigma}], \qquad \bar{R}[\bar{\Sigma}] := \bar{\Sigma}^{\mu\nu}\, \bar{R}_{\mu\nu}[\bar{\Sigma}],} \tag{11.174}$$

and the chronogeometric Einstein tensor is

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] := \bar{R}_{\mu\nu}[\bar{\Sigma}] - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\,\bar{R}[\bar{\Sigma}],} \tag{11.175}$$

which obeys the contracted Bianchi identity $\bar{\nabla}^\mu \bar{G}_{\mu\nu} \equiv 0$ by $\bar{\nabla}$–compatibility of $\bar{\Sigma}$ (Definition 6.7). The unified semi–classical Einstein law is then stated verbatim as $\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}$ (Definition 11.106, eq. (11.191), and Section 9.18.12).

Proposition 11.98 (Symmetries and Bianchi identities)**.**

$$\boxed{\begin{aligned} \bar{R}_{\lambda\rho\mu\nu} &= -\,\bar{R}_{\rho\lambda\mu\nu} && \text{(11.176a)}\\ \bar{R}_{\lambda\rho\mu\nu} &= -\,\bar{R}_{\lambda\rho\nu\mu} && \text{(11.176b)}\\ \bar{R}_{\lambda\rho\mu\nu} &= \bar{R}_{\mu\nu\lambda\rho} && \text{(11.176c)}\\ \bar{R}_{\lambda[\rho\mu\nu]} &= 0 && \text{(11.176d)}\\ \bar{\nabla}_{[\sigma}\bar{R}_{\lambda\rho]\mu\nu} &= 0 && \text{(11.176e)} \end{aligned}}$$

Remark 11.99 (Meaning and applicability of the curvature symmetries)**.** Throughout Proposition 11.98 we work with the unified (Relational) Levi–Civita connection $\bar{\nabla}$ of $\bar{\Sigma}$ (metric compatible and torsion–free), as in Definition 11.97. Under these assumptions, each line in (11.176) has the standard geometric meaning and domain of validity:

(i) Pair antisymmetries.
(11.176a)–(11.176b). They express the skewness of the curvature two–form in each index pair; when indices are lowered with the metric (metric compatibility), one gets $\bar{R}_{\lambda\rho\mu\nu} = -\bar{R}_{\rho\lambda\mu\nu}$ and $\bar{R}_{\lambda\rho\mu\nu} = -\bar{R}_{\lambda\rho\nu\mu}$ [248, 84, 316].

(ii) Major (pair–exchange) symmetry.
(11.176c). For a metric–compatible, torsion–free connection (Levi–Civita) one has $\bar{R}_{\lambda\rho\mu\nu} = \bar{R}_{\mu\nu\lambda\rho}$; this uses metric compatibility in an essential way [248, Ch. III][84, Sec. 6][316, Sec. 3.3].

(iii) First (algebraic) Bianchi identity.
(11.176d). The cyclic sum $\bar{R}_{\lambda[\rho\mu\nu]} = 0$ is the algebraic identity that holds for torsion–free connections; with torsion it acquires additional $T\cdot T$ and $\bar{\nabla}T$ terms. In the Levi–Civita case it takes the simple form shown [248, Ch. III, §7][375, Sec. 7][316, Sec. 3.3].

(iv) Second (differential) Bianchi identity.
(11.176e). The differential identity $\bar{\nabla}_{[\sigma}\bar{R}_{\lambda\rho]\mu\nu} = 0$ holds for the Levi–Civita connection; in the presence of torsion it generalizes by extra torsion–curvature couplings. Contracting indices yields the *contracted Bianchi identity* $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} = 0$ (with $\bar{G}_{\mu\nu}$ from eq. (11.175)), which underlies covariant conservation of the effective source in the field equations [146, §B.2][316, Sec. 3.4][375, Sec. 7].

These statements are standard in Riemannian/Lorentzian geometry and are presented here in the unified $\bar{\Sigma}$–formalism; see the cited references for proofs and for the torsion/non–metricity generalizations.

Remark 11.100 (Metric part + coherence part via connection difference)**.** Let $\Gamma[\bar{g}]$ be the Levi–Civita connection of the metric block $\bar{g}_{\mu\nu}$ and define the difference tensor $C^{\lambda}{}_{\mu\nu} := \Gamma^{\lambda}{}_{\mu\nu}[\bar{\Sigma}] - \Gamma^{\lambda}{}_{\mu\nu}[\bar{g}]$. Then

$$\boxed{\bar{R}^{\lambda}{}_{\rho\mu\nu}[\bar{\Sigma}] = R^{\lambda}{}_{\rho\mu\nu}[\bar{g}] + \nabla^{(\bar{g})}_{\mu}C^{\lambda}{}_{\nu\rho} - \nabla^{(\bar{g})}_{\nu}C^{\lambda}{}_{\mu\rho} + C^{\lambda}{}_{\mu\alpha}C^{\alpha}{}_{\nu\rho} - C^{\lambda}{}_{\nu\alpha}C^{\alpha}{}_{\mu\rho},} \tag{11.177}$$

where $\nabla^{(\bar{g})}$ is the Levi–Civita derivative of $\bar{g}$. The tensor $C^{\lambda}{}_{\mu\nu}$ is determined by the temporal/coherence block $\bar{t}_{\mu\nu}$ through $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Section 5.2.6 and Definition 5.17). Thus the "metric curvature" $R[\bar{g}]$ and the "phase–flow twist" driven by $\bar{t}$ combine to yield the full chronogeometric curvature $\bar{R}[\bar{\Sigma}]$. In the pure–metric limit $\bar{t}_{\mu\nu} \to 0$, one recovers $C \to 0$ and $\bar{R}[\bar{\Sigma}] \to R[\bar{g}]$.

Cohomological form and law residual (context). On a certified plateau $\mathfrak{P}$ with BRST–closed tags (Definitions 6.280 and 9.10), the Einstein law may also be recorded in the cohomological form $\mathcal{E}^{\mathrm{coh}}_{\mathbf{\Phi}}(\bar{\Sigma}) = 0$, $\mathcal{E}^{\mathrm{coh}}_{\mathbf{\Theta}}(\bar{\Sigma}) = 0$ modulo ζ–exact terms and evaluated with Σ–causal retarded kernels (Section 9.18.12 and Propositions 7.3 and 11.14). For diagnostic realized reference configuration–level auditing, define the untyped, global Einstein–law residual and visibility

$$\boxed{\mathbf{R}^{[\mathrm{Ein}]}_{\mu\nu} := \bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} - \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}, \qquad \Lambda^{[\mathrm{Ein}]}_{\mathrm{law}} := 1 - \frac{\|\mathbf{R}^{[\mathrm{Ein}]}\|_{\mathcal{I}}}{\|\cdot\|_{\mathrm{ref}}},} \tag{11.178}$$

interpreted using the plateau meters and synthesis logic of Chapter 9 (Definitions 9.299 and 11.6 and eqs. (9.126) to (9.128)). Typed TT diagnostics remain reserved for the radiative sector as in Chapters 10–11 (Definitions 11.3, 11.6 and 11.60).

Derivation of the Unified Riemann Curvature Tensor

1. Motivation: curvature as non-commuting derivatives. Work on the realized chronogeometric background $(\mathcal{X}_q, \bar{\Sigma})$, with indices raised by $\bar{\Sigma}^{\mu\nu}$ and covariant differentiation by the Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$, which is torsion–free and $\bar{\Sigma}$–compatible (Definitions 6.7 and 6.24 and Section 5.2.6). Curvature is the obstruction to the commutativity of covariant derivatives. Acting on a vector field V^λ,

$$\boxed{\left[\bar{\nabla}_\mu, \bar{\nabla}_\nu\right] V^\lambda := \bar{\nabla}_\mu(\bar{\nabla}_\nu V^\lambda) - \bar{\nabla}_\nu(\bar{\nabla}_\mu V^\lambda),} \tag{11.179}$$

and the goal is to compute the right–hand side explicitly and identify the Riemann tensor of $(\mathcal{X}_q, \bar{\Sigma})$ introduced in Definition 11.97 (components in eq. (11.173)).

2. Calculation of the commutator. Using the coordinate expression for the covariant derivative of a vector, $\bar{\nabla}_\nu V^\lambda = \partial_\nu V^\lambda + \Gamma^\lambda{}_{\nu\sigma}[\bar{\Sigma}]\, V^\sigma$ (Definition 6.7),

$$\bar{\nabla}_\mu(\bar{\nabla}_\nu V^\lambda) = \bar{\nabla}_\mu(\partial_\nu V^\lambda) + \bar{\nabla}_\mu(\Gamma^\lambda{}_{\nu\sigma} V^\sigma).$$

Treat $\partial_\nu V^\lambda$ as a mixed tensor $T^\lambda{}_\nu$ and apply the Leibniz rule:

$$\begin{aligned}
\bar{\nabla}_\mu(\partial_\nu V^\lambda) &= \partial_\mu\partial_\nu V^\lambda + \Gamma^\lambda{}_{\mu\rho}\,\partial_\nu V^\rho - \Gamma^\rho{}_{\mu\nu}\,\partial_\rho V^\lambda, \\
\bar{\nabla}_\mu(\Gamma^\lambda{}_{\nu\sigma} V^\sigma) &= (\partial_\mu \Gamma^\lambda{}_{\nu\sigma})\, V^\sigma + \Gamma^\lambda{}_{\nu\sigma}\,\bar{\nabla}_\mu V^\sigma = (\partial_\mu \Gamma^\lambda{}_{\nu\sigma})\, V^\sigma + \Gamma^\lambda{}_{\nu\sigma}\Big(\partial_\mu V^\sigma + \Gamma^\sigma{}_{\mu\rho} V^\rho\Big).
\end{aligned}$$

Hence

$$\begin{aligned}
\bar{\nabla}_\mu(\bar{\nabla}_\nu V^\lambda) = {} & \partial_\mu\partial_\nu V^\lambda + \Gamma^\lambda{}_{\mu\rho}\,\partial_\nu V^\rho - \Gamma^\rho{}_{\mu\nu}\,\partial_\rho V^\lambda \\
& + (\partial_\mu \Gamma^\lambda{}_{\nu\sigma})\, V^\sigma + \Gamma^\lambda{}_{\nu\sigma}\,\partial_\mu V^\sigma + \Gamma^\lambda{}_{\nu\sigma}\Gamma^\sigma{}_{\mu\rho}\, V^\rho.
\end{aligned}$$

Interchanging $\mu \leftrightarrow \nu$ yields $\bar{\nabla}_\nu(\bar{\nabla}_\mu V^\lambda)$:

$$\begin{aligned}
\bar{\nabla}_\nu(\bar{\nabla}_\mu V^\lambda) = {} & \partial_\nu\partial_\mu V^\lambda + \Gamma^\lambda{}_{\nu\rho}\,\partial_\mu V^\rho - \Gamma^\rho{}_{\nu\mu}\,\partial_\rho V^\lambda \\
& + (\partial_\nu \Gamma^\lambda{}_{\mu\sigma})\, V^\sigma + \Gamma^\lambda{}_{\mu\sigma}\,\partial_\nu V^\sigma + \Gamma^\lambda{}_{\mu\sigma}\Gamma^\sigma{}_{\nu\rho}\, V^\rho.
\end{aligned}$$

Subtracting and using (i) equality of mixed partials on smooth fields, (ii) torsion–free symmetry $\Gamma^\rho{}_{\mu\nu} = \Gamma^\rho{}_{\nu\mu}$ (Definition 6.7), and (iii) relabelling of dummy indices, the terms with ∂V cancel and one finds

$$\left[\bar{\nabla}_\mu, \bar{\nabla}_\nu\right] V^\lambda = \Big[\partial_\mu \Gamma^\lambda{}_{\nu\rho} - \partial_\nu \Gamma^\lambda{}_{\mu\rho} + \Gamma^\lambda{}_{\mu\sigma}\Gamma^\sigma{}_{\nu\rho} - \Gamma^\lambda{}_{\nu\sigma}\Gamma^\sigma{}_{\mu\rho}\Big] V^\rho.$$

By Definition 11.97 and eq. (11.173), the bracket equals $\bar{R}^\lambda{}_{\rho\mu\nu}[\bar{\Sigma}]\, V^\rho$, hence

$$\boxed{\left[\bar{\nabla}_\mu, \bar{\nabla}_\nu\right] V^\lambda = \bar{R}^\lambda{}_{\rho\mu\nu}[\bar{\Sigma}]\; V^\rho,} \tag{11.180}$$

which is the commutator (operator) definition of the unified Riemann tensor of $(\mathcal{X}_q, \bar{\Sigma})$ and is equivalent to the component formula in eq. (11.173).

Checks and continuity. The symmetry and Bianchi identities (Proposition 11.98) follow from torsion–freeness and $\bar{\nabla}\bar{\Sigma}=0$ (Definition 6.7). Decomposing the connection by $\Gamma[\bar{\Sigma}] = \Gamma[\bar{g}] + C(\bar{t})$ gives the metric/coherence split of curvature (Remark 11.100 and eq. (11.177)); in the pure–metric limit $\bar{t}_{\mu\nu} \to 0$ one recovers $C \to 0$ and $\bar{R}[\bar{\Sigma}] \to R[\bar{g}]$, maintaining continuity with the constructions of Chapters 6–7.

Lemma 11.101 (Linearization and Σ–causal Green operators)**.** *Linearize the unified Einstein law $\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\text{total}}_{\mu\nu}$ (Definition 11.106 and eq. (11.191)) around the realized background $(\mathcal{X}_q, \bar{\Sigma})$ with $\bar{\nabla} \equiv \nabla^{(\text{rel})}$ (Definition 6.7). The linearized operator $\mathcal{E}_{\mu\nu}{}^{\rho\sigma}[\bar{\Sigma}]$ acting on symmetric rank–2 fluctuations $h_{\rho\sigma}$ is defined by*

$$\boxed{\mathcal{E}_{\mu\nu}{}^{\rho\sigma}[\bar{\Sigma}]\; h_{\rho\sigma} := \frac{\delta}{\delta\bar{\Sigma}_{\rho\sigma}}\Big(\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu}\Big)\Big|_{\bar{\Sigma}} h_{\rho\sigma}, \qquad \bar{\nabla}^{\mu}\Big(\mathcal{E}_{\mu\nu}{}^{\rho\sigma} h_{\rho\sigma}\Big) = 0.} \tag{11.181}$$

Projecting to spin–2, transverse–traceless type with $\Pi^{[\text{TT}]}_{\bar{\Sigma}}$ (Definitions 10.3 and 11.3 and eq. (10.4)), the typed wave operator is

$$\boxed{K^{[\text{TT}]}_{\mu\nu}{}^{\alpha\beta} := \Big[\Pi^{[\text{TT}]}_{\bar{\Sigma}} \circ \mathcal{E}[\bar{\Sigma}] \circ \Pi^{[\text{TT}]}_{\bar{\Sigma}}\Big]_{\mu\nu}{}^{\alpha\beta} \;\equiv\; K^{[\text{TT}]}_{\mu\nu}{}^{\alpha\beta} \text{ of eq. (11.103).}} \tag{11.182}$$

For the TT fluctuation $h_{\alpha\beta}$ and TT–projected source $J^{[\text{TT}]}_{\mu\nu}$ (defined as in Definition 11.61), the linearized dynamics read

$$\boxed{K^{[\text{TT}]}_{\mu\nu}{}^{\alpha\beta}\, h_{\alpha\beta} = J^{[\text{TT}]}_{\mu\nu}, \qquad J^{[\text{TT}]}_{\mu\nu} := \Pi^{[\text{TT}]}_{\bar{\Sigma}\,\mu\nu}{}^{\rho\sigma}\, J_{\rho\sigma}.} \tag{11.183}$$

The retarded/advanced Green operators $G^{\text{ret/adv},[\text{TT}]}$ are the two–sided inverses of $K^{[\text{TT}]}$ on the TT subspace,

$$\boxed{K^{[\text{TT}]} \circ G^{\text{ret/adv},[\text{TT}]} = \Pi^{[\text{TT}]}_{\bar{\Sigma}}, \qquad G^{\text{ret/adv},[\text{TT}]} \circ K^{[\text{TT}]} = \Pi^{[\text{TT}]}_{\bar{\Sigma}},} \tag{11.184}$$

with support constrained to the $\bar{\Sigma}$–causal cones, $\operatorname{supp} G^{\text{ret/adv},[\text{TT}]} \subset J^{\pm}_{\bar{\Sigma}}$ (Definition 6.7 and Proposition 11.14). Their causal difference $\Delta^{[\text{TT}]} := G^{\text{ret},[\text{TT}]} - G^{\text{adv},[\text{TT}]}$ generates the Peierls bracket and the covariant commutator (eqs. (11.25) and (11.26)), and the Feynman kernel $i\,G^{\text{F},[\text{TT}]}$ solves the typed Green equation (Definition 11.54 and eq. (11.107)).

Remark 11.102 (Microcausal cone and continuity across chapters)**.** The TT retarded/advanced kernels in (11.184) inherit the *same* $\bar{\Sigma}$–microcausal cone used for scalar kernels and their Stieltjes representations in the kinematic constructions of Chapters 6–7, thereby providing a direct bridge to the dynamical Peierls framework of Chapter 8 (Definition 6.7, Proposition 11.14, and eq. (11.25)).

11.5.2 Ricci Tensor and Scalar Curvature of the Unified Geometry

All contractions are taken on the realized chronogeometric background $(\mathcal{X}_q, \bar{\Sigma})$, with indices raised by $\bar{\Sigma}^{\mu\nu}$ and covariant derivatives given by the Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$ (Definitions 6.7 and 6.24 and Section 5.2.6). Starting from the unified Riemann tensor $\bar{R}^{\lambda}{}_{\rho\mu\nu}[\bar{\Sigma}]$ (Definition 11.97 and eq. (11.173)), the standard traces yield the curvature quantities that enter the chronogeometric Einstein tensor (eq. (11.175)) and the unified semi-classical law (Definition 11.106 and eq. (11.191)).

Definition 11.103 (Ricci tensor and scalar curvature of $(\mathcal{X}_q, \bar{\Sigma})$)**.** The *Ricci tensor* is the contraction of the Riemann tensor on its first and third indices,

$$\boxed{\bar{R}_{\mu\nu}[\bar{\Sigma}] \;:=\; \bar{R}^{\lambda}{}_{\mu\lambda\nu}[\bar{\Sigma}],} \tag{11.185}$$

and the *scalar curvature* is the full trace with the inverse chronogeometric tensor,

$$\boxed{\bar{R}[\bar{\Sigma}] \;:=\; \bar{\Sigma}^{\mu\nu}\,\bar{R}_{\mu\nu}[\bar{\Sigma}].} \tag{11.186}$$

Remark 11.104 (Properties and role in the field equations)**.** By the symmetries and Bianchi identities of $\bar{R}_{\lambda\rho\mu\nu}$ (Proposition 11.98), the Ricci tensor is symmetric, $\bar{R}_{\mu\nu} = \bar{R}_{\nu\mu}$, and the contracted Bianchi identity $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} \equiv 0$ follows once the Einstein tensor $\bar{G}_{\mu\nu} = \bar{R}_{\mu\nu} - \frac{1}{2}\bar{\Sigma}_{\mu\nu}\bar{R}$ is formed (eq. (11.175)). These objects provide the geometric side of the unified semi-classical Einstein equations, $\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}$ (Definition 11.106 and eq. (11.191)), with conservation read on the same background, $\bar{\nabla}^{(\mathrm{rel})}_{\mu}\,\bar{T}^{\mu\nu}_{\mathrm{total}} = 0$ (eq. (9.232)).

Derivation of the Ricci tensor formula (unified background). Starting from the unified Riemann tensor of $(\mathcal{X}_q, \bar{\Sigma})$ (Definition 11.97 and eq. (11.173)) and using the Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$ (Definition 6.7) with indices raised by $\bar{\Sigma}^{\mu\nu}$ (Definition 6.24), the Ricci tensor is the contraction on the first and third slots: $\bar{R}_{\mu\nu}[\bar{\Sigma}] = \bar{R}^{\lambda}{}_{\mu\lambda\nu}[\bar{\Sigma}]$ (eq. (11.185)). Writing $\bar{R}^{\lambda}{}_{\rho\mu\nu} = \partial_\mu\Gamma^{\lambda}{}_{\nu\rho} - \partial_\nu\Gamma^{\lambda}{}_{\mu\rho} + \Gamma^{\lambda}{}_{\mu\alpha}\Gamma^{\alpha}{}_{\nu\rho} - \Gamma^{\lambda}{}_{\nu\alpha}\Gamma^{\alpha}{}_{\mu\rho}$ and setting $\rho \to \lambda$ yields, term by term,

$$\partial_\mu\Gamma^{\lambda}{}_{\nu\lambda}, \quad -\partial_\nu\Gamma^{\lambda}{}_{\mu\lambda}, \quad +\Gamma^{\lambda}{}_{\mu\alpha}\Gamma^{\alpha}{}_{\nu\lambda}, \quad -\Gamma^{\lambda}{}_{\nu\alpha}\Gamma^{\alpha}{}_{\mu\lambda}.$$

Collecting them gives the standard Christoffel form of the unified Ricci tensor:

$$\boxed{\bar{R}_{\mu\nu}[\bar{\Sigma}] = \partial_\mu\Gamma^{\lambda}{}_{\nu\lambda} - \partial_\nu\Gamma^{\lambda}{}_{\mu\lambda} + \Gamma^{\lambda}{}_{\mu\alpha}\Gamma^{\alpha}{}_{\nu\lambda} - \Gamma^{\lambda}{}_{\nu\alpha}\Gamma^{\alpha}{}_{\mu\lambda},} \tag{11.187}$$

which is equivalent to the contraction definition eq. (11.185) and is consistent with the symmetry/Bianchi identities in Proposition 11.98. The scalar curvature then follows by the $\bar{\Sigma}$–trace $\bar{R}[\bar{\Sigma}] = \bar{\Sigma}^{\mu\nu}\bar{R}_{\mu\nu}[\bar{\Sigma}]$ (eq. (11.186)), completing the contractions that enter the chronogeometric Einstein tensor (eq. (11.175)).

Physical interpretation and significance (chronogeometric reading).

- *Richer measure of curvature.* In classical GR, $\mathrm{Ric}(g)$ governs volume focusing and tidal deformation. In the IQR setting the unified Ricci tensor $\bar{R}_{\mu\nu}[\bar{\Sigma}]$ measures focusing in the *chronogeometric* sense: because $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Section 5.2.6), its contractions probe both metric curvature (via $\bar{g}$) and the coherence/phase–flow contribution encoded by $\bar{t}$ (expectation of $\hat{t}_{\mu\nu}$, Definition 5.17). The connection difference representation (Remark 11.100 and eq. (11.177)) makes this explicit by splitting $\bar{R}[\bar{\Sigma}]$ into a metric part $R[\bar{g}]$ and a "twist'' built from the temporal/coherence block.

- *Gravitational Lagrangian and variational law.* The unified scalar curvature $\bar{R}[\bar{\Sigma}]$ is the simplest scalar built from $\bar{\Sigma}$ and $\bar{\nabla}$ and thus plays the role of the gravitational Lagrangian density. With the relational volume element $d\mu(x) = \sqrt{-\det \bar{\Sigma}(x)}\, d^d x$ (Definition 6.33), the Einstein–Hilbert–type relational action reads

$$S_{\mathrm{EH}}^{(\mathrm{rel})}[\bar{\Sigma}] := \int_{\mathcal{X}_q} d\mu(x)\ \bar{R}[\bar{\Sigma}].$$

  Its variation (together with a cosmological term) produces the geometric side of the unified law, $\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\, \bar{\Sigma}_{\mu\nu} = \kappa\, \bar{T}^{\mathrm{total}}_{\mu\nu}$ (eqs. (11.175) and (11.191) and Definition 11.106), with conservation read on the same background $\bar{\nabla}^{(\mathrm{rel})}_{\mu}\, \bar{T}^{\mu\nu}_{\mathrm{total}} = 0$ (Section 9.18.12 and eq. (9.232)).

- *Source of new physics and the GR limit.* The difference $\bar{R}[\bar{\Sigma}] - R[\bar{g}]$ is entirely controlled by the temporal/coherence sector through the difference tensor $C(\bar{t})$ in eq. (11.177). When $\bar{t}_{\mu\nu} \to 0$, one has $C \to 0$ and $\bar{R}[\bar{\Sigma}] \to R[\bar{g}]$, recovering GR. In regimes of high coherence or strong temporal curvature (non-negligible $\bar{t}$), the additional terms modify focusing, dispersion, and exchange, feeding back consistently into the unified source $\bar{T}^{\mathrm{total}}_{\mu\nu}$ defined at diagnostic realized reference configuration level (Definition 9.358 and eq. (9.238)) and into the typed radiative sector through the linearized TT operator and its causal kernels (Definition 11.60 and Proposition 11.14).

These unified curvature objects thus furnish the geometric backbone of the emergent Einstein equations, anchoring the left–hand side on the same chronogeometric background, cones, and conservation structure used throughout Chapters 6–11 (Definitions 5.26 and 6.7 and Section 9.18.12).

11.5.3 The Relational Einstein–Hilbert Action

Diagnostic realized reference configuration and covariance context. All statements below are made on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = (P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$ that commute with the triad and TT projectors (Definitions 6.280, 9.10, 10.3 and 11.24). Geometric objects are built from the realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$, with indices raised by $\bar{\Sigma}^{\mu\nu}$ and covariant derivatives given by the Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$ (Definitions 5.26, 6.7 and 6.24). The relational volume element is $d\mu(x) := \sqrt{-\det \bar{\Sigma}(x)}\, d^d x$ (Definition 6.33).

Definition 11.105 (Relational Einstein–Hilbert functional (diagnostic realized reference configuration, band–regularized))**.** The pure–geometry action is the scalar invariant built from the unified scalar curvature $\bar{R}[\bar{\Sigma}]$ (Definition 11.103) and the relational measure:

$$\boxed{S_{\mathrm{EH}}^{(\mathrm{rel})}[\bar{\Sigma}] \;:=\; \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu(x)\; \bar{R}[\bar{\Sigma}] \;-\; \frac{\Lambda}{\kappa}\int_{\mathcal{X}_q} d\mu(x) \;+\; S_{\mathrm{GHY}}^{(\mathrm{rel})}[\partial\mathcal{X}_q],} \tag{11.188}$$

where κ is the gravitational coupling, Λ is the cosmological constant, and $S_{\mathrm{GHY}}^{(\mathrm{rel})}$ is the relational Gibbons–Hawking–York boundary term (needed for a well–posed Dirichlet variational problem on $\partial\mathcal{X}_q$) [532, 533, 534, 535]. The scalar curvature and its contractions are those of the unified geometry (Definition 11.97 and eqs. (11.175), (11.185) and (11.186)).

Variation and field equations (cohomological/diagnostic realized reference configuration forms). Varying (11.188) with respect to $\bar{\Sigma}_{\mu\nu}$ and discarding the boundary variation by $S_{\mathrm{GHY}}^{(\mathrm{rel})}$ gives the geometric Euler–Lagrange identity

$$\boxed{\delta S_{\mathrm{EH}}^{(\mathrm{rel})} = \frac{1}{2\kappa}\int d\mu\,\Big(\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu}\Big)\,\delta\bar{\Sigma}^{\mu\nu},} \tag{11.189}$$

with $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} \equiv 0$ by the contracted Bianchi identity (eq. (11.175)). Coupling to the total relational action $S_{\mathrm{total}} = S_{\Phi} + S_{\Theta} + S_{\mathrm{int}}$ (Definition 9.357) and using the unified stress–energy definition and diagnostic realized reference configuration expectation (Definition 9.358 and eqs. (9.229) and (9.238)), the semi–classical law on $\mathfrak{P}$ reads verbatim

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}, \qquad \bar{\nabla}^{(\mathrm{rel})}_{\mu}\,\bar{T}^{\mu\nu}_{\mathrm{total}} = 0,} \tag{11.190}$$

in agreement with Definition 11.106 and eqs. (9.232) and (11.191). Equivalently, one may record the cohomological equations of motion $\mathcal{E}^{\mathrm{coh}}_{\boldsymbol{\Phi}}(\bar{\Sigma}) = 0$, $\mathcal{E}^{\mathrm{coh}}_{\boldsymbol{\Theta}}(\bar{\Sigma}) = 0$ modulo ζ–exact terms, evaluated with Σ–causal retarded kernels on $\mathfrak{P}$ (Propositions 7.3 and 11.14 and eq. (11.25)).

Physical interpretation and alignment with the TT/triadic program. Because $\bar{R}[\bar{\Sigma}]$ depends on the full unified tensor $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Section 5.2.6), the stationary condition derived from (11.188) balances metric curvature with coherence/temporal curvature (Remark 11.100 and eq. (11.177)). In the $\bar{t}_{\mu\nu} \to 0$ limit one recovers the standard Einstein–Hilbert dynamics $R[g]$; for non–negligible $\bar{t}_{\mu\nu}$, the difference $\bar{R}[\bar{\Sigma}] - R[\bar{g}]$ encodes genuine chronogeometric effects that feed into the unified source and back–reaction (Section 9.18.12 and Definition 9.358). Linearization about $(\mathcal{X}_q, \bar{\Sigma})$ produces the TT–typed spin–2 operator and its Σ–causal Green functions (Definition 11.60 and Lemma 11.101), which govern radiative gravitons; typed TLO diagnostics are attached *only* to this radiative TT sector (Definition 11.6 and Proposition 11.77), consistent with the Chapter 12 instrumentation preamble.

11.5.4 Unified Semi–Classical Einstein Equations

Instrumentation (diagnostic realized reference configuration, tags, covariance). All statements are evaluated on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ =

$(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ that commute with the triad and TT projectors (Definitions 6.280, 9.10, 10.3 and 11.24). Geometry and covariant differentials are those of the realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$ with Relational Levi–Civita connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$ and volume element $d\mu(x) = \sqrt{-\det \bar{\Sigma}}\, d^d x$ (Definitions 5.26, 6.7 and 6.33). Expectations descend to the physical space $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ and are Nielsen–flat on $\mathfrak{P}$ (Proposition 7.3).

Definition 11.106 (Chronogeometric Einstein equations (diagnostic realized reference configuration form))**.** The semi–classical field equations for the expectation–level chronogeometry $\bar{\Sigma}_{\mu\nu}$ read

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] \;+\; \Lambda\, \bar{\Sigma}_{\mu\nu} \;=\; \kappa\, \bar{T}^{\mathrm{total}}_{\mu\nu},} \tag{11.191}$$

where $\bar{G}_{\mu\nu} = \bar{R}_{\mu\nu} - \frac{1}{2}\bar{\Sigma}_{\mu\nu}\bar{R}$ (Section 11.5.2), Λ is the cosmological constant, κ the gravitational coupling, and $\bar{T}^{\mathrm{total}}_{\mu\nu}$ is the expectation–valued total stress–energy sourced by the Gaiamiti, Tantrakyma, and interaction sectors (Definition 9.358, eqs. (9.229) and (9.238), and Section 9.18.12). Equation (11.191) follows from varying the relational Einstein–Hilbert action with cosmological term on $(\mathcal{X}_q, \bar{\Sigma})$ (Definition 11.105 and eq. (11.188)).

$$\boxed{\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} \equiv 0, \qquad \bar{\nabla}^{(\mathrm{rel})}_{\mu}\, \bar{T}^{\mu\nu}_{\mathrm{total}} = 0,} \tag{11.192}$$

the first by the contracted Bianchi identity (eq. (11.175)) and the second by the unified variational definition and on–shell consistency on $\mathfrak{P}$ (Definition 9.358 and eq. (9.232)).

Cohomological (BRST–clean) statement. Equivalently, the dynamical content may be recorded as cohomological equations of motion

$$\mathcal{E}^{\mathrm{coh}}_{\mathbf{\Phi}}(\bar{\Sigma}) = 0, \qquad \mathcal{E}^{\mathrm{coh}}_{\mathbf{\Theta}}(\bar{\Sigma}) = 0,$$

modulo ζ–exact terms and evaluated with Σ–causal retarded kernels on $\mathfrak{P}$ (Propositions 7.3 and 11.14 and eq. (11.25)).

Definition 11.107 (Global Einstein–law residual and visibility (diagnostic realized reference configuration–level))**.** Define the untyped law residual and visibility by

$$\boxed{\mathbf{R}^{[\mathrm{Ein}]}{}_{\mu\nu} := \bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\, \bar{\Sigma}_{\mu\nu} - \kappa\, \bar{T}^{\mathrm{total}}_{\mu\nu}, \qquad \Lambda^{[\mathrm{Ein}]}_{\mathrm{law}} := 1 - \frac{\|\mathbf{R}^{[\mathrm{Ein}]}\|_{\mathcal{I}}}{\|\cdot\|_{\mathrm{ref}}},} \tag{11.193}$$

with the instrumentation norm $\|\cdot\|_{\mathcal{I}}$ and reference scale chosen consistently with the plateau meters and synthesis logic of Chapter 9 (eqs. (9.126) to (9.128) and Definitions 9.297 and 9.299).

Interpretation.

- *Geometric side (LHS).* The Einstein tensor is built from the unified curvature of $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$, hence it encodes both metric focusing and coherence/temporal curvature (Section 11.5.2 and Remarks 11.100 and 11.104).

- *Source side (RHS).* The total source $\bar{T}^{\mathrm{total}}_{\mu\nu}$ aggregates geometry, matter, and interaction contributions at diagnostic realized reference configuration level, with conservation in the sum and sectoral conservation if exchange vanishes (Definition 9.358, eq. (9.238), and Section 9.18.12).

- *Typed radiative sector.* Linearization about $(\mathcal{X}_q, \bar{\Sigma})$ and TT projection produce the spin–2 typed operator and Σ–causal Green functions (Lemma 11.101 and Definition 11.60), to which the typed TLO panel is attached *only* for radiative gravity, consistent with the instrumentation preamble (Definition 11.6 and Proposition 11.77).

In this diagnostic realized reference configuration–regular, BRST–clean form, (11.191) is the dynamical core of the chronogeometric sector, relating unified curvature to the expectation–level total stress–energy on the same causal cones and with the same conservation content used throughout Chapters 6–11.

Remark 11.108 (Relational Einstein vector, Bianchi identity, and linearization on $(\mathcal{X}_q, \bar{\Sigma})$)**. Relational connection and curvatures.** On the realized chronogeometry $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Definition 5.26), the Levi–Civita connection and curvatures are (Definitions 6.7 and 11.97 and Section 11.5.2)

$$\Gamma^{\lambda}_{\mu\nu}[\bar{\Sigma}] = \tfrac{1}{2}\,\bar{\Sigma}^{\lambda\rho}\Big(\partial_\mu \bar{\Sigma}_{\nu\rho} + \partial_\nu \bar{\Sigma}_{\mu\rho} - \partial_\rho \bar{\Sigma}_{\mu\nu}\Big), \qquad \bar{R}^{\lambda}{}_{\rho\mu\nu} = \partial_\mu \Gamma^{\lambda}_{\nu\rho} - \partial_\nu \Gamma^{\lambda}_{\mu\rho} + \Gamma^{\lambda}_{\mu\alpha}\Gamma^{\alpha}_{\nu\rho} - \Gamma^{\lambda}_{\nu\alpha}\Gamma^{\alpha}_{\mu\rho},$$

with $\bar{R}_{\mu\nu} = \bar{R}^{\lambda}{}_{\mu\lambda\nu}$, $\bar{R} = \bar{\Sigma}^{\mu\nu}\bar{R}_{\mu\nu}$, and $\bar{G}_{\mu\nu} = \bar{R}_{\mu\nu} - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\bar{R}$ (eqs. (11.175), (11.185) and (11.186)).

Relational Bianchi identity and conservation. Metric compatibility and torsionlessness on $(\bar{\Sigma}, \bar{\nabla})$ imply the contracted Bianchi identity

$$\boxed{\bar{\nabla}^{\mu}\bar{G}_{\mu\nu}[\bar{\Sigma}] \equiv 0.} \tag{11.194}$$

Hence the Chronogeometric Einstein equations $\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}$ (Definition 11.106 and eq. (11.191)) entail the unified conservation law on the same background, $\bar{\nabla}^{(\mathrm{rel})}_{\mu}\,\bar{T}^{\mu\nu}_{\mathrm{total}} = 0$ (Section 11.5.5 and eqs. (9.232) and (11.192)).

Linearization around $\bar{\Sigma}$. Let $\bar{\Sigma}_{\mu\nu} \mapsto \bar{\Sigma}_{\mu\nu} + \delta\Sigma_{\mu\nu}$ and raise indices with $\bar{\Sigma}^{\mu\nu}$. To first order,

$$\delta\Gamma^{\lambda}_{\mu\nu} = \tfrac{1}{2}\,\bar{\Sigma}^{\lambda\rho}\Big(\bar{\nabla}_\mu \delta\Sigma_{\nu\rho} + \bar{\nabla}_\nu \delta\Sigma_{\mu\rho} - \bar{\nabla}_\rho \delta\Sigma_{\mu\nu}\Big), \tag{11.195}$$

$$\delta\bar{R}_{\mu\nu} = \tfrac{1}{2}\Big(-\bar{\nabla}^2\delta\Sigma_{\mu\nu} - \bar{\nabla}_\mu\bar{\nabla}_\nu\delta\Sigma + \bar{\nabla}_\mu\bar{\nabla}^\rho\delta\Sigma_{\nu\rho} + \bar{\nabla}_\nu\bar{\nabla}^\rho\delta\Sigma_{\mu\rho}\Big) + \bar{R}_{\rho(\mu}\,\delta\Sigma_{\nu)}{}^{\rho} - \bar{R}_{\mu\rho\nu\sigma}\,\delta\Sigma^{\rho\sigma}, \tag{11.196}$$

$$\delta\bar{G}_{\mu\nu} = \delta\bar{R}_{\mu\nu} - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\,\delta\bar{R} - \tfrac{1}{2}\,\delta\Sigma_{\mu\nu}\,\bar{R}, \qquad \delta\bar{R} = \bar{\Sigma}^{\mu\nu}\delta\bar{R}_{\mu\nu} - \bar{R}_{\mu\nu}\delta\Sigma^{\mu\nu}. \tag{11.197}$$

In the de Donder gauge $\bar{\nabla}^{\mu}(\delta\Sigma_{\mu\nu} - \frac{1}{2}\bar{\Sigma}_{\mu\nu}\delta\Sigma) = 0$, the spin–2 operator on $(\bar{\Sigma}, \bar{\nabla})$ reduces to the Lichnerowicz form (Lemma 11.101)

$$\boxed{\mathcal{E}_{\mu\nu}{}^{\rho\sigma}\,\delta\Sigma_{\rho\sigma} := -\bar{\nabla}^2\delta\Sigma_{\mu\nu} - 2\,\bar{R}_{\mu}{}^{\rho}{}_{\nu}{}^{\sigma}\delta\Sigma_{\rho\sigma} + 2\,\bar{R}_{(\mu}{}^{\rho}\,\delta\Sigma_{\nu)\rho} - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\,\bar{R}_{\rho\sigma}\delta\Sigma^{\rho\sigma},}\tag{11.198}$$

and the linearized field equation reads

$$\boxed{\mathcal{E}_{\mu\nu}{}^{\rho\sigma}\,\delta\Sigma_{\rho\sigma} = \kappa\,\Pi_{\mu\nu}{}^{\rho\sigma}\,\delta T^{\text{total}}_{\rho\sigma} \;+\; (\text{terms from } \Lambda),} \tag{11.199}$$

with Π the appropriate algebraic projector (TT in the spin–2 sector), consistent with the typed operator in Definition 11.60.

Causal Green kernels and typed sector. The retarded/advanced inverses of $\mathcal{E}$ on $(\bar{\Sigma}, \bar{\nabla})$ define graviton Green kernels whose Pauli–Jordan difference has support on the same relational cones $J^{\pm}_{\bar{\Sigma}}$ (Lemma 11.101 and Proposition 11.14). Via the Peierls construction (eq. (11.25)) this causal kernel generates the covariant (commutator) algebra; TT projection then yields the typed propagator and ETCR in the radiative sector (Definition 11.60 and Proposition 11.4). These kernels inherit the microcausal cone also used by the scalar Stieltjes representations, thereby bridging kinematics (Chs. 6–7) to dynamics (Ch. 8) and the Einstein sector (Ch. 10) within the Chapter 12 chronogeometric framework (Sections 5.4.7 and 9.18.12).

11.5.5 Derivation of the Unified Semi–Classical Einstein Equations

Instrumentation (diagnostic realized reference configuration, tags, covariance). All derivations are performed on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\text{UV}},\ell} = (P_x(\lambda_{\text{UV}}), K^{(\ell)}_{\text{IR}})$ that commute with the triad and TT projectors (Definitions 6.280, 9.10, 10.3 and 11.24). Expectations descend to $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$ (Proposition 7.3). Geometry and covariant derivatives are those of the realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$ with Relational Levi–Civita connection $\bar{\nabla}$ and relational measure $d\mu(x) = \sqrt{-\det \bar{\Sigma}}\, d^d x$ (Definitions 5.26, 6.7 and 6.33).

Step 1: Emergent chronogeometry from the Holo–State

As established in Proposition 1.28, the expectation values of the operator–valued metric and temporal/coherence tensors in the Quantum Holo–State $|\mathring{\mathbf{\Psi}}\rangle$ define the unified chronogeometric tensor:

$$\begin{aligned} &\bar{g}_{\mu\nu}(x) := \langle \mathring{\mathbf{\Psi}} | \hat{g}_{\mu\nu}(x) | \mathring{\mathbf{\Psi}} \rangle, \qquad \bar{t}_{\mu\nu}(x) := \langle \mathring{\mathbf{\Psi}} | \hat{t}_{\mu\nu}(x) | \mathring{\mathbf{\Psi}} \rangle, \\ &\bar{\Sigma}_{\mu\nu}(x) := \bar{g}_{\mu\nu}(x) + \bar{t}_{\mu\nu}(x) \qquad (\text{unified tensor; } \textit{Definition } 5.26). \end{aligned}$$

Step 2: Curvatures from the Relational Levi–Civita connection

Treating $\bar{\Sigma}_{\mu\nu}$ as fundamental, the Relational Levi–Civita connection $\Gamma^{\lambda}_{\mu\nu}[\bar{\Sigma}]$ and curvatures are constructed as in Definitions 6.7 and 11.97. Contractions yield the Ricci tensor and scalar $\bar{R}_{\mu\nu}[\bar{\Sigma}]$, $\bar{R}[\bar{\Sigma}]$ (Section 11.5.2), and the Einstein tensor

$$\bar{G}_{\mu\nu}[\bar{\Sigma}] := \bar{R}_{\mu\nu}[\bar{\Sigma}] - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\,\bar{R}[\bar{\Sigma}] \quad (\textit{eq. } (11.175)).$$

Step 3: Expectation–valued total stress–energy

The operator–valued stress–energy tensors of the Gaiamiti and Tantrakyma sectors, $\hat{T}^{\mu\nu}_{(\Phi)}$ and $\hat{T}^{\mu\nu}_{(\Theta)}$ (Section 9.17.9 and Definition 9.356), together with the interaction contribution $\hat{T}^{\mu\nu}_{(\mathrm{int})}$ (variationally defined from S_{int}; eq. (9.237)), give

$$\hat{T}^{\mu\nu}_{\mathrm{total}} := \hat{T}^{\mu\nu}_{(\Phi)} + \hat{T}^{\mu\nu}_{(\Theta)} + \hat{T}^{\mu\nu}_{(\mathrm{int})}, \quad T^{\mu\nu}_{\mathrm{total}} := \mathrm{Tr}\{\hat{T}^{\mu\nu}_{\mathrm{total}}\} \quad (\textit{Definition 9.357 and eq. (9.229)}).$$

The expectation–level source on $\mathfrak{P}$ is

$$\boxed{\bar{T}^{\mu\nu}_{\mathrm{total}}(x) := \left\langle \mathring{\boldsymbol{\Psi}} \,\middle|\, \mathsf{P}_{\mathrm{phys}}\, T^{\mu\nu}_{\mathrm{total}}(x) \,\middle|\, \mathring{\boldsymbol{\Psi}} \right\rangle \qquad (\textit{Definition 9.358 and eq. (9.238)}).} \tag{11.200}$$

Step 4: Assembling the field equation (Hilbert variation and diagnostic realized reference configuration conservation)

The Relational Einstein–Hilbert functional with cosmological term (Definition 11.105 and eq. (11.188)) satisfies the Hilbert variational identity

$$\delta S^{(\mathrm{rel})}_{\mathrm{EH}} = \frac{1}{2\kappa}\int d\mu \left(\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\, \bar{\Sigma}_{\mu\nu}\right) \delta\bar{\Sigma}^{\mu\nu} \quad (\textit{eq. (11.189)}),$$

while variation of S_{total} defines $T^{\mu\nu}_{\mathrm{total}}$ and its diagnostic realized reference configuration expectation (Definitions 9.357 and 9.358). Equating the geometric and matter variations and using eq. (11.200) gives the semi–classical law

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\, \bar{\Sigma}_{\mu\nu} = \kappa\, \bar{T}^{\mathrm{total}}_{\mu\nu},} \tag{11.201}$$

which coincides with eq. (11.191). By the contracted Bianchi identity on $(\bar{\Sigma}, \bar{\nabla})$ and the unified variational definition, the diagnostic realized reference configuration conservation law holds on the same background,

$$\boxed{\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} \equiv 0, \qquad \bar{\nabla}^{(\mathrm{rel})}_{\mu}\, \bar{T}^{\mu\nu}_{\mathrm{total}} = 0 \quad (\textit{eqs. (9.232) and (11.192)}).} \tag{11.202}$$

Cohomological form (BRST–clean). Equivalently, the equations of motion may be written cohomologically as $\mathcal{E}^{\mathrm{coh}}_{\boldsymbol{\Phi}}(\bar{\Sigma}) = 0$ and $\mathcal{E}^{\mathrm{coh}}_{\boldsymbol{\Theta}}(\bar{\Sigma}) = 0$ modulo ζ–exact terms, evaluated with Σ–causal retarded kernels on $\mathfrak{P}$ (Propositions 7.3 and 11.14 and eq. (11.25)).

Alternative derivation from the Relational Einstein–Hilbert functional

Setup and conventions (diagnostic realized reference configuration, tags, covariance). All variations are performed on a certified plateau $\mathfrak{P}$ with BRST–closed band tags $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ that commute with the triad and TT projectors (Definitions 6.280, 9.10, 10.3 and 11.24). Expectations descend to $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3). Geometry, measure, and covariant derivatives are those of $(\mathcal{X}_q, \bar{\Sigma})$ with Relational Levi–Civita connection and relational volume element (Definitions 6.7 and 6.33).

Relational gravitational functional. Start from the Relational Einstein–Hilbert action including a cosmological term and the standard normalization,

$$\boxed{S_{\mathrm{Relational}}[\bar{\Sigma}] := \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu(x)\,\Big(\,\bar{R}[\bar{\Sigma}](x) - 2\Lambda\,\Big), \qquad d\mu(x) = \sqrt{-\det\bar{\Sigma}(x)}\,d^dx,} \tag{11.203}$$

with $\bar{R}[\bar{\Sigma}]$ defined from the Relational Levi–Civita connection (Definitions 11.97 and 11.105 and Section 11.5.2).

Step 1: Hilbert variation (geometric side). Varying with respect to $\bar{\Sigma}^{\mu\nu}$ and using $\delta(\sqrt{-\det\bar{\Sigma}}) = -\frac{1}{2}\sqrt{-\det\bar{\Sigma}}\,\bar{\Sigma}_{\mu\nu}\,\delta\bar{\Sigma}^{\mu\nu}$ together with the Palatini identity (discarding the boundary term under the usual conditions), one obtains the standard Hilbert identity

$$\delta S_{\mathrm{Relational}} = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu\,\Big(\bar{R}_{\mu\nu} - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\,\bar{R} + \Lambda\,\bar{\Sigma}_{\mu\nu}\Big)\,\delta\bar{\Sigma}^{\mu\nu} = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu\,\Big(\bar{G}_{\mu\nu} + \Lambda\,\bar{\Sigma}_{\mu\nu}\Big)\,\delta\bar{\Sigma}^{\mu\nu},$$

where $\bar{G}_{\mu\nu} = \bar{R}_{\mu\nu} - \frac{1}{2}\,\bar{\Sigma}_{\mu\nu}\bar{R}$ (eq. (11.175)). The contracted Bianchi identity $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu}\equiv 0$ holds on $(\bar{\Sigma},\bar{\nabla})$ (Proposition 11.98 and eq. (11.176e)).

Step 2: Coupling to fields and variational definition of the source. Augment the geometric functional with the field actions as in the total relational action (Definition 9.357),

$$S_{\mathrm{total}}[\bar{\Sigma},\hat{\mathbf{\Phi}},\hat{\mathbf{\Theta}}] = S_{\mathrm{Relational}}[\bar{\Sigma}] + S_{\Phi}[\hat{\mathbf{\Phi}}] + S_{\Theta}[\hat{\mathbf{\Theta}}] + S_{\mathrm{int}}[\hat{\mathbf{\Phi}},\hat{\mathbf{\Theta}}\,],$$

with S_{Φ}, S_{Θ} built from the operator–valued kernels and the same measure (Section 6.5 and Definitions 9.301 and 9.310) and S_{int} encoding geometry–matter exchange. By definition of the (scalar, fiber–traced) stress–energy, the variation of the field part with respect to $\bar{\Sigma}$ reads

$$\boxed{\delta\Big(S_{\Phi} + S_{\Theta} + S_{\mathrm{int}}\Big) = \frac{1}{2}\int_{\mathcal{X}_q} d\mu\; T^{\mu\nu}_{\mathrm{total}}(x)\,\delta\bar{\Sigma}_{\mu\nu}(x), \qquad T^{\mu\nu}_{\mathrm{total}} := \mathrm{Tr}\{\hat{T}^{\mu\nu}_{(\Phi)} + \hat{T}^{\mu\nu}_{(\Theta)} + \hat{T}^{\mu\nu}_{(\mathrm{int})}\},}$$

(11.204)

consistent with eqs. (9.224) and (9.237). On the diagnostic realized reference configuration, the expectation source is $\bar{T}^{\mu\nu}_{\mathrm{total}} = \langle \mathsf{P}_{\mathrm{phys}}\,T^{\mu\nu}_{\mathrm{total}}\rangle_{\mathfrak{P}}$ (Definition 9.358 and eq. (9.238)).

Step 3: Field equation and conservation. Stationarity of S_{total} under arbitrary $\delta\bar{\Sigma}^{\mu\nu}$ gives, after taking the diagnostic realized reference configuration expectation on $\mathfrak{P}$,

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu},} \tag{11.205}$$

which is eq. (11.191). By $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu}\equiv 0$ and the unified variational definition,

$$\bar{\nabla}^{(\mathrm{rel})}_{\mu}\,\bar{T}^{\mu\nu}_{\mathrm{total}} = 0,$$

in agreement with Section 11.5.5 and eq. (9.232).

Cohomological (BRST–clean) form and diagnostic realized reference configuration visibility. On $\mathfrak{P}$, the equations admit a cohomological expression $\mathcal{E}^{\mathrm{coh}}_{\mathbf{\Phi}}(\bar{\Sigma}) = 0$, $\mathcal{E}^{\mathrm{coh}}_{\mathbf{\Theta}}(\bar{\Sigma}) = 0$ modulo ζ–exact terms (Proposition 7.3). A global (diagnostic realized reference configuration–level) Einstein–law residual and visibility may be attached,

$$\boxed{\mathbf{R}^{[\mathrm{Ein}]}_{\mu\nu} := \bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} - \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}, \qquad \Lambda^{[\mathrm{Ein}]}_{\mathrm{law}} := 1 - \|\mathbf{R}^{[\mathrm{Ein}]}\|_{\mathcal{I}}/\|\cdot\|_{\mathrm{ref}},}\tag{11.206}$$

following the Parasymmetric T–L–O diagnostics of Chapter 9 (Definitions 9.299 and 9.306).

Notes on linearization and typed projection. Linearizing (11.205) around $\bar{\Sigma}$ produces the Lichnerowicz operator $\mathcal{E}_{\mu\nu}{}^{\rho\sigma}$ on $(\bar{\Sigma}, \bar{\nabla})$ (Remark 11.108 and Definition 11.60). Its retarded/advanced inverses are supported on $J^{\pm}_{\bar{\Sigma}}$ and generate, via the Peierls bracket, the covariant algebra whose equal–time limit reproduces the typed ETCR in the TT sector (eq. (11.25) and Propositions 11.4 and 11.14).

1. Variation of the geometric action (Hilbert identity, diagnostic realized reference configuration form) With the normalization and cosmological term fixed in Definition 11.105 (see also eq. (11.203)),

$$S_{\mathrm{Relational}}[\bar{\Sigma}] = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu(x)\,\Big(\bar{R}[\bar{\Sigma}](x) - 2\Lambda\Big), \qquad d\mu(x) = \sqrt{-\det\bar{\Sigma}(x)}\,d^d x,$$

the Palatini–Hilbert variation with respect to the *inverse* unified tensor $\bar{\Sigma}^{\mu\nu}$ (discarding the total derivative under standard boundary conditions) yields the standard result

$$\boxed{\delta S_{\mathrm{Relational}} = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu\,\Big(\bar{R}_{\mu\nu} - \tfrac{1}{2}\,\bar{\Sigma}_{\mu\nu}\,\bar{R} + \Lambda\,\bar{\Sigma}_{\mu\nu}\Big)\,\delta\bar{\Sigma}^{\mu\nu} = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu\,\Big(\bar{G}_{\mu\nu} + \Lambda\,\bar{\Sigma}_{\mu\nu}\Big)\,\delta\bar{\Sigma}^{\mu\nu},}\tag{11.207}$$

with $\bar{G}_{\mu\nu} = \bar{R}_{\mu\nu} - \frac{1}{2}\,\bar{\Sigma}_{\mu\nu}\bar{R}$ (Definition 11.97 and Section 11.5.2). The relational volume element is that of Definition 6.33 and all curvatures are those of the Relational Levi–Civita connection (Definition 6.7).

2. Variation of the field action and the source definition For the field part $S_{\mathrm{fields}} := S_{\Phi} + S_{\Theta} + S_{\mathrm{int}}$ (Definitions 9.310 and 9.357, Section 6.5, and eq. (9.237)), the *scalar* (fiber–traced) stress–energy is defined variationally by

$$\boxed{T^{\mathrm{total}}_{\mu\nu}(x) := -\frac{2}{\sqrt{-\det\bar{\Sigma}(x)}}\,\frac{\delta S_{\mathrm{fields}}}{\delta\bar{\Sigma}^{\mu\nu}(x)}\,, \qquad \Rightarrow \quad \delta S_{\mathrm{fields}} = -\frac{1}{2}\int_{\mathcal{X}_q} d\mu\,T^{\mathrm{total}}_{\mu\nu}\,\delta\bar{\Sigma}^{\mu\nu},}\tag{11.208}$$

consistent with eq. (9.224). On a certified plateau $\mathfrak{P}$ the expectation (diagnostic realized reference configuration) source is

$$\boxed{\bar{T}^{\mathrm{total}}_{\mu\nu}(x) := \Big\langle \mathring{\mathbf{\Psi}}\ \Big|\ \mathsf{P}_{\mathrm{phys}}\,\mathrm{Tr}\Big\{\hat{T}_{(\Phi)\mu\nu} + \hat{T}_{(\Theta)\mu\nu} + \hat{T}_{(\mathrm{int})\mu\nu}\Big\}(x)\ \Big|\ \mathring{\mathbf{\Psi}}\Big\rangle,}\tag{11.209}$$

as in Definition 9.358 and eq. (9.238), with BRST/Nielsen cleanliness supplied by Proposition 7.3.

Note. Here "total" is *field-only*, i.e. it refers to $S_\Phi + S_\Theta + S_{\rm int}$; the coherence/chronokymon sector contributes a separate $T^{(\tau)}_{\mu\nu}[K^{(\tau)}, \mathcal{F}^{(\tau)}]$ that appears explicitly in (11.257)–(11.258) and is TT–null ($\Pi^{[\rm TT]}_{\bar\Sigma}\hat\tau_{\mu\nu} = 0$; cf. (10.139)), so TT equations and diagnostics remain unchanged.

3. Assembling the total variation and the field equations Adding Section 11.5.5 gives

$$\boxed{\delta S_{\rm total} = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu\,\left(\bar G_{\mu\nu} + \Lambda\,\bar\Sigma_{\mu\nu}\right)\delta\bar\Sigma^{\mu\nu} - \frac{1}{2}\int_{\mathcal{X}_q} d\mu\,T^{\rm total}_{\mu\nu}\,\delta\bar\Sigma^{\mu\nu}.} \tag{11.210}$$

Stationarity for arbitrary $\delta\bar\Sigma^{\mu\nu}$ implies

$$\bar G_{\mu\nu} + \Lambda\,\bar\Sigma_{\mu\nu} = \kappa\,T^{\rm total}_{\mu\nu},$$

and, upon taking the diagnostic realized reference configuration expectation on $\mathfrak{P}$,

$$\boxed{\bar G_{\mu\nu}[\bar\Sigma] + \Lambda\,\bar\Sigma_{\mu\nu} = \kappa\,\bar T^{\rm total}_{\mu\nu},} \tag{11.211}$$

which reproduces Definition 11.106 and eq. (11.191). By the relational Bianchi identity $\bar\nabla^\mu\bar G_{\mu\nu} \equiv 0$ and the unified variational definition, one has $\bar\nabla^{(\rm rel)}_\mu\,\bar T^{\mu\nu}_{\rm total} = 0$ (Section 11.5.5 and Remark 11.108).

Step 4: Field equations, normalization, and the emergent coupling κ With the normalization chosen in Definition 11.105, the gravitational coupling κ enters with the standard dimensional weight (curvature $\sim$ energy density), so no *post hoc* insertion is required. In the IQR viewpoint, κ may be treated as an *emergent* diagnostic realized reference configuration parameter determined by the universal state and tags on the certified plateau $\mathfrak{P}$ (cohomological/Nielsen–flat semantics; Proposition 7.3), while the operational content of the law remains the Chronogeometric Einstein equation of Definition 11.106.

Diagnostic realized reference configuration form and stationarity. Starting from the normalized relational action with cosmological term (Definition 11.105),

$$S_{\rm Relational}[\bar\Sigma] = \frac{1}{2\kappa}\int_{\mathcal{X}_q} d\mu\,\left(\bar R[\bar\Sigma] - 2\Lambda\right), \qquad d\mu := \sqrt{-\det\bar\Sigma}\,d^dx,$$

and adding the field part $S_{\rm fields}$ (Definition 9.357), the total variation is

$$\delta S_{\rm total} = \frac{1}{2\kappa}\int d\mu\,(\bar G_{\mu\nu} + \Lambda\bar\Sigma_{\mu\nu})\,\delta\bar\Sigma^{\mu\nu} - \frac{1}{2}\int d\mu\,T^{\rm total}_{\mu\nu}\,\delta\bar\Sigma^{\mu\nu}.$$

Stationarity for arbitrary $\delta\bar\Sigma^{\mu\nu}$ gives the unified Einstein law

$$\boxed{\bar G_{\mu\nu}[\bar\Sigma] + \Lambda\,\bar\Sigma_{\mu\nu} = \kappa\,\bar T^{\rm total}_{\mu\nu},} \tag{11.212}$$

with the diagnostic realized reference configuration/expectation source $\bar{T}^{\text{total}}_{\mu\nu}$ defined in Definition 9.358. By the relational Bianchi identity $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} \equiv 0$, one has $\bar{\nabla}^{\mu}\bar{T}^{\text{total}}_{\mu\nu} = 0$ on the same background $(\bar{\Sigma}, \bar{\nabla})$ (Remark 11.108).
Normalization variant. If one begins from a *simplified* geometric action without the prefactor (effectively setting $\kappa = \frac{1}{2}$), the stationarity condition yields $\bar{G}_{\mu\nu} = \frac{1}{2}\bar{T}^{\text{total}}_{\mu\nu}$. Restoring physical units corresponds to reinstating the coupling κ, recovering (11.212) and the canonical statement of Definition 11.106.

11.5.6 The Emergent Gravitational Coupling Tensor

In the IQR framework, structural consistency requires that the gravitational coupling arise from the same quantum–relational substrate that generates both geometry and matter. Concretely, the geometry–matter interaction is encoded by the off–diagonal entries of the Unified Inter–Modal Correlator, i.e. the matter–geometry kernels $\hat{\mathbf{G}}_{\mathbf{\Phi\Theta}}$ and $\hat{\mathbf{G}}_{\mathbf{\Theta\Phi}}$, which enter the interaction action (Definition 10.223):

$$S_{\text{int}}\Big[\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}\Big] = \int d\mu_{\bar{\Sigma}}(x) \int d\mu_{\bar{\Sigma}}(x')\ \mathrm{Tr}\Big\{\hat{\mathbf{\Phi}}^{\dagger}(x)\, \mathcal{U}_{\mathbf{\Phi\Theta}}(x,x')\, \hat{\mathbf{\Theta}}(x')\Big\},$$
$$\mathcal{U}_{\mathbf{\Phi\Theta}}(x,x') := \hat{\mathbf{G}}_{\mathbf{\Phi\Theta}}(x,x') \ + \ \hat{\mathbf{G}}^{\dagger}_{\mathbf{\Theta\Phi}}(x',x), \qquad d\mu_{\bar{\Sigma}}(x) := \sqrt{-\det \bar{\Sigma}(x)}\, d^d x.$$

The semi–classical Chronogeometric Einstein law (Definition 11.106) is then promoted to a causal, tensorial response in which curvature at x is sourced by stress–energy at x' via a retarded bi–tensor kernel built on $(\mathcal{X}_q, \bar{\Sigma})$ (cf. Remark 11.108).

Definition 11.109 (Operator–valued gravitational coupling (retarded, causal))**.** Let $\mathcal{E}_{\alpha\beta}{}^{\gamma\delta}$ denote the linearized Einstein/Lichnerowicz operator on $(\bar{\Sigma}, \bar{\nabla})$ (Remark 11.108 and Definition 11.60), and let $G^{\text{ret}\,\gamma\delta}_{\alpha\beta}(x,x')$ be its retarded Green bi–solution supported on the $\bar{\Sigma}$–causal cones (Proposition 11.14). Define the operator–valued type–$(2,2)$ superoperator kernel

$$\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') : \ \hat{T}_{\rho\sigma}(x') \ \mapsto \ \hat{G}_{\mu\nu}(x),$$

by the composition

$$\boxed{\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') := \ \mathbb{P}^{(\text{Ein})\,\alpha\beta}_{\mu\nu}\ G^{\text{ret}\,\gamma\delta}_{\alpha\beta}(x,x')\ \mathbb{J}_{\gamma\delta}{}^{\rho\sigma},} \tag{11.213}$$

where: (i) $\mathbb{P}^{(\text{Ein})}$ is the algebraic map from metric fluctuations to the Einstein operator (linearized at $\bar{\Sigma}$), (ii) $\mathbb{J}$ is the index–symmetrizer onto the $(\rho\sigma)$ channel, and (iii) G^{ret} is computed with respect to the Relational Levi–Civita connection of $\bar{\Sigma}$ (Definition 6.7). The corresponding covariant response is

$$\boxed{\begin{aligned} &\hat{G}_{\mu\nu}(x) = \int_{\mathcal{X}_q} d\mu_{\bar{\Sigma}}(x')\ \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \ \circ \ \Big[\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\rho}{}^{\rho'}\, \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\sigma}{}^{\sigma'}\, \hat{T}_{\rho'\sigma'}(x')\Big], \\ &d\mu_{\bar{\Sigma}}(x') := \sqrt{-\det \bar{\Sigma}(x')}\, d^d x', \qquad A \circ B := \tfrac{1}{2}(AB + BA), \end{aligned}} \tag{11.214}$$

with $\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')$ the Levi–Civita parallel transporter of $\bar{\Sigma}$ for covariant index carriage.

Remark 11.110 (Covariance, causality, and consistency of (11.214))**.**

- **Parallel transport.** Since $\hat{T}_{\rho\sigma}(x') \in T^*_{x'}\mathcal{X}_q \otimes T^*_{x'}\mathcal{X}_q$, parallel transport to x is required before contraction with a kernel at x. The factors $\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_\rho{}^{\rho'}$, $\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_\sigma{}^{\sigma'}$ implement this transport with the Relational Levi–Civita connection (Definition 6.7).
- **Volume element.** The use of the relational measure $d\mu_{\bar{\Sigma}} = \sqrt{-\det \bar{\Sigma}}\, d^d x$ (Definition 6.33) ensures diffeomorphism covariance of the response.
- **Operator ordering / self–adjointness.** The Jordan product $A \circ B := \frac{1}{2}(AB + BA)$ preserves self–adjointness of $\hat{G}_{\mu\nu}(x)$ when the kernel and the source act on the same fiber Hilbert space (cf. operator hermiticity conventions in Section 9.17.9 and Definition 9.356).
- **Index flow.** In (11.213), the symmetrizer $\mathbb{J}_{\gamma\delta}{}^{\rho\sigma}$ prepares the source indices, $G^{\mathrm{ret}}{}_{\alpha\beta}^{\gamma\delta}$ gives causal propagation from x' to x (with TT restriction when working in the radiative sector, cf. Definition 11.60 and Proposition 11.14), and $\mathbb{P}^{(\mathrm{Ein})\alpha\beta}_{\mu\nu}$ maps the propagated metric fluctuation to the Einstein operator at x. The result is a type–$(2,2)$ bitensor with input $(\rho\sigma)$ and output $(\mu\nu)$.
- **Bianchi identity and conservation.** Because G^{ret} is built from the linearized operator on $(\bar{\Sigma}, \bar{\nabla})$ and $\mathbb{P}^{(\mathrm{Ein})}$ is algebraically $\bar{\nabla}$–compatible, one has $\bar{\nabla}^\mu_x \hat{G}_{\mu\nu}(x) = 0$ provided the source obeys $\bar{\nabla}'_\rho \hat{T}^\rho{}_\sigma(x') = 0$ and the transporter is Levi–Civita (cf. Remark 11.108).
- **Short convention (bitensor–density).** Equivalently, one may absorb parallel transport and the density factor into the definition of $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ (treating it as a bitensor–density in the primed slots), yielding the compact form

$$\hat{G}_{\mu\nu}(x) = \int d^d x'\, \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \;\circ\; \hat{T}_{\rho\sigma}(x'),$$

  which is exactly equivalent to (11.214) if used consistently throughout the chapter.

Typed/radiative specialization (optional). When focusing on the radiative spin–2 content, replace G^{ret} by its TT–projected version $G^{\mathrm{ret},[\mathrm{TT}]}$ built from the typed operator $K^{[\mathrm{TT}]}$ (Definition 11.60); microcausal cone support and BRST/Nielsen safety then follow from Propositions 7.3 and 11.14. This specialization aligns the response law with the TT exchange and dressing formulas used elsewhere (Definitions 11.67 and 11.71).

Definition 11.111 (Emergent Gravitational Coupling Tensor)**.** Adopt the causal operator kernel $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ of Definition 11.109, which implements the retarded metric–response to a stress–energy insertion on $(\mathcal{X}_q, \bar{\Sigma})$ via eq. (11.214). On a certified plateau $\mathfrak{P}$ with physical projector $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to H^0(\hat{Q}_{\mathrm{BRST}})$ (Proposition 7.3), the *Emergent Gravitational Coupling Tensor* is the diagnostic realized reference configuration (expectation–level) bitensor

$$\boxed{\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') := \Big\langle \overset{\circ}{\boldsymbol{\Psi}} \Big|\, \mathsf{P}_{\mathrm{phys}}\, \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \,\Big|\, \overset{\circ}{\boldsymbol{\Psi}} \Big\rangle,} \tag{11.215}$$

with indices raised/lowered by $\bar{\Sigma}_{\alpha\beta}$ and its inverse (Definition 5.26). In the "short" convention of Definition 11.109 (bitensor–density in the primed slots), one may write a pointwise

version $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x)$, keeping in mind that parallel transport and the density factor are implicit (eq. (11.214)).

Properties.

(i) Operator origin and index structure.
$\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ acts on the fiber Hilbert space $\mathcal{H}_{\rm em}$ and is of type $(2,2)$ in spacetime indices, mapping an input (matter/source) pair $(\rho\sigma)$ at x' to an output (geometry/response) pair $(\mu\nu)$ at x (Definition 11.109). Its diagnostic realized reference configuration expectation (11.215) defines a c-number bitensor that enters the linear response of the Chronogeometric Einstein law (Definition 11.106 and Remark 11.108). Symmetry on each index pair is assumed, $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} = \bar{\mathcal{C}}_{\nu\mu}{}^{\rho\sigma} = \bar{\mathcal{C}}_{\mu\nu}{}^{\sigma\rho}$, and, when appropriate, pair–exchange symmetry with respect to the $\bar{\Sigma}$ inner product, $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} = \bar{\mathcal{C}}^{\rho\sigma}{}_{\mu\nu}$.

(ii) Functional dependence and causality.
$\hat{\mathcal{C}}$ is built from the linearized Lichnerowicz/Einstein operator on $(\bar{\Sigma},\bar{\nabla})$ and its retarded Green kernel (Remark 11.108), along with the index maps $\mathbb{J}$ and $\mathbb{P}^{(\rm Ein)}$ (Definition 11.109). Hence supp $\bar{\mathcal{C}}(\cdot;x') \subset J^+_{\bar{\Sigma}}(x')$ (Proposition 11.14), i.e. the coupling is microcausal on the $\bar{\Sigma}$–cone used throughout.

(iii) Triadic/typed compatibility.
$\hat{\mathcal{C}}$ commutes with the triad projectors $\Pi^{(a)}$ and, in the radiative spin–2 sector, with the TT projector $\Pi^{[\rm TT]}_{\bar{\Sigma}}$ (Definitions 11.24 and 11.60 and Proposition 11.77). Consequently, its contractions with typed/triadic sources remain block–diagonal by $a \in \{\mathrm{corr},\mathrm{vac},\mathrm{spec}\}$ and TT–pure where required.

(iv) State and band dependence (diagnostic realized reference configuration semantics).
The diagnostic realized reference configuration expectation in (11.215) is taken at fixed band tags that commute with the projectors (Definitions 6.280 and 9.10); by Nielsen–flatness the resulting $\bar{\mathcal{C}}$ is gauge–parameter independent on $\mathfrak{P}$ (Proposition 7.3 and Corollary 11.5).

(v) GR limit.
In the local, weak–field GR limit the bitensor reduces to a point–localized, pair–symmetrized coupling,

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \;\longrightarrow\; \kappa\,\tfrac{1}{2}\big(\delta_\mu{}^\rho\delta_\nu{}^\sigma + \delta_\mu{}^\sigma\delta_\nu{}^\rho\big)\,\delta^{(d)}(x-x'),$$

recovering Definition 11.106.

(vi) Local response form (short convention).
Suppressing explicit transport and density factors (Definition 11.109), the pointwise relation reads

$$\bar{G}_{\mu\nu}(x) = \int d^dx'\,\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')\,\bar{T}^{\rm total}_{\rho\sigma}(x'),$$

and in the ultra–local approximation, $\bar{G}_{\mu\nu}(x) = \bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x)\,\bar{T}^{\rm total}_{\rho\sigma}(x)$, with conservation guaranteed by the relational Bianchi identity (Remark 11.108).

Proposition 11.112 (Generalized Chronogeometric Einstein equation (retarded response form))**.** *Work on a certified plateau $\mathfrak{P}$ with BRST–closed band tags that commute with the triad and TT projectors (Definitions 6.280 and 9.10 and Proposition 7.3). Let $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ be*

the Emergent Gravitational Coupling Tensor of Definition 11.111, obtained from the operator kernel of Definition 11.109 and evaluated as a diagnostic realized reference configuration expectation. Then the semi–classical gravitational response of the unified geometry satisfies the causal, bitensor equation

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}](x) + \Lambda\,\bar{\Sigma}_{\mu\nu}(x) \;=\; \int_{\mathcal{X}_q} d\mu_{\bar{\Sigma}}(x')\;\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')\,\bar{T}^{\mathrm{total}}_{\rho\sigma}(x')\,,}\tag{11.216}$$

with $d\mu_{\bar{\Sigma}}(x') = \sqrt{-\det\bar{\Sigma}(x')}\,d^dx'$ *and* $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ *built from the relational Levi–Civita geometry (Definition 11.97, Section 11.5.2, and Remark 11.108). In the ultra–local GR limit,*

$$\boxed{\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \;\longrightarrow\; \kappa\,\tfrac{1}{2}\Big(\delta_\mu{}^\rho\delta_\nu{}^\sigma + \delta_\mu{}^\sigma\delta_\nu{}^\rho\Big)\,\delta^{(d)}(x-x')\,,}\tag{11.217}$$

(11.216) *reduces to the Chronogeometric Einstein equations*

$$\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}\,,\qquad \textit{(Definition 11.106).}\tag{11.218}$$

Sketch. By Definition 11.109, the operator–valued response kernel $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ is the composition of: (i) the algebraic map to Einstein form $\mathbb{P}^{(\mathrm{Ein})}$, (ii) the retarded Green kernel of the linearized Lichnerowicz/Einstein operator on $(\bar{\Sigma},\bar{\nabla})$, and (iii) the source–symmetrizing map $\mathbb{J}$ (Remark 11.108). Taking the diagnostic realized reference configuration expectation on $\mathfrak{P}$ (Proposition 7.3) yields the c–number bitensor $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ of Definition 11.111. Causality of the retarded kernel implies $\operatorname{supp}\bar{\mathcal{C}}(\cdot;x') \subset J^+_{\bar{\Sigma}}(x')$ (Proposition 11.14), ensuring that the right–hand side of (11.216) is microcausal on the same cone as used elsewhere. Metric compatibility and the bitensor construction give $\bar{\nabla}^\mu_x\bar{G}_{\mu\nu} \equiv 0$ and, provided $\bar{\nabla}'_\rho\bar{T}^\rho{}_\sigma(x') = 0$, $\bar{\nabla}^\mu_x$ of the right–hand side vanishes; thus the relational Bianchi identity and conservation law remain consistent (Remark 11.108). In the ultra–local limit (11.217) one recovers the standard Einstein coupling with constant κ, proving the reduction to Definition 11.106. □

Interpretation and consistency with the chapter plan. Equation (11.216) presents the Chronogeometric Einstein law in BRST/cohomological, band–regular form on $\mathfrak{P}$, with a state– and tag–dependent emergent coupling (Definition 11.111). The kernel is compatible with the typed/triadic realized weave configuration: it commutes with the sector projectors and, in the radiative spin–2 block, with the TT projector (Definitions 11.24 and 11.60 and Proposition 11.77), so TT–typed TLO diagnostics attach only to the radiative sector as prescribed in the plan. The local GR law Definition 11.106 is recovered as the ultra–local limit of the same structure, with κ playing the usual role of a (diagnostic realized reference configuration–normalized) coupling constant (Section 11.5.5).

11.5.7 Scalarisation, Universality, and Variation Bounds of the Gravitational Coupling Tensor

A. EP–safe scalarisation (when $\bar{\mathcal{C}}$ reduces to a scalar). Work on the diagnostic realized reference configuration $\mathfrak{P}$ with BRST–closed tags commuting with the triad and TT projectors

(Definitions 6.280 and 9.10 and Proposition 7.3). Let $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x)$ be the (expectation–level) Emergent Gravitational Coupling Tensor of Definition 11.111, entering the generalized Einstein response (Proposition 11.112). On the bundle $\mathrm{Sym}^2(T^*\mathcal{X}_q)$ of symmetric $(0,2)$ tensors define the identity and pure–trace projector

$$I_{\mu\nu}{}^{\rho\sigma} := \tfrac{1}{2}\big(\delta_\mu{}^\rho\delta_\nu{}^\sigma + \delta_\mu{}^\sigma\delta_\nu{}^\rho\big), \qquad (P_{\mathrm{tr}})_{\mu\nu}{}^{\rho\sigma} := \tfrac{1}{d}\,\bar{\Sigma}_{\mu\nu}\bar{\Sigma}^{\rho\sigma},$$

respectively [249, 146].[2]

Algebraic symmetry / self–adjointness. Assume $\bar{\mathcal{C}}$ is symmetric on Sym^2 with respect to the $\bar{\Sigma}$–inner product:

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} = \bar{\mathcal{C}}_{\nu\mu}{}^{\rho\sigma} = \bar{\mathcal{C}}_{\mu\nu}{}^{\sigma\rho}, \qquad \bar{\mathcal{C}}_{\mu\nu,\rho\sigma} := \bar{\Sigma}_{\rho\alpha}\bar{\Sigma}_{\sigma\beta}\,\bar{\mathcal{C}}_{\mu\nu}{}^{\alpha\beta} = \bar{\mathcal{C}}_{\rho\sigma,\mu\nu}, \tag{11.219}$$

so a local $\bar{\Sigma}$–orthonormal frame diagonalises $\bar{\mathcal{C}}$ [536, 404].

Scalarisation ansatz. Decompose into an isotropic (species–blind) scalar and a trace–free anisotropic remainder:

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x) = \kappa_{\mathrm{eff}}(x)\, I_{\mu\nu}{}^{\rho\sigma} + \Delta_{\mu\nu}{}^{\rho\sigma}(x), \qquad \mathrm{tr}_{\mathrm{Sym}^2}\Delta = 0, \tag{11.220}$$

with the scalar defined by the operator trace on Sym^2,

$$\kappa_{\mathrm{eff}}(x) \;:=\; \frac{1}{N_d}\,\mathrm{tr}_{\mathrm{Sym}^2}\big[\bar{\mathcal{C}}(x)\big] \;=\; \frac{2}{d(d{+}1)}\,\bar{\mathcal{C}}_{\mu\nu}{}^{\mu\nu}(x), \qquad N_d = \tfrac{d(d+1)}{2} = \dim \mathrm{Sym}^2, \tag{11.221}$$

so that (11.220) is the unique orthogonal split (w.r.t. the operator trace).

Trace–free projection (unambiguous). For any endomorphism $\mathcal{E}_{\mu\nu}{}^{\rho\sigma}$ on Sym^2, define its pair–trace and $\bar{\Sigma}$–trace–free part by

$$(\mathcal{E}\cdot\bar{\Sigma})_{\mu\nu} := \mathcal{E}_{\mu\nu}{}^{\rho\sigma}\bar{\Sigma}_{\rho\sigma}, \qquad \mathrm{TF}_{\bar{\Sigma}}\,\mathcal{E} \;:=\; \mathcal{E} - \frac{1}{d}\,(\mathcal{E}\cdot\bar{\Sigma})\otimes\bar{\Sigma}^{\rho\sigma}, \tag{11.222}$$

so $(\mathrm{TF}_{\bar{\Sigma}}\,\mathcal{E})\cdot\bar{\Sigma} = 0$ for any d. (Here $(A\otimes B)_{\mu\nu}{}^{\rho\sigma} := A_{\mu\nu}B^{\rho\sigma}$.)

Norms and slow–variation regime. Let all norms be Hilbert–Schmidt norms induced by $\bar{\Sigma}$:

$$\|X\|^2_{\mathrm{HS}} := X_{\mu\nu}{}^{\rho\sigma}X_{\alpha\beta}{}^{\gamma\delta}\,\bar{\Sigma}^{\mu\alpha}\bar{\Sigma}^{\nu\beta}\bar{\Sigma}_{\rho\gamma}\bar{\Sigma}_{\sigma\delta}, \qquad \|Y\|^2_{\mathrm{HS}} := Y_{\mu\nu}Y_{\alpha\beta}\,\bar{\Sigma}^{\mu\alpha}\bar{\Sigma}^{\nu\beta}.$$

In the coherence–controlled regime (cf. Section 11.6), introduce

$$\varepsilon_{\mathrm{aniso}}(x) := \frac{\|\mathrm{TF}_{\bar{\Sigma}}\,\bar{\mathcal{C}}(x)\|_{\mathrm{HS}}}{\|\bar{\mathcal{C}}(x)\|_{\mathrm{HS}}} \ll 1, \qquad \varepsilon_{\mathrm{grad}}(x) := \max\Big\{L_{\mathrm{exp}}\tfrac{\|\nabla\bar{t}\|_{\mathrm{HS}}}{1+\|\bar{t}\|_{\mathrm{HS}}},\; L^2_{\mathrm{exp}}\tfrac{\|\nabla\nabla\bar{t}\|_{\mathrm{HS}}}{1+\|\bar{t}\|_{\mathrm{HS}}}\Big\} \ll 1, \tag{11.223}$$

with an experimental scale L_{exp}. Since $\bar{\mathcal{C}} = \langle\hat{\mathcal{C}}[\mathcal{U}_{\boldsymbol{\Phi\Theta}}[\bar{t},\ldots]]\rangle$ (Definitions 11.109 and 11.111), assume Lipschitz–type control

$$\|\nabla^k\bar{\mathcal{C}}\|_{\mathrm{HS}} \;\le\; L_k\,\|\nabla^k\bar{t}\|_{\mathrm{HS}}, \qquad k\in\{1,2\}, \tag{11.224}$$

for state–dependent L_k.

[2] For any symmetric $X_{\rho\sigma}$, $I_{\mu\nu}{}^{\rho\sigma}X_{\rho\sigma} = X_{\mu\nu}$. We write I to emphasize action on $\mathrm{End}(\mathrm{Sym}^2)$.

Local isotropy to leading order. Under (11.219)–(11.224), there exists a local $\bar{\Sigma}$–orthonormal frame with

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x) = \kappa_{\mathrm{eff}}(x)\, I_{\mu\nu}{}^{\rho\sigma} + \mathcal{O}\Big(\varepsilon_{\mathrm{aniso}} + \varepsilon_{\mathrm{grad}}\Big), \tag{11.225}$$

so the generalized field equation (Proposition 11.112) reduces locally to the GR form with a slowly varying effective coupling $\kappa_{\mathrm{eff}}(x)$ [6, 146]. In the radiative spin–2 block, compatibility with TT typing is automatic because $\bar{\mathcal{C}}$, built from the $\bar{\Sigma}$–Lichnerowicz/Einstein operator and retarded kernels, commutes with the TT projector (Definition 11.60 and Proposition 11.77).

Variation bound (diagnostic realized reference configuration form). Let $A : B$ denote full index contraction (bilinear pairing) on Sym^2. Using Cauchy–Schwarz for the Hilbert–Schmidt norm and (11.220), one has the pointwise bound

$$\boxed{\Big\| \Big(\bar{\mathcal{C}} - \kappa_{\mathrm{eff}} I\Big) : \bar{T}^{\mathrm{total}} \Big\|_{\mathrm{HS}} \;\le\; \|\Delta\|_{\mathrm{HS}}\, \|\bar{T}^{\mathrm{total}}\|_{\mathrm{HS}} \;\lesssim\; \Big(\varepsilon_{\mathrm{aniso}} + \varepsilon_{\mathrm{grad}}\Big)\, \|\bar{\mathcal{C}}\|_{\mathrm{HS}}\, \|\bar{T}^{\mathrm{total}}\|_{\mathrm{HS}},} \tag{11.226}$$

so departures from the scalarised law are suppressed by the anisotropy and slow–variation controls. Consequently, universality tests (free fall) are satisfied to the indicated accuracy whenever $\varepsilon_{\mathrm{aniso}}, \varepsilon_{\mathrm{grad}} \ll 1$ [479].

Species–blindness (EP universality). On the BRST/GNS physical sector $\mathcal{H}_{\mathrm{phys}}$ the coupling acts trivially on internal matter indices,

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} \;\otimes\; \mathbf{1}_{\mathrm{int}},$$

so in the scalarised limit it multiplies the total stress tensor $\bar{T}^{\mathrm{total}}_{\rho\sigma}$, preserving universality of free fall [479]. This is consistent with the ultra–local GR limit $\bar{\mathcal{C}} \to \kappa\, I\, \delta^{(d)}(x-x')$ (Definition 11.106, Proposition 11.112, and Section 11.5.5).

B. Variation bounds compatible with EP/PPN tests. *Diagnostic realized reference configuration semantics and scope.* All statements below are evaluated on the certified plateau $\mathfrak{P}$ with BRST–closed tags commuting with the triad and TT projectors (Nielsen–flat readouts; Definitions 6.280 and 9.10 and Proposition 7.3). They constrain departures of the Emergent Gravitational Coupling Tensor $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}$ from its scalarised limit $\kappa_{\mathrm{eff}} I$ (Definition 11.111 and Section 11.5.7) in regimes probed by weak–field experiments (EP/PPN).

Instrument–facing tolerances. To parameterize observable deviations from a constant, isotropic coupling, introduce four tolerances $\mathcal{B}_\gamma$, $\mathcal{B}_{\mathrm{EP}}$, $\mathcal{B}_{\dot{G}}$, $\mathcal{B}_{\nabla G}$:

1. **Isotropy (PPN γ on AU scales).** Trace–free anisotropy of the coupling endomorphism is small,
$$\varepsilon_{\mathrm{aniso}} \;\lesssim\; \mathcal{B}_\gamma \qquad \text{(solar–system regime; cf. Section 11.5.7).}$$

2. **Universality of free fall (Eötvös–type bounds).** Composition dependence in the scalarised response obeys
$$\left.\frac{\Delta\kappa_{\mathrm{eff}}}{\kappa_{\mathrm{eff}}}\right|_{\mathrm{materials}} \;\lesssim\; \mathcal{B}_{\mathrm{EP}} \qquad \text{(near–Earth / Earth–orbit experiments).}$$

3. **Temporal drift (e.g. LLR).** The fractional time variation satisfies

$$\left|\frac{\dot{\kappa}_{\rm eff}}{\kappa_{\rm eff}}\right| \lesssim \mathcal{B}_{\dot{G}} \qquad \text{(per unit time)}.$$

4. **Spatial gradients (laboratory / planetary baselines).** Over a baseline L,

$$\left|\frac{\Delta\kappa_{\rm eff}}{\kappa_{\rm eff}}\right| \lesssim \mathcal{B}_{\nabla G}(L), \qquad \text{equivalently} \qquad \left|\frac{\nabla\kappa_{\rm eff}}{\kappa_{\rm eff}}\right| \lesssim \frac{\mathcal{B}_{\nabla G}(L)}{L}.$$

Calibration note: Concrete numerical values for $(\mathcal{B}_\gamma, \mathcal{B}_{\rm EP}, \mathcal{B}_{\dot{G}}, \mathcal{B}_{\nabla G})$ may be set to current best–fit limits in an appendix; the theory development here is independent of those numbers.

Covariant variation bounds from scalarisation. Using the definition of the effective scalar coupling (eq. (11.221)) and the Lipschitz–type controls linking $\bar{\mathcal{C}}$ to the temporal texture $\bar{t}$ (eq. (11.224)), one finds

$$\boxed{\left|\nabla\kappa_{\rm eff}\right| = \frac{2}{d(d+1)}\left|\nabla\bar{\mathcal{C}}_{\mu\nu}{}^{\mu\nu}\right| \le \frac{2}{d(d+1)}\,\|\nabla\bar{\mathcal{C}}\|_{\rm HS} \le \frac{2L_1}{d(d+1)}\,\|\nabla\bar{t}\|_{\rm HS},} \tag{11.227}$$

and similarly $\left|\nabla\nabla\kappa_{\rm eff}\right| \le \frac{2L_2}{d(d+1)}\,\|\nabla\nabla\bar{t}\|_{\rm HS}$, which dovetail with the slow–variation control $\varepsilon_{\rm grad}$ defined in Section 11.5.7. Together with the anisotropy bound $\varepsilon_{\rm aniso} \ll 1$ and species–blind action of $\bar{\mathcal{C}}$ on the BRST/GNS physical sector (Section 11.5.7), these estimates ensure compatibility with EP and weak–field PPN tests while remaining fully consistent with the generalized response law and its GR limit (Proposition 11.112, Definition 11.106, and Section 11.5.5).

C. EP–safe scalarisation.

Proposition 11.113 (EP–safe scalarisation)**.** *Work on a certified plateau $\mathfrak{P}$ with BRST–closed band tags commuting with the triad and TT projectors (Nielsen–flat readouts; Definitions 6.280 and 9.10 and Proposition 7.3). Let the coupling endomorphism $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}$ obey the symmetry/-self–adjointness in eq. (11.219) and the scalarisation split $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} = \kappa_{\rm eff} I_{\mu\nu}{}^{\rho\sigma} + \Delta_{\mu\nu}{}^{\rho\sigma}$ with $\kappa_{\rm eff}$ defined in eq. (11.221). If, on a spacetime region, the anisotropy and slow–variation controls from Section 11.5.7 satisfy $\varepsilon_{aniso} \ll 1$ and $\varepsilon_{grad} \ll 1$, then the generalized law $\bar{G}_{\mu\nu} = \bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}\,\bar{T}^{\rm total}_{\rho\sigma}$ (Proposition 11.112) reduces to*

$$\bar{G}_{\mu\nu}(x) = \kappa_{\rm eff}(x)\,\bar{T}^{\rm total}_{\mu\nu}(x) + \mathcal{O}\Big(\varepsilon_{aniso} + \varepsilon_{grad}\Big),$$

with $\kappa_{\rm eff}$ species–blind *on the BRST/GNS physical sector (universality; Section 11.5.7). If, in addition, the drifts satisfy the instrument–facing bounds of Section 11.5.7 (items 1–4) together with the covariant estimates eq. (11.227), then the theory is compatible with current null–tests of the Equivalence Principle and weak–field PPN constraints [479].*

Sketch. Contracting the scalarisation split (eq. (11.220)) with $\bar{T}^{\rm total}$ gives $\bar{\mathcal{C}} : \bar{T}^{\rm total} = \kappa_{\rm eff}\,\bar{T}^{\rm total} + \Delta : \bar{T}^{\rm total}$. The symmetry eq. (11.219) allows a local $\bar{\Sigma}$–orthonormal frame that diagonalises $\bar{\mathcal{C}}$; the HS–norm control implies $\|\Delta : \bar{T}^{\rm total}\|_{\rm HS} \le \|\Delta\|_{\rm HS}\|\bar{T}^{\rm total}\|_{\rm HS} =$

$\mathcal{O}(\varepsilon_{\mathrm{aniso}})\|\bar{\mathcal{C}}\|_{\mathrm{HS}}\|\bar{T}^{\mathrm{total}}\|_{\mathrm{HS}}$. Slow variation ($\varepsilon_{\mathrm{grad}} \ll 1$) ensures that gradients of $\bar{\mathcal{C}}$ only induce subleading corrections in covariant conservation and matching conditions. Species–blindness (Sec. Section 11.5.7) guarantees that κ_{eff} multiplies the total stress tensor on the physical sector. Finally, the variation bounds eq. (11.227) together with the EP/PPN tolerances (items 1–4 in Section 11.5.7) place the residual deviations below experimental sensitivity, yielding the stated reduction and observational compatibility [479]. □

Remark 11.114 (Bianchi identity and conservation in the scalarised regime)**.** By the relational Bianchi identity (Remark 11.108), $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} = 0$, hence the generalized response law implies

$$\bar{\nabla}^{\mu}\Big(\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}\,\bar{T}^{\mathrm{total}}_{\rho\sigma}\Big) = 0.$$

In the scalarised limit (Section 11.5.7),

$$(\bar{\nabla}^{\mu}\kappa_{\mathrm{eff}})\,\bar{T}^{\mathrm{total}}_{\mu\nu} + \kappa_{\mathrm{eff}}\,\bar{\nabla}^{\mu}\bar{T}^{\mathrm{total}}_{\mu\nu} = 0.$$

Thus GR–like conservation, $\bar{\nabla}^{\mu}\bar{T}^{\mathrm{total}}_{\mu\nu} \approx 0$, obtains whenever $\bar{\nabla}\kappa_{\mathrm{eff}}$ is negligible on the probed scales (controlled by eq. (11.227) and $\varepsilon_{\mathrm{grad}}$) or any residual exchange with the coupling sector is higher order in $(\varepsilon_{\mathrm{aniso}}, \varepsilon_{\mathrm{grad}})$ [7, 146]. This is consistent with the diagnostic realized reference configuration semantics and Nielsen–flatness of the readouts on $\mathfrak{P}$ (Proposition 7.3).

11.5.8 Recovery of General Relativity in the Spectral Limit

Classical gravity should emerge from the IQR dynamics in the regime of weak fields, low energies, and negligible coherence. In the typed/triadic language, this corresponds to working on a certified plateau $\mathfrak{P}$ (BRST–clean, Nielsen–flat) with band tags that commute with the triad projectors and the TT projector (Definitions 6.280 and 9.10 and Proposition 7.3), and then focusing on the *spectral* channel of the triad decomposition (Definition 11.24). In this limit the correlation (corr) and vacuum (vac) channels decouple from macroscopic matter dynamics, while the spectral (spec) channel dominates the geometry–matter response. At the level of the emergent coupling tensor this reads

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} = \bar{\mathcal{C}}^{(\mathrm{corr})\rho\sigma}_{\mu\nu} + \bar{\mathcal{C}}^{(\mathrm{vac})\rho\sigma}_{\mu\nu} + \bar{\mathcal{C}}^{(\mathrm{spec})\rho\sigma}_{\mu\nu} \xrightarrow{\text{classical limit}} \bar{\mathcal{C}}^{(\mathrm{spec})\rho\sigma}_{\mu\nu},$$

with $\bar{\mathcal{C}}$ defined at diagnostic realized reference configuration level in Definition 11.111 and entering the generalized Einstein law of Proposition 11.112. Consistency with EP/PPN tests is ensured by the scalarisation analysis in Section 11.5.7 and Proposition 11.113.

Proposition 11.115 (Recovery of General Relativity)**.** *In the weak–field, low–energy, low–coherence regime on $\mathfrak{P}$, the spectral–channel coupling reduces to the identity endomorphism on* Sym^2 *times a constant,*

$$\bar{\mathcal{C}}^{(\mathrm{spec})\rho\sigma}_{\mu\nu}(x) \;\longrightarrow\; \kappa\,\Pi_{\mu\nu}{}^{\rho\sigma}, \qquad \Pi_{\mu\nu}{}^{\rho\sigma} := \tfrac{1}{2}\Big(\delta_{\mu}{}^{\rho}\delta_{\nu}{}^{\sigma} + \delta_{\mu}{}^{\sigma}\delta_{\nu}{}^{\rho}\Big),$$

with κ fixed by the Newtonian/PPN matching (Section 11.5.5). Consequently, the Chronogeometric Einstein equations recover the GR form,

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}(x), \qquad (\textit{equivalently } \bar{G}_{\mu\nu} + \Lambda\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}),} \tag{11.228}$$

coinciding with Definition 11.106.

Proof. Step 1 (Linearised spectral sector and TT support). Expand around a smooth background $\bar{\Sigma}$ in a $\bar{\Sigma}$–orthonormal frame, $\bar{\Sigma}_{\mu\nu} \mapsto \bar{\Sigma}_{\mu\nu} + \epsilon\,\delta\Sigma_{\mu\nu}$ with $\epsilon \ll 1$. In the spin–2 sector the typed fluctuation is the TT graviton $\hat{h}_{\mu\nu} := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\delta\hat{g}_{\mu\nu}$ (Definitions 11.3 and 11.28). Its dynamics are governed by the typed Lichnerowicz operator $K^{[\mathrm{TT}]}$ (Definition 11.60), with retarded/advanced Green kernels and Pauli–Jordan bi–solution supported on the $\bar{\Sigma}$–cones (Proposition 11.14). TT Ward identities enforce that only physical polarizations couple to matter vertices (Proposition 11.77), and the triad decomposition is block–diagonal at the linearized level (Proposition 11.20).

Step 2 (Operator response and long–wavelength limit). The operator–valued coupling kernel is the causal composition

$$\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') = \mathbb{P}^{(\mathrm{Ein})\,\alpha\beta}_{\mu\nu}\,\hat{\Delta}^{\mathrm{ret}\,\gamma\delta}_{\alpha\beta}(x,x')\,\mathbb{J}_{\gamma\delta}{}^{\rho\sigma}, \qquad \text{(Definition 11.109)},$$

where $\hat{\Delta}^{\mathrm{ret}}$ is the (typed) retarded graviton kernel, $\mathbb{P}^{(\mathrm{Ein})}$ the linearized Einstein map, and $\mathbb{J}$ the symmetric matter vertex compatible with the conservation constraints. In the spectral channel and for wavelengths large compared to any microscopic length (long–wavelength-/low–frequency limit consistent with diagnostic realized reference configuration tags), the nonlocal kernel reduces to its local leading term,

$$\hat{\Delta}^{\mathrm{ret}\,\gamma\delta}_{\alpha\beta}(x,x') \;\sim\; C_0\,\Pi_{\alpha\beta}{}^{\gamma\delta}\,\delta^{(d)}(x-x')\,\hat{\mathbf{1}} \quad\Rightarrow\quad \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \;\sim\; C_0\,\Pi_{\mu\nu}{}^{\rho\sigma}\,\delta^{(d)}(x-x')\,\hat{\mathbf{1}},$$

using that the TT projector commutes through the composition and preserves the symmetric identity on Sym^2 (TT purity; Propositions 11.20 and 11.77). Taking the Holo–State expectation (Definition 11.111) yields the c–number kernel with the same local structure.

Step 3 (Matching and conclusion). Plugging the local kernel into the generalized law (Proposition 11.112) gives $\bar{G}_{\mu\nu}(x) = C_0\,\Pi_{\mu\nu}{}^{\rho\sigma}\bar{T}^{\mathrm{total}}_{\rho\sigma}(x) = C_0\,\bar{T}^{\mathrm{total}}_{\mu\nu}(x)$. Fix $C_0 = \kappa$ by the Newtonian/PPN matching discussed in Section 11.5.5 (equivalently, by the scalarisation normalisation in Section 11.5.7), which recovers (11.228). The inclusion of Λ is immediate from the action–level derivation (Definition 11.105 and Section 11.5.5). □

Discussion. Equation (11.228) shows that, once (i) TT purity and triad block–diagonality hold (Propositions 11.20 and 11.77), (ii) the retarded kernels share the $\bar{\Sigma}$–microcausal cones (Proposition 11.14), and (iii) the coupling scalarises in the sense of Section 11.5.7, the IQR equations reduce to the standard Einstein equations with constant κ (diagnostic realized reference configuration–matched) and the usual conservation laws (Bianchi identity; Remark 11.108). This anchors the classical limit of the IQR framework squarely within GR while retaining a clear pathway for controlled departures outside the spectral, low–coherence regime.

In summary, the typed exchange in the spectral channel reproduces the classical response: by Definition 11.67 and eq. (11.137) and the recovery result Proposition 11.115, the sector–resolved amplitude obeys

$$\mathcal{A}^{(\mathrm{spec})}_{\mathrm{grav}} \xrightarrow[\text{weak field / low coherence}]{} \text{General Relativity},$$

consistently with the Chronogeometric Einstein law Definition 11.106 and its diagnostic realized reference configuration derivation Section 11.5.5. This is precisely the spectral–limit

realization of the classical "vertex–propagator–vertex" picture developed earlier for the TT sector (Section 11.3.5 and eq. (11.115)).

Signature & invertibility conditions (Lorentz window). Write the expectation–level unified tensor as $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$, with $\bar{t}^{\rm sym}_{\mu\nu} := \frac{1}{2}(\bar{t}_{\mu\nu} + \bar{t}_{\nu\mu})$ and $\bar{t}^{\rm anti}_{\mu\nu} := \frac{1}{2}(\bar{t}_{\mu\nu} - \bar{t}_{\nu\mu})$ (cf. Section 5.4 and eq. (11.232)). Define the effective Lorentzian metric extracted from the unified tensor, $\bar{g}^{\rm Lor}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}^{\rm sym}_{\mu\nu}$ (eq. (11.232)); this is the metric that carries the Relational Levi–Civita connection used throughout Section 11.5.1 and Remark 11.108.

Assumption 11.116 (Lorentz window for the temporal sector)**.** *There exists* $0 < \varepsilon < 1$ *such that, for all non–null* v^μ*,*

$$\frac{\left|\bar{t}^{\rm sym}_{\mu\nu} v^\mu v^\nu\right|}{\left|\bar{g}_{\mu\nu} v^\mu v^\nu\right|} \;\le\; \varepsilon, \qquad \textit{and} \qquad \left\| \, (\bar{g}^{\rm Lor})^{-1} \cdot \bar{t}^{\rm anti} \, \right\| \;<\; 1, \tag{11.229}$$

where $\|\cdot\|$ *is any operator norm induced by* $\bar{g}^{\rm Lor}$*.*

Proposition 11.117 (Persistence of Lorentz signature)**.** *Under Assumption 11.116, the quadratic form* $\bar{g}^{\rm Lor}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}^{\rm sym}_{\mu\nu}$ *is non–degenerate and has the same inertia as* $\bar{g}_{\mu\nu}$*. Hence,* $\mathrm{signature}(\bar{g}^{\rm Lor}) = (+,-,-,-)$ *in* $d = 4$ *[7, 146].*

Proof sketch. The Rayleigh–quotient bound implied by (11.229) gives $(1-\varepsilon)\,|\bar{g}(v,v)| \le |\bar{g}^{\rm Lor}(v,v)| \le (1+\varepsilon)\,|\bar{g}(v,v)|$ for all non–null v, along the homotopy $\bar{g}_\lambda := \bar{g} + \lambda\,\bar{t}^{\rm sym}$, $\lambda \in [0,1]$. No root or sign flip can occur without violating the bound, so non–degeneracy and inertia persist by continuity (Sylvester's law). The second inequality in (11.229) ensures the endomorphism $\mathrm{id} + (\bar{g}^{\rm Lor})^{-1}\cdot \bar{t}^{\rm anti}$ is invertible (Neumann series), guaranteeing that raising/lowering with $\bar{g}^{\rm Lor}$ and transporting with its Levi–Civita connection remain well–posed. □

Remark 11.118 (Why the Lorentz window matters here)**.** The bounds (11.229) ensure: (i) the causal cones defined by $\bar{g}^{\rm Lor}$ coincide perturbatively with those used in the TT/Peierls construction, so retarded/advanced kernels retain support on $J^{\pm}_{\bar{\Sigma}}$ (Proposition 11.14); (ii) parallel transport and Green–operator inversion on $(\mathcal{X}_q, \bar{\Sigma})$ are well–defined, which is required by the response formulas and effective actions in Section 11.3.5 and eq. (11.115); and (iii) the Bianchi identity and conservation statements proven on $\bar{\Sigma}$ (Remark 11.108 and Section 11.5.5) apply without modification, anchoring the GR recovery in Proposition 11.115.

Proposition 11.119 (Invertibility of $\bar{\Sigma}$ and control of the determinant)**.** *Assume the Lorentz window of Assumption 11.116 holds and, in particular, the second bound in (11.229). If* $\bar{g}^{\rm Lor}$ *is Lorentzian and non–degenerate (by Proposition 11.117), then*

$$\bar{\Sigma} = \bar{g}^{\rm Lor} + \bar{t}^{\rm anti} = \bar{g}^{\rm Lor}\cdot\Big(\mathbf{1} + (\bar{g}^{\rm Lor})^{-1}\bar{t}^{\rm anti}\Big)$$

is invertible. Moreover,

$$\det\bar{\Sigma} = \det\bar{g}^{\rm Lor}\;\det\Big(\mathbf{1} + (\bar{g}^{\rm Lor})^{-1}\bar{t}^{\rm anti}\Big) \neq 0,$$

and the Neumann series for $\Big(\mathbf{1} + (\bar{g}^{\rm Lor})^{-1}\bar{t}^{\rm anti}\Big)^{-1}$ *converges. Hence* $\bar{\Sigma}^{-1}$ *exists on any domain where (11.229) holds uniformly [536].*

Proof. Set $A := (\bar{g}^{\mathrm{Lor}})^{-1}\bar{t}^{\mathrm{anti}}$. The second bound in (11.229) gives $\|A\| < 1$ (for any operator norm induced by $\bar{g}^{\mathrm{Lor}}$), so the Neumann series

$$(\mathbf{1} + A)^{-1} = \sum_{n=0}^{\infty} (-A)^n$$

converges absolutely. Thus $\mathbf{1} + A$ is invertible and

$$\bar{\Sigma}^{-1} = (\mathbf{1} + A)^{-1} \cdot (\bar{g}^{\mathrm{Lor}})^{-1}.$$

Since $\det(\cdot)$ is multiplicative, $\det \bar{\Sigma} = \det \bar{g}^{\mathrm{Lor}} \ \det(\mathbf{1} + A)$, and $\det(\mathbf{1} + A) \neq 0$ because $\mathbf{1} + A$ is invertible. Non–degeneracy of $\bar{g}^{\mathrm{Lor}}$ is guaranteed by Proposition 11.117, hence $\det \bar{g}^{\mathrm{Lor}} \neq 0$, completing the proof. □

Remark 11.120 (Determinant and inverse: placement in the text)**.** The inverse $\bar{\Sigma}^{\mu\nu}$ exists precisely on open regions where $\bar{\Sigma}$ is non–degenerate (cf. the general inverse rule for the unified tensor in Definition 5.26 and the linearization formulas in Remark 11.108). Accordingly, the volume elements $\sqrt{-\det \bar{g}^{\mathrm{Lor}}}$ and $\sqrt{-\det \bar{\Sigma}}$ that appear in the measure $d\mu_{\bar{\Sigma}}$ and in the Relational Einstein–Hilbert action are well–defined on those regions (see Sections 11.5.3 and 11.5.5).

Corollary 11.121 (Stability under small field fluctuations)**.** *Let Assumption 11.116 hold with margin $\varepsilon < 1$ at a given background $(\bar{g}, \bar{t})$. Because $\bar{g}$ and $\bar{t}$ depend smoothly on the Holo-State and on the fields $(\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})$, there exists $\eta > 0$ such that for all fluctuations with $\|\delta\bar{g}\| + \|\delta\bar{t}\| < \eta$ (induced by small operator variations $\delta\hat{\mathbf{\Phi}}$, $\delta\hat{\mathbf{\Theta}}$), the inequalities (11.229) persist. Hence Lorentzian signature (Proposition 11.117) and invertibility (Proposition 11.119) are* stable *under sufficiently small fluctuations [536].*

11.6 A Coherence–Energy Condition (Relational NEC)

All statements in this section are made on a certified plateau $\mathfrak{P}$ with BRST-closed band tags commuting with the triad and TT projectors; expectation values are taken on the physical space $\mathcal{H}_{\mathrm{phys}}$ (diagnostic realized reference configuration semantics; cf. Proposition 7.3 and Definition 6.280). The causal and differential structures are those of the expectation–level chronogeometric tensor $\bar{\Sigma}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Definition 5.26), with Levi–Civita connection and curvatures defined in Definitions 6.7 and 11.97 and Section 11.5.2. Null directions and cones are always taken with respect to $\bar{\Sigma}$ (or, equivalently, $\bar{g}^{\mathrm{Lor}}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}^{\mathrm{sym}}_{\mu\nu}$ when the Lorentz window holds; cf. eq. (11.232), Assumption 11.116, and Proposition 11.117).

Definition 11.122 (Relational Null Energy/Coherence Condition (RNEC))**.** Let k^μ be any $\bar{\Sigma}$–null vector, $\bar{\Sigma}_{\mu\nu}k^\mu k^\nu = 0$. Define the diagnostic realized reference configuration/expectation effective source

$$\boxed{\bar{T}^{\mathrm{eff}}_{\mu\nu} \ := \ \bar{T}^{\mathrm{total}}_{\mu\nu} \ + \ \gamma\, \mathcal{Q}_{\mu\nu}[\bar{t}]\ , \qquad \bar{T}^{\mathrm{total}}_{\mu\nu} \text{ as in } \textit{Definition } 9.358,} \tag{11.230}$$

where $\gamma \geq 0$ and $\mathcal{Q}_{\mu\nu}[\bar{t}]$ is a symmetric, diagnostic realized reference configuration-safe, covariant functional of the temporal sector that vanishes when $\bar{t}_{\mu\nu} = 0$ (coherence off). The *Relational NEC* requires

$$\boxed{\forall\, k^\mu \ \bar{\Sigma}\text{–null:} \qquad k^\mu k^\nu \, \bar{T}^{\text{eff}}_{\mu\nu} \ \geq \ 0\,.} \tag{11.231}$$

Comments and normalization.

- **Vacuum piece.** If the cosmological term is placed on the right of the chronogeometric Einstein law $\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda \bar{\Sigma}_{\mu\nu} = \kappa\, \bar{T}^{\text{total}}_{\mu\nu}$ (Definition 11.106), one may incorporate it into $\bar{T}^{\text{total}}$ via $\bar{T}^{\text{vac}}_{\mu\nu} := -(\Lambda/\kappa)\, \bar{\Sigma}_{\mu\nu}$. This does not affect (11.231) because $k^\mu k^\nu \bar{\Sigma}_{\mu\nu} = 0$ for $\bar{\Sigma}$–null k^μ.
- **GR limit and focusing.** In the decohered regime $\bar{t}_{\mu\nu} \to 0$ (hence $\mathcal{Q}_{\mu\nu} \to 0$), (11.231) reduces to the standard NEC, $k^\mu k^\nu \bar{T}^{\text{total}}_{\mu\nu} \geq 0$, reproducing the classical focusing theorems for null congruences [240, 7].
- **Cone, causality, and Peierls.** Using $\bar{\Sigma}$–null k^μ aligns the energy condition with the same cone that governs the linearized Lichnerowicz operator and its retarded/advanced Green functions; the Pauli–Jordan kernel is supported on $J^{\pm}_{\bar{\Sigma}}$ and the covariant algebra follows by Peierls (Remark 11.108 and Proposition 11.14).

Physical sector and TT consistency. All expectations are evaluated on $\mathcal{H}_{\text{phys}}$ with Nielsen-flat law channel (Proposition 7.3). The temporal–curvature fluctuations $\hat{\tau}_{\mu\nu} := \delta\hat{\bar{t}}_{\mu\nu}$ furnish the coherence contribution $\mathcal{Q}_{\mu\nu}[\bar{t}]$ but do *not* carry spin–2 radiative content: τ–typed insertions are TT-null and the typed Ward identities enforce transversality/tracelessness in the graviton channel (Proposition 11.77 and Corollary 11.73). Thus the RNEC adds coherence control to the source without spoiling the TT graviton algebra or its causal support.

Equivalent presentations. One may keep $\bar{T}^{\text{total}}$ on the right-hand side of the Einstein equation and view $\gamma\, \mathcal{Q}_{\mu\nu}$ as an additive, state-dependent correction to the source diagnostics; or reabsorb (parts of) $\mathcal{Q}_{\mu\nu}$ into an effective, slowly varying coupling $\kappa_{\text{eff}}(x)$ when the scalarisation conditions of Section 11.5.7 hold. Both presentations are diagnostic realized reference configuration-equivalent and reduce to GR with constant κ in the spectral, low-coherence limit (Section 11.5.8).

Operational reading. The RNEC is the instrument-facing positivity that ties the chronogeometric law to causal propagation and dispersion: it uses the same cone as the TT kernels, is compatible with BRST/diagnostic realized reference configuration discipline, and collapses to the standard NEC when coherence is negligible. Standard vacuum-stress treatments on curved backgrounds provide the reference behavior for the matter/vacuum pieces of $\bar{T}^{\text{total}}$ [244, 11], while the coherence addendum $\mathcal{Q}_{\mu\nu}$ is state-controlled and vanishes in the GR limit.

1. Kinematic setup and the null cone. Let the expectation–level chronogeometric tensor be $\bar{\Sigma}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Definition 5.26), with $\bar{t}_{\mu\nu}$ the temporal–curvature tensor from the temporal functional (Definition 5.17). Following the causal/temporal structures of Section 5.4, split $\bar{t}_{\mu\nu}$ into symmetric/antisymmetric parts,

$$\bar{t}^{\mathrm{sym}}_{\mu\nu} := \tfrac{1}{2}(\bar{t}_{\mu\nu} + \bar{t}_{\nu\mu}), \qquad \bar{t}^{\mathrm{anti}}_{\mu\nu} := \tfrac{1}{2}(\bar{t}_{\mu\nu} - \bar{t}_{\nu\mu}),$$

and define the effective Lorentzian tensor

$$\bar{g}^{\mathrm{Lor}}_{\mu\nu} \;:=\; \bar{g}_{\mu\nu} + \bar{t}^{\mathrm{sym}}_{\mu\nu}, \tag{11.232}$$

assumed smooth with Lorentzian signature on the domain of interest (Assumption 11.116 and Proposition 11.117). A (contravariant) vector k^μ is *null* iff

$$k^\mu k^\nu\, \bar{g}^{\mathrm{Lor}}_{\mu\nu} = 0, \tag{11.233}$$

and we use the Levi–Civita connection of $\bar{g}^{\mathrm{Lor}}$ as the *relational* connection $\bar{\nabla} \equiv \nabla^{(\mathrm{rel})}$ (cf. Definition 6.7) for causal/kinematic constructions. In particular, null congruences satisfy

$$k^\nu \bar{\nabla}_\nu k^\mu = 0, \qquad \frac{d\theta}{d\lambda} = -\frac{1}{2}\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - \bar{R}_{\mu\nu}[\bar{g}^{\mathrm{Lor}}]\, k^\mu k^\nu, \tag{11.234}$$

where $(\theta, \sigma_{\mu\nu}, \omega_{\mu\nu})$ are the expansion, shear, and twist of the congruence defined with $\bar{g}^{\mathrm{Lor}}$ (cf. [240, 7] and Definition 11.97 and Section 11.5.2).

Lemma 11.123 (Null–cone equivalence and vacuum drop-out)**.** *For any vector k^μ, $k^\mu k^\nu\, \bar{\Sigma}_{\mu\nu} = k^\mu k^\nu\, \bar{g}^{\mathrm{Lor}}_{\mu\nu}$. Hence k^μ is $\bar{g}^{\mathrm{Lor}}$-null iff it is $\bar{\Sigma}$-null; moreover, for the cosmological vacuum stress $\bar{T}^{\mathrm{vac}}_{\mu\nu} = -(\Lambda/\kappa)\,\bar{\Sigma}_{\mu\nu}$ (cf. Definition 11.106), one has $k^\mu k^\nu \bar{T}^{\mathrm{vac}}_{\mu\nu} = 0$ on null k^μ.*

Proof. Write $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}^{\mathrm{sym}}_{\mu\nu} + \bar{t}^{\mathrm{anti}}_{\mu\nu}$. Because $k^\mu k^\nu$ is symmetric, $k^\mu k^\nu \bar{t}^{\mathrm{anti}}_{\mu\nu} = 0$. Thus $k^\mu k^\nu \bar{\Sigma}_{\mu\nu} = k^\mu k^\nu (\bar{g}_{\mu\nu} + \bar{t}^{\mathrm{sym}}_{\mu\nu}) = k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu}$, proving both cone equivalence and vacuum drop-out. □

Consequently, in evaluating the Relational NEC (Definition 11.122), the null directions determined by $\bar{g}^{\mathrm{Lor}}$ coincide with those of $\bar{\Sigma}$, and the vacuum term makes no contribution to the null contraction. This isolates the matter and coherence stresses as the only kinematic sources relevant for focusing and energy–condition analyses on the relational cone (Definitions 9.358 and 11.122).

2. The coherence stress $\mathcal{Q}_{\mu\nu}[\bar{t}]$. Decompose the temporal–curvature tensor into symmetric/antisymmetric parts,

$$\bar{t}_{\mu\nu} = S_{\mu\nu} + A_{\mu\nu}, \qquad S_{\mu\nu} := \tfrac{1}{2}(\bar{t}_{\mu\nu} + \bar{t}_{\nu\mu}), \quad A_{\mu\nu} := \tfrac{1}{2}(\bar{t}_{\mu\nu} - \bar{t}_{\nu\mu}).$$

Index convention in this subsection: when forming $\mathcal{Q}_{\mu\nu}$ and working on the null screen, raise/lower with $\bar{g}^{\mathrm{Lor}}$; for null contractions, the $\bar{\Sigma}$–trace piece drops out by Lemma 11.123.

Motivated by the electromagnetic/superenergy template [146, 7], define the *coherence stress* as the (dimension-adjusted) quadratic:

$$\boxed{\mathcal{Q}_{\mu\nu}[\bar{t}] := S_{\mu\alpha}\,S_{\nu}{}^{\alpha} + A_{\mu\alpha}\,A_{\nu}{}^{\alpha} - \frac{1}{d}\,\bar{g}^{\mathrm{Lor}}_{\mu\nu}\Big(S_{\alpha\beta}S^{\alpha\beta} + A_{\alpha\beta}A^{\alpha\beta}\Big)\,,} \tag{11.235}$$

where $d = \dim \mathcal{X}_q$. *In $d = 4$, (11.235) coincides with the earlier $1/4$ normalization.*

Basic properties.

- *Symmetry.* $\mathcal{Q}_{\mu\nu} = \mathcal{Q}_{\nu\mu}$, since each term in (11.235) is manifestly symmetric in (μ, ν).
- *$\bar{g}^{\mathrm{Lor}}$–tracefree (dimension-exact).* Contracting (11.235) with $\bar{g}^{\mathrm{Lor}\,\mu\nu}$ gives

$$\bar{g}^{\mathrm{Lor}\,\mu\nu}\mathcal{Q}_{\mu\nu} = S_{\alpha\beta}S^{\alpha\beta} + A_{\alpha\beta}A^{\alpha\beta} - \frac{d}{d}\Big(S_{\alpha\beta}S^{\alpha\beta} + A_{\alpha\beta}A^{\alpha\beta}\Big) = 0.$$

  (If you fix $d = 4$ from the outset, replace $1/d$ by $1/4$ to keep this property.)

- *Null positivity (Relational NEC contribution).* For any $\bar{g}^{\mathrm{Lor}}$–null k^μ,

$$\begin{aligned} k^\mu k^\nu \mathcal{Q}_{\mu\nu} &= (S{\cdot}k)_\alpha (S{\cdot}k)^\alpha + (A{\cdot}k)_\alpha (A{\cdot}k)^\alpha \\ &\quad - \frac{1}{d}\,(\bar{g}^{\mathrm{Lor}}_{\mu\nu}k^\mu k^\nu)\,\Big(S_{\rho\sigma}S^{\rho\sigma} + A_{\rho\sigma}A^{\rho\sigma}\Big) \\ &= \|(S{\cdot}k)\|^2 + \|(A{\cdot}k)\|^2 \;\geq 0. \end{aligned}$$

  so $\mathcal{Q}_{\mu\nu}$ contributes non-negatively to the Relational NEC (Section 11.6, and vanishes in the decohered limit $\bar{t} \to 0$.

- *Quadratic scaling and vanishing.* For any scalar λ, $\mathcal{Q}_{\mu\nu}[\lambda\bar{t}] = \lambda^2\,\mathcal{Q}_{\mu\nu}[\bar{t}]$; in particular, $\bar{t} \equiv 0 \Rightarrow \mathcal{Q}_{\mu\nu} \equiv 0$.
- *Local covariance.* $\mathcal{Q}_{\mu\nu}$ is a bona-fide $(0,2)$ tensor built locally from $(\bar{g}^{\mathrm{Lor}}, \bar{t})$; diffeomorphisms act covariantly. Any further divergence property follows from the evolution/-constraint equations for $\bar{t}$ (see eq. (16.467)) and the Bianchi identity for $\bar{G}_{\mu\nu}$.
- *TT isolation and SM orthogonality.* With $\mathcal{P}^{(2)}[\hat{\tau}] = 0$ and the coherence projector $\mathcal{P}^{\mathrm{coh}}_G$ (eq. (13.113) and Definition 13.1), the coherence channel carries no spin-2 radiative content and remains orthogonal to SM excitations; this keeps the TT graviton sector (Chapter 11) clean while allowing $\mathcal{Q}_{\mu\nu}$ to enter energy-condition and focusing analyses.

Lemma 11.124 (Vacuum term vanishes on nulls)**.** *For any $\bar{g}^{\mathrm{Lor}}$–null covector k^μ,*

$$k^\mu k^\nu\, T^{\mathrm{vac}}_{\mu\nu} = -(\Lambda/\kappa')\,k^\mu k^\nu\,\bar{\Sigma}_{\mu\nu} = 0.$$

Proof. By Lemma 11.123, $k^\mu k^\nu \bar{\Sigma}_{\mu\nu} = k^\mu k^\nu(\bar{g}_{\mu\nu} + \bar{t}^{\mathrm{sym}}_{\mu\nu}) = k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} = 0$ for any $\bar{g}^{\mathrm{Lor}}$–null k^μ; the antisymmetric part does not contribute because $k^\mu k^\nu$ is symmetric. Hence the result. □

Lemma 11.125 (Positivity of the coherence term on nulls (sufficient conditions))**.** *Let k^μ be $\bar{g}^{\mathrm{Lor}}$–null and write $\bar{t}_{\mu\nu} = S_{\mu\nu} + A_{\mu\nu}$ with $S_{\mu\nu} = S_{\nu\mu}$ and $A_{\mu\nu} = -A_{\nu\mu}$. Then:*

1. *The antisymmetric part contributes non–negatively:*

$$k^\mu k^\nu\, A_{\mu\alpha}A_\nu{}^\alpha \;\geq\; 0.$$

2. *If, in addition, the* screen–orthogonality *condition*

$$k^\mu k^\nu\, S_{\mu\nu} = 0$$

holds along the null congruence (no longitudinal squeezing), then

$$k^\mu k^\nu\, S_{\mu\alpha}S_\nu{}^\alpha \;\geq\; 0.$$

Consequently, with the same condition one has

$$k^\mu k^\nu\, \mathcal{Q}_{\mu\nu}[\bar{t}] \;\geq\; 0$$

for the coherence stress defined in (11.235).

Proof. Choose an auxiliary null covector ℓ^μ with $k\cdot\ell = -1$ and define the *screen* (transverse) metric

$$q_{\mu\nu} := \bar{g}^{\mathrm{Lor}}_{\mu\nu} + k_\mu\ell_\nu + \ell_\mu k_\nu,$$

which is positive–definite on the 2–plane orthogonal to $\{k,\ell\}$ (see, e.g., [7]). Define the transverse vectors $V^\alpha := (S\cdot k)^\alpha := S^\alpha{}_\beta k^\beta$ and $W^\alpha := (A\cdot k)^\alpha := A^\alpha{}_\beta k^\beta$.

(1) Antisymmetric part. Since $A_{\mu\nu}$ is antisymmetric, $k_\alpha W^\alpha = A_{\alpha\beta}k^\alpha k^\beta = 0$, so W^α lies in the screen. Hence

$$k^\mu k^\nu\, A_{\mu\alpha}A_\nu{}^\alpha = W_\alpha W^\alpha = q_{\alpha\beta}\, W^\alpha W^\beta \;\geq\; 0,$$

because $q_{\alpha\beta}$ is positive–definite on the screen.

(2) Symmetric part. If $k^\mu k^\nu S_{\mu\nu} = 0$, then $k_\alpha V^\alpha = S_{\alpha\beta}k^\alpha k^\beta = 0$, so V^α is also purely transverse. Therefore

$$k^\mu k^\nu\, S_{\mu\alpha}S_\nu{}^\alpha = V_\alpha V^\alpha = q_{\alpha\beta}\, V^\alpha V^\beta \;\geq\; 0.$$

Finally, in the null contraction of (11.235) the trace term drops out because $k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} = 0$, so $k^\mu k^\nu \mathcal{Q}_{\mu\nu} = V_\alpha V^\alpha + W_\alpha W^\alpha \geq 0$ under the stated condition. □

Remark 11.126 (Unconditional positivity via a screen–improved definition)**.** If one prefers a version that is *unconditionally* non–negative on nulls (without the extra condition on S), replace (11.235) by the *screen–projected* quadratic

$$\mathcal{Q}^\perp_{\mu\nu} := \left(S^\perp_{\mu\alpha}S^\perp_{\nu\beta} + A^\perp_{\mu\alpha}A^\perp_{\nu\beta}\right) q^{\alpha\beta} - \frac{1}{d}\, q_{\mu\nu}\left(S^\perp_{\alpha\beta}S^\perp_{\gamma\delta} + A^\perp_{\alpha\beta}A^\perp_{\gamma\delta}\right) q^{\alpha\gamma}q^{\beta\delta},$$

with $S^\perp_{\mu\nu} := q_\mu{}^\rho q_\nu{}^\sigma S_{\rho\sigma}$ and similarly for $A^\perp_{\mu\nu}$. Then

$$k^\mu k^\nu\, \mathcal{Q}^\perp_{\mu\nu} = q_{\alpha\beta}(S\cdot k)^\alpha(S\cdot k)^\beta + q_{\alpha\beta}(A\cdot k)^\alpha(A\cdot k)^\beta \;\geq\; 0$$

for every null k^μ, by positive–definiteness of $q_{\alpha\beta}$ [537]. This "Bel–type improvement" leaves local NEC tests and the Einstein equation unaffected at the level of null contractions used in Section 11.6, while making the positivity manifest [538, 537].

Remark 11.127 (Bel–type improvement and manifest null-positivity)**.** Fix a null pair (k^μ, ℓ^μ) with $k^\mu k_\mu = 0$, $\ell^\mu \ell_\mu = 0$ and $k\cdot\ell = -1$, and let the screen metric be

$$q_{\mu\nu} := \bar{g}^{\mathrm{Lor}}_{\mu\nu} + k_\mu \ell_\nu + \ell_\mu k_\nu, \qquad q^\mu{}_\nu := \bar{g}^{\mu\rho} q_{\rho\nu},$$

which is positive–definite on the $(d-2)$–dimensional subspace orthogonal to $\{k, \ell\}$ and obeys $k^\mu q_{\mu\nu} = q_{\mu\nu} k^\nu = 0$ [537]. Define the screen–projected tensors $S^\perp_{\mu\nu} := q_\mu{}^\rho q_\nu{}^\sigma S_{\rho\sigma}$ and $A^\perp_{\mu\nu} := q_\mu{}^\rho q_\nu{}^\sigma A_{\rho\sigma}$ and set

$$\mathcal{Q}^\perp_{\mu\nu} := \left(S^\perp_{\mu\alpha} S^\perp_{\nu\beta} + A^\perp_{\mu\alpha} A^\perp_{\nu\beta}\right) q^{\alpha\beta} \;-\; \frac{1}{d}\, q_{\mu\nu} \left(S^\perp_{\alpha\beta} S^\perp_{\gamma\delta} + A^\perp_{\alpha\beta} A^\perp_{\gamma\delta}\right) q^{\alpha\gamma} q^{\beta\delta}. \tag{11.236}$$

This is the "Bel–type improvement'' of $\mathcal{Q}_{\mu\nu}$ (cf. (11.235)) [538, 537]. It has the following properties:

1. **Screen–tracelessness.** $q^{\mu\nu}\mathcal{Q}^\perp_{\mu\nu} = 0$ by construction.
2. **Manifest null–positivity.** For every null k^μ,

$$k^\mu k^\nu\, \mathcal{Q}^\perp_{\mu\nu} = q_{\alpha\beta}(S\cdot k)^\alpha (S\cdot k)^\beta + q_{\alpha\beta}(A\cdot k)^\alpha (A\cdot k)^\beta \;\geq\; 0, \tag{11.237}$$

   where $(S\cdot k)^\alpha := S^\alpha{}_\beta k^\beta$ and $(A\cdot k)^\alpha := A^\alpha{}_\beta k^\beta$, using the positive–definiteness of $q_{\alpha\beta}$ on the screen [537].
3. **Null–contraction invariance (for NEC/NCC steps).** Since $k^\mu k^\nu q_{\mu\nu} = 0$, the trace–subtraction term in (11.236) drops out under $k^\mu k^\nu(\,\cdot\,)$, and the screen projection does not alter the right–hand side of (11.237). Consequently,

$$k^\mu k^\nu \mathcal{Q}^\perp_{\mu\nu} = k^\mu k^\nu \mathcal{Q}_{\mu\nu},$$

   so local null–energy tests and the null contractions entering the relational Einstein equations in Section 11.6, Theorem 11.128 and Corollary 11.129 are unchanged, while positivity becomes manifest via (11.237) [537].

Theorem 11.128 (NCC from Coherence Positivity)**.** *Assume (on the BRST/GNS physical sector) that the ordinary matter sector satisfies the NEC with respect to $\bar{g}^{\mathrm{Lor}}$, i.e. $k^\mu k^\nu T^{\mathrm{matter}}_{\mu\nu} \geq 0$ for all $\bar{g}^{\mathrm{Lor}}$–null k^μ. If $\gamma \geq 0$ in (11.230), then for all such k^μ,*

$$k^\mu k^\nu T^{\mathrm{eff}}_{\mu\nu} = k^\mu k^\nu T^{\mathrm{matter}}_{\mu\nu} \;+\; \gamma\, k^\mu k^\nu \mathcal{Q}_{\mu\nu}[\bar{t}] \;\geq\; 0,$$

so the Relational NEC *holds.*

Proof. By definition (11.230), $T^{\mathrm{eff}}_{\mu\nu} = T^{\mathrm{matter}}_{\mu\nu} + T^{\mathrm{vac}}_{\mu\nu} + \gamma\, \mathcal{Q}_{\mu\nu}[\bar{t}]$ with $T^{\mathrm{vac}}_{\mu\nu} = -(\Lambda/\kappa')\,\bar{\Sigma}_{\mu\nu}$. Lemma Lemma 11.124 shows $k^\mu k^\nu T^{\mathrm{vac}}_{\mu\nu} = 0$ on $\bar{g}^{\mathrm{Lor}}$–null k^μ, and Lemma Lemma 11.125 gives $k^\mu k^\nu \mathcal{Q}_{\mu\nu}[\bar{t}] \geq 0$. With the matter NEC and $\gamma \geq 0$, the sum is non-negative. □

Corollary 11.129 (Relational NCC under the field equations)**.** *Assume the hypotheses and conclusion of Theorem 11.128, namely that for every $\bar{g}^{\mathrm{Lor}}$–null k^μ,*

$$k^\mu k^\nu T^{\mathrm{eff}}_{\mu\nu} \;\geq\; 0, \qquad T^{\mathrm{eff}}_{\mu\nu} = T^{\mathrm{matter}}_{\mu\nu} + \gamma\, \mathcal{Q}_{\mu\nu}[\bar{t}] \;\; \textit{with} \;\; \gamma \geq 0 \;\; \textit{(cf. (11.230)).} \tag{11.238}$$

If, in addition, the relational Einstein equations hold on the same background,

$$\bar{G}_{\mu\nu}[\bar{g}^{\mathrm{Lor}}] + \Lambda\, \bar{g}^{\mathrm{Lor}}_{\mu\nu} \;=\; \kappa\, T^{\mathrm{eff}}_{\mu\nu}, \tag{11.239}$$

then for all $\bar{g}^{\mathrm{Lor}}$–null k^μ one has the Relational Null Convergence Condition (Relational NCC)

$$\boxed{R_{\mu\nu}[\bar{g}^{\mathrm{Lor}}]\, k^\mu k^\nu \;\geq\; 0.} \tag{11.240}$$

Proof. Contract (11.239) with $k^\mu k^\nu$ and use $G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2} R\, \bar{g}^{\mathrm{Lor}}_{\mu\nu}$:

$$k^\mu k^\nu R_{\mu\nu} \;-\; \tfrac{1}{2} R\, k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} \;+\; \Lambda\, k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} \;=\; \kappa\, k^\mu k^\nu T^{\mathrm{eff}}_{\mu\nu}.$$

Since k^μ is null, $k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} = 0$, so the trace and cosmological terms vanish. Hence

$$k^\mu k^\nu R_{\mu\nu} \;=\; \kappa\, k^\mu k^\nu T^{\mathrm{eff}}_{\mu\nu}.$$

By Theorem 11.128 and the displayed inequality (11.238), the right-hand side is nonnegative for all null k^μ. Therefore $R_{\mu\nu} k^\mu k^\nu \geq 0$, which is (11.240). □

3. Raychaudhuri focusing and the scalarised coupling. Contract the generalized Einstein law (Proposition 11.112) along a null k^μ:

$$R_{\mu\nu}[\bar{g}^{\mathrm{Lor}}]\, k^\mu k^\nu = k^\mu k^\nu\, \bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x)\, \bar{T}^{\mathrm{total}}_{\rho\sigma}(x).$$

In the EP-safe (scalarised) regime of Section 11.5.7 one has

$$R_{\mu\nu}[\bar{g}^{\mathrm{Lor}}]\, k^\mu k^\nu = \kappa_{\mathrm{eff}}(x)\, k^\mu k^\nu \Big(T^{\mathrm{matter}}_{\mu\nu} + \gamma\, \mathcal{Q}_{\mu\nu}[\bar{t}] \Big),$$

since the vacuum term drops out by Lemma Lemma 11.124. Inserting this into the relational Raychaudhuri equation (11.234) with vanishing twist ($\omega_{\mu\nu} = 0$) yields

$$\frac{d\theta}{d\lambda} = -\frac{1}{2}\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} - \kappa_{\mathrm{eff}}\, k^\mu k^\nu \Big(T^{\mathrm{matter}}_{\mu\nu} + \gamma\, \mathcal{Q}_{\mu\nu}[\bar{t}] \Big) \;\leq\; -\frac{1}{2}\theta^2,$$

whenever the Relational NCC holds (Theorem Theorem 11.128). Therefore, if $\theta(0) < 0$ initially,

$$\theta(\lambda) \to -\infty \quad \text{by} \quad \lambda \leq \frac{2}{|\theta(0)|},$$

recovering the standard focusing bound, with κ_{eff} absorbed into the source normalization (cf. Section 11.5.7).

Remark 11.130 (NEC, Relational NEC, and NCC in the $\bar{\Sigma}$–framework)**.** In this chapter all null tests are performed with respect to the background Lorentzian metric $\bar{g}^{\mathrm{Lor}}_{\mu\nu}$ and null vectors k^μ (cf. Section 11.6). The three conditions used in Section 11.6 and in Theorem 11.128 and Corollary 11.129 are:

1. **NEC (standard Null Energy Condition).** For every $\bar{g}^{\mathrm{Lor}}$–null k^μ,
$$k^\mu k^\nu \bar{T}_{\mu\nu} \geq 0.$$
This is a *matter–side* inequality (domain: $\bar{T}_{\mu\nu}$).
2. **Relational NEC.** With the relational/effective source
$$T^{\mathrm{rel}}_{\mu\nu} := \bar{T}_{\mu\nu} + \mathcal{Q}_{\mu\nu}.$$
(See eq. (11.235).)
Here we prove the *null–positivity* of the $\mathcal{Q}$–piece:
$$k^\mu k^\nu \mathcal{Q}_{\mu\nu} = V_\alpha V^\alpha + W_\alpha W^\alpha \geq 0,$$
where $q_{\mu\nu} = \bar{g}^{\mathrm{Lor}}_{\mu\nu} + k_\mu \ell_\nu + \ell_\mu k_\nu$ is the screen metric and $V^\alpha := (S{\cdot}k)^\alpha$, $W^\alpha := (A{\cdot}k)^\alpha$ are the transverse projections; positivity follows from the positive–definiteness of $q_{\alpha\beta}$ on the screen and the null–trace drop $k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} = 0$ (cf. Section 11.6 and Remark 11.127). Thus $k^\mu k^\nu T^{\mathrm{rel}}_{\mu\nu} \geq 0$ holds whenever $k^\mu k^\nu \bar{T}_{\mu\nu} \geq 0$ (and even beyond, by the added non–negative $\mathcal{Q}$).
3. **NCC (Null Convergence Condition).** A *geometry–side* requirement on the Ricci tensor of $\bar{g}^{\mathrm{Lor}}$:
$$R_{\mu\nu}\, k^\mu k^\nu \geq 0 \quad \text{for all null } k^\mu.$$
It is used with Raychaudhuri to infer focusing of null congruences.

Same vs. different, and how they connect.

- *Domains.* NEC constrains the matter tensor $\bar{T}_{\mu\nu}$; Relational NEC constrains the effective source $T^{\mathrm{rel}}_{\mu\nu} = \bar{T}_{\mu\nu} + \mathcal{Q}_{\mu\nu}$; NCC constrains the geometry $R_{\mu\nu}$.
- *Null–trace identity.* For any null k^μ, $k^\mu k^\nu \bar{g}^{\mathrm{Lor}}_{\mu\nu} = 0$; this removes metric trace terms and is the algebraic reason the screen argument isolates $V_\alpha V^\alpha + W_\alpha W^\alpha$ in $k^\mu k^\nu \mathcal{Q}_{\mu\nu}$ (cf. Section 11.6).
- *Implications under the field equations.* With the relational Einstein equations (11.239),
$$k^\mu k^\nu R_{\mu\nu} = \kappa\, k^\mu k^\nu T^{(\cdot)}_{\mu\nu} \quad \text{(trace terms drop by nullness)},$$
so *NEC* $\Rightarrow$ *NCC* in classical GR, and *Relational NEC* $\Rightarrow$ *NCC* in the relational theory (see Theorem 11.128 and Corollary 11.129).
- *Relative strength.* Because $\mathcal{Q}_{\mu\nu}$ is null–positive, the Relational NEC is (weakly) easier to satisfy than the standard NEC: even if $\bar{T}_{\mu\nu}k^\mu k^\nu < 0$ slightly, a sufficiently positive $k^\mu k^\nu \mathcal{Q}_{\mu\nu}$ can still yield $k^\mu k^\nu T^{\mathrm{rel}}_{\mu\nu} \geq 0$ (cf. Section 11.6).
- *Saturation of the $\mathcal{Q}$–piece.* The equality $k^\mu k^\nu \mathcal{Q}_{\mu\nu} = 0$ holds iff the transverse projections vanish for that null direction, $V^\alpha = W^\alpha = 0$.

In short, NEC and NCC live on opposite sides of the field equations; the Relational NEC strengthens the source–side inequality by adding a *provably* null–positive $\mathcal{Q}_{\mu\nu}$, so that—once (11.239) and the null–trace drop are used—Relational NEC implies Relational NCC exactly as formalized in Corollary 11.129.

Remark 11.131 (Operator–algebraic route to NCC)**.** Let $\hat{\tau}_{\mu\nu} = \delta\hat{t}_{\mu\nu}$ denote the tau–kairos fluctuation in the coherence channel (eq. (13.113) and Definition 13.1). For a null generator k^μ and a smooth compactly supported test 1–form φ_α on a null screen Σ_k, define the smeared flux operator

$$\hat{\mathcal{J}}_k[\varphi] := \int_{\Sigma_k} \mathrm{d}\Sigma\, \varphi_\alpha\, k^\mu\, \hat{\tau}_\mu{}^\alpha.$$

On the BRST/GNS physical space (§12.3) one has positivity $\langle(\hat{\mathcal{J}}_k[\varphi])^\dagger \hat{\mathcal{J}}_k[\varphi]\rangle \geq 0$. Unpacking this quadratic form and using the screen decomposition underlying (11.235) shows that the corresponding c-number density satisfies $k^\mu k^\nu \mathcal{Q}_{\mu\nu}[\bar{t}] \geq 0$ (equivalently, the transverse amplitudes $(\bar{t}\cdot k)^\perp$ have non-negative norm), hence Theorem 11.128. This complements the Newman–Penrose screen-space proof in Lemma 11.125 and is compatible with the TT isolation/SM orthogonality enforced by the coherence projectors (eq. (13.113) and Definition 13.1).

Operator–algebraic strengthening (GNS positivity). Let $\hat{t}_{\mu\nu}$ be the operator–valued temporal–curvature tensor (Definition 5.17), and define its centered fluctuation (*tau–kairos*) by $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu} = \hat{t}_{\mu\nu} - \bar{t}_{\mu\nu}$ (Section 11.6). Fix a $\bar{g}^{\mathrm{Lor}}$–null hypersurface Σ_k with future–null normal k^μ (eqs. (11.232) and (11.233)), pick an auxiliary null ℓ^μ with $k\cdot\ell = -1$, and define the screen metric and projector

$$h_{\mu\nu} := \bar{g}^{\mathrm{Lor}}_{\mu\nu} + k_\mu\ell_\nu + \ell_\mu k_\nu, \qquad \Pi^\alpha{}_\beta := \delta^\alpha{}_\beta + k^\alpha\ell_\beta + \ell^\alpha k_\beta,$$

so that $h_{\mu\nu}$ is positive–definite on vectors orthogonal to $\{k, \ell\}$ and $\Pi^\alpha{}_\beta$ projects to the screen ($\Pi^\alpha{}_\beta k^\beta = \Pi^\alpha{}_\beta \ell^\beta = 0$). For any smooth, compactly supported 1–form φ_α on Σ_k satisfying $k^\alpha\varphi_\alpha = 0$, define the smeared null–coherence operator

$$\hat{\mathcal{J}}_k[\varphi] \;:=\; \int_{\Sigma_k} \mathrm{d}\Sigma(x)\, \varphi_\alpha(x)\, k^\mu(x) \left(\Pi^\alpha{}_\beta\, \hat{\tau}_\mu{}^\beta\right)(x), \tag{11.241}$$

and the positive screen norm

$$\|\varphi\|_k^2 \;:=\; \int_{\Sigma_k} \mathrm{d}\Sigma(x)\, \overline{\varphi_\alpha(x)}\, \varphi_\beta(x)\, h^{\alpha\beta}(x), \qquad h^{\alpha\beta}h_{\beta\gamma} = \Pi^\alpha{}_\gamma. \tag{11.242}$$

(When correlating insertions at x and y along Σ_k, screen indices are compared with the Levi–Civita parallel transporter of $\bar{g}^{\mathrm{Lor}}$, $\mathcal{U}_{\bar{g}^{\mathrm{Lor}}}(x \leftarrow y)$, built from Definition 6.7; cf. the bitensor use in Definition 11.109.)

On the certified plateau $\mathfrak{P}$ (BRST–closed, diagnostic realized reference configuration semantics; Proposition 7.3), GNS/Wightman positivity on the BRST/GNS physical sector implies

$$\left\langle \left(\hat{\mathcal{J}}_k[\varphi]\right)^\dagger \hat{\mathcal{J}}_k[\varphi] \right\rangle \;\geq\; 0, \tag{11.243}$$

for all transverse test 1–forms φ [381, 241, 255]. Expanding (11.243) yields a positive semi–definite bi–kernel on Σ_k,

$$0 \;\leq\; \int_{\Sigma_k} \mathrm{d}\Sigma(x) \int_{\Sigma_k} \mathrm{d}\Sigma(y)\, \overline{\varphi_\alpha(x)}\, \varphi_\beta(y)\, k^\mu(x) k^\nu(y)\, \Pi^\alpha{}_{\alpha'}(x) \left\langle \hat{\tau}_\mu{}^{\alpha'}(x)\, \mathcal{U}_{\alpha'}{}^{\beta'}(x \leftarrow y)\, \hat{\tau}_{\nu\,\beta'}(y) \right\rangle,$$

with $\mathcal{U}_{\alpha'}{}^{\beta'}(x \leftarrow y)$ the $\bar{g}^{\mathrm{Lor}}$ parallel transporter on the screen (Definition 6.7). In the local Hadamard point–split limit on Σ_k (Section 5.4.7), the projector isolates the transverse null–screen amplitudes. Using the trace subtraction in the coherence stress definition (eq. (11.235)), one obtains the operator–algebraic strengthening of Lemma 11.125:

$$\boxed{k^\mu k^\nu \, \mathcal{Q}_{\mu\nu}[\bar{t}] \;=\; \inf_{\varphi\neq 0} \frac{\big\langle (\hat{\mathcal{J}}_k[\varphi])^\dagger \hat{\mathcal{J}}_k[\varphi]\big\rangle}{\|\varphi\|_k^2} \;\geq\; 0,} \tag{11.244}$$

where $\|\cdot\|_k$ is given by (11.242). Thus null–positivity of $\mathcal{Q}_{\mu\nu}$ is elevated from the classical identity on the screen (Lemma 11.125) to a direct consequence of operator–algebraic positivity, compatible with the relational null cone (Lemma 11.123) and the NCC of Section 11.6 and eq. (11.231).

Remark 11.132 (Centering vs. background subtraction in $\hat{\mathcal{J}}_k$)**.** For the GNS/Wightman positivity argument—and thus for the Relational NEC—it is immaterial whether the smeared operator $\hat{\mathcal{J}}_k$ is built from the centered fluctuation $\hat{\tau}_{\mu\nu} := \hat{t}_{\mu\nu} - \bar{t}_{\mu\nu}$ or from the full operator $\hat{t}_{\mu\nu}$.

1) Centering. By definition, $\hat{\tau}_{\mu\nu} = \hat{t}_{\mu\nu} - \bar{t}_{\mu\nu}$ with $\langle\hat{\tau}_{\mu\nu}\rangle = 0$. Let Σ_k be a $\bar{g}^{\mathrm{Lor}}$–null screen with normal k^μ and auxiliary null ℓ^μ, and let $\Pi^\alpha{}_\beta$ be the screen projector (eqs. (11.232), (11.233) and (11.242)). The $\hat{t}$–smeared and centered smearings are

$$\hat{\mathcal{J}}_k^{(t)}[\varphi] := \int_{\Sigma_k} \mathrm{d}\Sigma \; \varphi_\alpha \, k^\mu \, (\Pi^\alpha{}_\beta \hat{t}_\mu{}^\beta), \qquad \hat{\mathcal{J}}_k^{(\tau)}[\varphi] := \int_{\Sigma_k} \mathrm{d}\Sigma \; \varphi_\alpha \, k^\mu \, (\Pi^\alpha{}_\beta \hat{\tau}_\mu{}^\beta), \tag{11.245}$$

which differ by the c–number

$$c[\varphi] := \int_{\Sigma_k} \mathrm{d}\Sigma \; \varphi_\alpha \, k^\mu \, (\Pi^\alpha{}_\beta \bar{t}_\mu{}^\beta). \tag{11.246}$$

(Parallel transport of screen indices between points on Σ_k is tacit via the Levi–Civita bitransporter of $\bar{g}^{\mathrm{Lor}}$, as in eq. (11.241).)

2) Positivity is invariant under c–number shifts. For any operator A and $c \in \mathbb{C}$, $\langle (A+c)^\dagger (A+c)\rangle = \langle A^\dagger A\rangle + |c|^2 + 2\,\mathrm{Re}\big(c^*\langle A\rangle\big) \geq 0$. Taking $A = \hat{\mathcal{J}}_k^{(\tau)}[\varphi]$ with $\langle A\rangle = 0$ gives

$$\Big\langle \big(\hat{\mathcal{J}}_k^{(t)}[\varphi]\big)^\dagger \hat{\mathcal{J}}_k^{(t)}[\varphi]\Big\rangle = \Big\langle \big(\hat{\mathcal{J}}_k^{(\tau)}[\varphi]\big)^\dagger \hat{\mathcal{J}}_k^{(\tau)}[\varphi]\Big\rangle + |c[\varphi]|^2 \;\geq\; 0,$$

so GNS positivity (eq. (11.243)) holds for either choice.

3) Variational formula and $\mathcal{Q}_{\mu\nu}$. The operator–to–classical bridge (eq. (11.244)) reads

$$k^\mu k^\nu \mathcal{Q}_{\mu\nu}[\bar{t}] \;=\; \inf_{\varphi\neq 0} \frac{\big\langle (\hat{\mathcal{J}}_k^{(\tau)}[\varphi])^\dagger \hat{\mathcal{J}}_k^{(\tau)}[\varphi]\big\rangle}{\|\varphi\|_k^2} \;\geq\; 0.$$

If one instead uses $\hat{t}$,

$$\inf_{\varphi\neq 0}\frac{\left\langle(\hat{\mathcal{J}}_k^{(t)}[\varphi])^\dagger\hat{\mathcal{J}}_k^{(t)}[\varphi]\right\rangle}{\|\varphi\|_k^2}=\inf_{\varphi\neq 0}\frac{\left\langle(\hat{\mathcal{J}}_k^{(\tau)}[\varphi])^\dagger\hat{\mathcal{J}}_k^{(\tau)}[\varphi]\right\rangle+|c[\varphi]|^2}{\|\varphi\|_k^2}\;\geq\;\inf_{\varphi\neq 0}\frac{\left\langle(\hat{\mathcal{J}}_k^{(\tau)}[\varphi])^\dagger\hat{\mathcal{J}}_k^{(\tau)}[\varphi]\right\rangle}{\|\varphi\|_k^2}.$$

Thus the lower bound needed for the NCC (Section 11.6) is unchanged or strengthened by using $\hat{t}$. If exact equality to $k^\mu k^\nu\mathcal{Q}_{\mu\nu}[\bar{t}]$ is desired with the non–centered smearing, replace $\langle\cdot\rangle$ by the connected correlator $\langle\cdot\rangle_c$, or use the centered $\hat{\mathcal{J}}_k^{(\tau)}$.

4) Physical takeaway. Using $\hat{\tau}$ centers the observable ($\langle\hat{\mathcal{J}}_k^{(\tau)}\rangle=0$) and lands the variational formula directly on $k^\mu k^\nu\mathcal{Q}_{\mu\nu}[\bar{t}]$ (eqs. (11.235) and (11.244) and Lemma 11.125). Using $\hat{t}$ is equally valid for positivity because c–number shifts cannot spoil $\langle A^\dagger A\rangle\geq 0$. Either choice is consistent with the tau–kairos (scalar–vector) split and TT isolation (eq. (13.113) and Definition 13.1) and leaves the NCC conclusion intact (Section 11.6).

Remark 11.133 (Null–coherence smearing and Chrono–Kymon content)**. (a) What $\hat{\mathcal{J}}_k[\varphi]$ probes.** In the coherence/NEC construction the smeared null–surface operator is built from $\hat{\tau}_{\mu\nu}:=\delta\hat{t}_{\mu\nu}$, projected transversely on Σ_k (transversality $k^\alpha\varphi_\alpha=0$):

$$\hat{\mathcal{J}}_k[\varphi]=\int_{\Sigma_k}\mathrm{d}\Sigma\,\varphi_\alpha\,k^\mu\,\hat{\tau}_\mu{}^\alpha,\qquad\left\langle(\hat{\mathcal{J}}_k[\varphi])^\dagger\hat{\mathcal{J}}_k[\varphi]\right\rangle\geq 0,\tag{11.247}$$

and the positivity (11.243) together with the Hadamard point-split limit yields the variational bridge (11.244).

(b) How the Chrono–Kymon enters. The tau–kairos splits into scalar and vector (Chrono–Kymon) pieces, and the antisymmetric temporal curvature corresponds to a kymonic field strength:

$$\hat{\tau}_{\mu\nu}=S_{\mu\nu}[\hat{\varphi}]\oplus A_{\mu\nu}[\hat{K}^{(\tau)}],\qquad\hat{t}_{[\mu\nu]}=\chi_\tau\,\hat{\mathcal{F}}^{(\tau)}_{\mu\nu},\qquad\hat{\mathcal{F}}^{(\tau)}_{\mu\nu}=2\,\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]},\tag{11.248}$$

so $\hat{\mathcal{J}}_k$ probes *transverse, null–projected components of the field strength* (derivatives of $K^{(\tau)}$) on the screen space orthogonal to k^μ, not the homogeneous background norm $K^{(\tau)}\cdot K^{(\tau)}$ used in cosmological calibration. This is precisely why the contraction $k^\mu k^\nu\mathcal{Q}_{\mu\nu}[\bar{t}]$ becomes a sum of positive screen–space squares.

Remark 11.134 (Chrono–kymon vs. τ–kairos: rationale and formalism)**.** There is a precise reason to introduce the *chrono–kymon* $K^{(\tau)}_\mu$ instead of working only with the τ-kairos tensor $\hat{\tau}_{\mu\nu}:=\delta\hat{t}_{\mu\nu}$ (eqs. (11.248) and (13.113)).

1. **Clean split of degrees of freedom.** The τ-kairos decomposes as

$$\hat{\tau}_{\mu\nu}=S_{\mu\nu}\oplus A_{\mu\nu},\qquad A_{\mu\nu}=2\,\bar{\nabla}_{[\mu}K^{(\tau)}_{\nu]}\;\equiv\;\mathcal{F}^{(\tau)}_{\mu\nu},$$

so the antisymmetric piece is an *exact two–form* (a spin–1 mode), clearly separated from the scalar mode in $S_{\mu\nu}$ (eqs. (11.248) and (13.113)). This keeps the spin–2 (TT) graviton sector orthogonal and unmixed.

2. **Gauge/BRST cleanliness.** Writing $A = dK^{(\tau)}$ equips the coherence vector with a U(1)–like gauge symmetry $K^{(\tau)} \mapsto K^{(\tau)} + \bar{\nabla}\alpha$. This makes the coherence sector BRST–amenable and preserves commutation with the typed/TT projectors (Proposition 7.3 and Corollary 11.5). Working directly with $\tau_{\mu\nu}$ obscures these redundancies.
3. **Local, causal dynamics.** Potentials admit local Lagrangians and retarded/advanced Green operators supported on the *same* relational cone $J^{\pm}_{\Sigma}$ as in the rest of the formalism, ensuring microcausality alignment with Chapters 6–8 (cf. the kernels in Remark 11.108).
4. **Null–screen positivity becomes manifest (Relational NEC).** The coherence stress $\mathcal{Q}_{\mu\nu}$ (eq. (11.235)) satisfies, for any $\bar{g}^{\mathrm{Lor}}$–null k^μ,

$$k^\mu k^\nu \mathcal{Q}_{\mu\nu}[\bar{t}] = \|(S\cdot k)\|^2 + \|(\mathcal{F}^{(\tau)}\cdot k)\|^2 \ \geq 0,$$

   which is the positivity used in the Relational NEC (Lemma 11.125 and Section 11.6). Expressing the antisymmetric content as a *field strength* turns the null contraction into a sum of *screen–space squares*, exactly what the GNS/point–split argument requires (eqs. (11.243) and (11.244) and Remark 11.133).
5. **Observable, gauge–invariant probes on null screens.** The smeared operator $\hat{\mathcal{J}}_k[\varphi]$ samples transverse components of the *field strength* (not the potential) and is therefore gauge–invariant and positive by construction (eqs. (11.241) and (11.247) and Remark 11.132). This gives a direct operator–algebraic route to the NEC via eqs. (11.243) and (11.244).
6. **EP–safe scalarisation and PPN bookkeeping.** Encoding the antisymmetric sector via $K^{(\tau)}$ clarifies how it contributes to the anisotropic piece of the emergent coupling $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}$ and why, in the EP–safe (scalarised) regime, such effects are projected out or suppressed by small, screened gradients (Section 11.5.7 and Proposition 11.113).
7. **Global note (local arguments suffice).** If A has nontrivial cohomology, $K^{(\tau)}$ exists patchwise. Our NEC/focusing and GNS arguments are *local* (Hadamard/point–split), so a potential description is always available on the charts we use.

In sum. The composite tensor $\tau_{\mu\nu}$ is the right object to *define* the coherence stress, but introducing the chrono–kymon $K^{(\tau)}$ renders the antisymmetric sector gauge–clean, causal, and positivity–transparent, while preserving TT isolation and the scalar–vector bookkeeping consistently across Chapters 6–12 (eqs. (11.235), (11.243) and (11.244), Lemma 11.125, and Remarks 11.132 and 11.133).

State class, domains, and renormalization (technical set-up). We work throughout in the BRST/GNS physical representation (Sections 1.4.1 and 12.2) and assume Hadamard regularity for two-point correlators in the temporal–curvature sector, both for the full operator $\hat{t}_{\mu\nu}$ and its centered fluctuation (tau–kairos) $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ (Section 5.2.1). Let Σ_k be a $\bar{g}^{\mathrm{Lor}}$–null hypersurface with future-directed null normal k^μ and induced measure $\mathrm{d}\Sigma$. Choose an auxiliary null ℓ^μ with $k\cdot\ell = -1$ and define the screen projector and metric

$$h_{\mu\nu} := \bar{g}^{\mathrm{Lor}}_{\mu\nu} + k_\mu\ell_\nu + k_\nu\ell_\mu, \qquad \Pi^\alpha{}_\beta := \delta^\alpha{}_\beta + \ell^\alpha k_\beta \quad (\Rightarrow\ k^\beta\Pi^\alpha{}_\beta = 0).$$

Define the transverse test space

$$\mathcal{T}_k \;:=\; \Big\{\; \varphi_\alpha \in C_0^\infty(T^*\Sigma_k) \;:\; k^\alpha \varphi_\alpha = 0 \;\Big\}.$$

For $\varphi \in \mathcal{T}_k$, the (centered) smeared null–coherence operator is

$$\hat{\mathcal{J}}_k[\varphi] \;:=\; \int_{\Sigma_k} \mathrm{d}\Sigma(x)\; \varphi_\alpha(x)\, k^\mu(x)\, \hat{\tau}_\mu{}^\alpha(x), \tag{11.249}$$

which is densely defined on the GNS domain, with positive screen norm

$$\|\varphi\|_k^2 \;:=\; \int_{\Sigma_k} \mathrm{d}\Sigma(x)\; \overline{\varphi_\alpha(x)}\, \varphi_\beta(x)\, h^{\alpha\beta}(x), \qquad h^{\alpha\beta} h_{\beta\gamma} = \Pi^\alpha{}_\gamma. \tag{11.250}$$

(For bi-local expressions on Σ_k, screen indices at y are parallel-transported to x using the Levi–Civita transporter $\mathcal{U}_{\bar{g}^{\mathrm{Lor}}}(x \leftarrow y)$.)
By GNS/Wightman positivity in the physical sector [381, 241, 255],

$$\Big\langle \big(\hat{\mathcal{J}}_k[\varphi]\big)^\dagger \hat{\mathcal{J}}_k[\varphi] \Big\rangle \;\geq\; 0, \qquad \forall\, \varphi \in \mathcal{T}_k, \tag{11.251}$$

(cf. eq. (11.243)). If one prefers the uncentered smearing with $\hat{t}_{\mu\nu}$, set $\hat{\mathcal{J}}_k^{(t)}[\varphi] := \int_{\Sigma_k} \mathrm{d}\Sigma\, \varphi_\alpha k^\mu \hat{t}_\mu{}^\alpha$; positivity is unchanged and the variational bound differs only by a harmless c-number shift (Remark 11.132).

To define the quadratic coherence stress as an operator-valued distribution, use point-splitting with a Hadamard parametrix and subtract local, covariant counterterms that preserve BRST closure and $\bar{g}^{\mathrm{Lor}}$–covariance (the standard finite renormalization freedom). Denote the Wick-ordered quadratic tensor by

$$:\!\mathcal{Q}_{\mu\nu}\!:\,[\bar{t}] \;:=\; :\!S_{\mu\alpha} S_\nu{}^\alpha\!: \;+\; :\!A_{\mu\alpha} A_\nu{}^\alpha\!: \;-\; \tfrac{1}{4}\, \bar{g}^{\mathrm{Lor}}_{\mu\nu} \Big(:\!S_{\alpha\beta} S^{\alpha\beta}\!: + :\!A_{\alpha\beta} A^{\alpha\beta}\!: \Big), \tag{11.252}$$

where $S_{\mu\nu} := \hat{\tau}_{(\mu\nu)}$, $A_{\mu\nu} := \hat{\tau}_{[\mu\nu]}$, and all products are Wick-ordered by the state's Hadamard two-point function (Section 1.4.1; cf. the classical definition eq. (11.235)). Possible finite counterterms are built from $\bar{g}^{\mathrm{Lor}}_{\mu\nu}$ and its curvatures; terms $\propto \bar{g}^{\mathrm{Lor}}_{\mu\nu}$ vanish after contraction with $k^\mu k^\nu$ by Lemma 11.123, and total-derivative terms can be arranged to vanish upon smearing on Σ_k (compact support). The tau–kairos TT isolation $\mathcal{P}^{(2)}[\hat{\tau}_{\mu\nu}] = 0$ (see the typed/triadic structure in Chap. 13 and Remark 11.133) guarantees no spin–2 leakage into $:\!\mathcal{Q}_{\mu\nu}\!:$, preserving the null-cone analysis and the Relational NEC (Section 11.6).

Proposition 11.135 (Null positivity of the Wick-ordered coherence stress)**.** *Let k^μ be a $\bar{g}^{\mathrm{Lor}}$-null vector field and let $f \in C_0^\infty(\Sigma_k)$ with $f \geq 0$. Then, in any BRST/GNS physical Hadamard state,*

$$\Big\langle\; :\!\mathcal{Q}_{\mu\nu}\!:\,[\bar{t}]\; k^\mu k^\nu \,,\; f \;\Big\rangle \;\geq\; 0, \tag{11.253}$$

i.e. the distribution $k^\mu k^\nu\; :\!\mathcal{Q}_{\mu\nu}\!:$ is positive on non-negative test densities supported on Σ_k.

Proof sketch consistent with eq. (11.251). Choose a family $\{\varphi^{(\epsilon)}\}_{\epsilon>0} \subset \mathcal{T}_k$ with $\varphi^{(\epsilon)} \to \sqrt{f}\, m_\alpha$ in C_0^∞ as $\epsilon \downarrow 0$, where m_α is any unit complex transverse covector on Σ_k (and similarly $\bar{m}_\alpha$ in a Newman–Penrose frame). By eq. (11.251),

$$\Big\langle \big(\hat{\mathcal{J}}_k[\varphi^{(\epsilon)}]\big)^\dagger \hat{\mathcal{J}}_k[\varphi^{(\epsilon)}] \Big\rangle \;\geq\; 0.$$

Perform point-splitting with a Hadamard parametrix, parallel-transport screen indices, and subtract the state-dependent singularity; in the limit $\epsilon \downarrow 0$ one obtains the Wick-squares of the transverse null contractions of $\hat{\tau}_{\mu\nu}$, i.e. the positive pieces in eq. (11.252) smeared by f. The trace subtraction in eq. (11.252) contributes only multiples of $\bar{g}^{\mathrm{Lor}}_{\mu\nu}$, which vanish under $k^\mu k^\nu$ by Lemma 11.123. Local, covariant finite counterterms (BRST-closed, $\bar{g}^{\mathrm{Lor}}$-covariant) either drop out on nulls or reduce to total divergences that vanish upon smearing on Σ_k (compact support). Hence $\langle :\mathcal{Q}_{\mu\nu}: \, k^\mu k^\nu, f\rangle \geq 0$. □

Corollary 11.136 (Operator-level strengthening of Lemma 11.125)**.** *With* $:\mathcal{Q}_{\mu\nu}:$ *defined by eq.* (11.252)*, the null inequality* $\langle :\mathcal{Q}_{\mu\nu}: \, k^\mu k^\nu, f\rangle \geq 0$ *holds for all non-negative* $f \in C_0^\infty(\Sigma_k)$*. In particular, for smooth, compactly supported congruence bundles,*

$$k^\mu k^\nu \, \mathcal{Q}_{\mu\nu}[\bar{t}] \;\geq\; 0$$

in the sense of quadratic forms, thereby upgrading Lemma 11.125 from a tetrad identity to an operator–algebraic statement consistent with eq. (11.251)*.*

The operator–algebraic positivity statement $\left\langle (\hat{\mathcal{J}}_k[\varphi])^\dagger \hat{\mathcal{J}}_k[\varphi] \right\rangle \geq 0$ on null screens (eq. (11.251)) promotes the classical null "sum of squares" identity for the coherence sector to a fully renormalized field-theoretic result. After Hadamard point-splitting and Wick ordering, this yields the positivity of the distribution $k^\mu k^\nu \, :\mathcal{Q}_{\mu\nu}:$ on every non-negative test density f supported on the null hypersurface Σ_k (Prop. Proposition 11.135, using the definition in eq. (11.252)). In other words, the coherence contribution cannot furnish negative energy along a light ray in any BRST/GNS physical Hadamard state.

The structural reason is the scalar–vector split of the tau–kairos tensor $\hat{\tau}_{\mu\nu}$ into a symmetric piece $S_{\mu\nu}$ and an antisymmetric piece $A_{\mu\nu}$, the latter expressed as the chrono–kymon field strength $\mathcal{F}^{(\tau)}_{\mu\nu} = 2\,\bar{\nabla}_{[\mu} K^{(\tau)}_{\nu]}$ (Remark 11.133 and eq. (11.248)). With the trace-adjusted definition of the coherence stress $\mathcal{Q}_{\mu\nu}$ (eq. (11.235)), the null contraction becomes a sum of positive screen–space squares, $k^\mu k^\nu \mathcal{Q}_{\mu\nu} = \|(S{\cdot}k)\|^2 + \|(\mathcal{F}^{(\tau)}{\cdot}k)\|^2 \geq 0$ (Lemma Lemma 11.125). The smeared operator $\hat{\mathcal{J}}_k[\varphi] = \int_{\Sigma_k} \mathrm{d}\Sigma \, \varphi_\alpha \, k^\mu \, \hat{\tau}_\mu{}^\alpha$ (eq. (11.249)), built with transverse test one-forms and the screen metric, probes precisely these gauge-invariant, transverse components and delivers the variational bridge from operator positivity to the classical inequality (eqs. (11.244) and (11.251) and Remarks 11.132 and 11.133).

Gravitationally, combining this null positivity with the vacuum drop-out $k^\mu k^\nu T^{\mathrm{vac}}_{\mu\nu} = 0$ (Lemma Lemma 11.124) and the ordinary NEC for matter on $\bar{g}^{\mathrm{Lor}}$ establishes the Relational NEC of Section 11.6 and its operator-level strengthening (Cor. Corollary 11.136). Contracting the field equations with $k^\mu k^\nu$ then feeds into the Raychaudhuri inequality on $(\bar{g}^{\mathrm{Lor}}, \bar{\nabla})$ (eq. (11.234)), ensuring standard null focusing whenever the scalarized source $k^\mu k^\nu \left(T^{\mathrm{matter}}_{\mu\nu} + \gamma \, \mathcal{Q}_{\mu\nu}\right)$ is non-negative. In the EP-safe (scalarized) regime (Section 11.5.7 and Proposition 11.113), this statement is preserved with a slowly varying κ_{eff}, maintaining consistency with the Chronogeometric Einstein law (Definition 11.106).

Focusing and Observational Handles. Let $\bar{\nabla}$ be the Levi–Civita connection of $\bar{g}^{\mathrm{Lor}}_{\mu\nu}$ (Definition 6.7). For an affinely parameterized null congruence with tangent k^μ ($k^\nu \bar{\nabla}_\nu k^\mu = 0$), the

Raychaudhuri equation takes the standard form [240, 7]:

$$\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} = -\tfrac{1}{2}\,\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - R_{\mu\nu}[\bar{g}^{\mathrm{Lor}}]\,k^\mu k^\nu, \tag{11.254}$$

where $\theta, \sigma_{\mu\nu}, \omega_{\mu\nu}$ are computed with $\bar{g}^{\mathrm{Lor}}$. Using the scalarised field equations of 11.5.7 one has

$$R_{\mu\nu}[\bar{g}^{\mathrm{Lor}}]\,k^\mu k^\nu = \kappa_{\mathrm{eff}}(x)\,k^\mu k^\nu\Big(T^{\mathrm{matter}}_{\mu\nu} + \gamma\,\mathcal{Q}_{\mu\nu}[\bar{t}]\Big),$$

and by Lemma 11.123 the vacuum term vanishes on nulls. For hypersurface–orthogonal congruences ($\omega_{\mu\nu} = 0$) and under the NCC (11.231) (with $\kappa_{\mathrm{eff}} \geq 0$),

$$\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} \;\leq\; -\tfrac{1}{2}\,\theta^2 \qquad \Rightarrow \qquad \theta(\lambda) \;\to\; -\infty \;\text{ by }\; \lambda \leq \frac{2}{|\theta(0)|} \;\text{ if } \theta(0) < 0,$$

i.e. focusing within a finite affine parameter, exactly as in GR, now with explicit sensitivity to the coherence stress through $\mathcal{Q}_{\mu\nu}[\bar{t}]$. This furnishes *observational handles*: null–congruence phenomena such as strong/weak lensing, Shapiro delay, echo/tail structures in waveforms, and standard–ruler distortions acquire coherence–dependent corrections controlled by $\gamma\,\mathcal{Q}_{\mu\nu}$ (cf. precision weak-field tests [479]).

Remark 11.137 (Optical scalars and their role in (11.254))**.** Fix an affinely–parameterized null congruence with tangent k^μ ($k^\nu\bar{\nabla}_\nu k^\mu = 0$) for the Levi–Civita connection $\bar{\nabla}$ of $\bar{g}^{\mathrm{Lor}}_{\mu\nu}$ (cf. Definition 6.7). Choose a null partner ℓ^μ with $k\cdot\ell = -1$ and define the screen metric $q_{\mu\nu} = \bar{g}^{\mathrm{Lor}}_{\mu\nu} + k_\mu\ell_\nu + \ell_\mu k_\nu$ (cf. Remark 11.127). The *optical tensor* is the projected gradient

$$B_{\mu\nu} \;:=\; q_\mu{}^\alpha\, q_\nu{}^\beta\, \bar{\nabla}_\alpha k_\beta, \qquad q_\mu{}^\alpha := \bar{g}^{\alpha\rho}q_{\rho\mu},$$

and decomposes into its trace, symmetric tracefree, and antisymmetric parts:

$$B_{\mu\nu} \;=\; \frac{1}{d-2}\,\theta\, q_{\mu\nu} \;+\; \sigma_{\mu\nu} \;+\; \omega_{\mu\nu}.$$

Here

- **Expansion** $\theta := B^\mu{}_\mu = q^{\mu\nu}\bar{\nabla}_\mu k_\nu$ measures the fractional rate of change of the beam's cross–sectional area (negative θ signals focusing).
- **Shear** $\sigma_{\mu\nu} := B_{(\mu\nu)} - \dfrac{\theta}{d-2}\,q_{\mu\nu}$ is symmetric and tracefree ($q^{\mu\nu}\sigma_{\mu\nu} = 0$), capturing shape distortions at fixed area.
- **Twist (vorticity)** $\omega_{\mu\nu} := B_{[\mu\nu]}$ measures the local rotation of the congruence; hypersurface–orthogonality (Frobenius) is equivalent to $\omega_{\mu\nu} = 0$.

With these definitions, the null Raychaudhuri equation (11.254) reads $\frac{d\theta}{d\lambda} = -\frac{1}{2}\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - R_{\mu\nu}k^\mu k^\nu$, where $\sigma_{\mu\nu}\sigma^{\mu\nu} \geq 0$ and $\omega_{\mu\nu}\omega^{\mu\nu} \geq 0$ are computed using $\bar{g}^{\mathrm{Lor}}$. In particular, for twist–free congruences ($\omega_{\mu\nu} = 0$) and under the (Relational) NCC ($R_{\mu\nu}k^\mu k^\nu \geq 0$), negative initial θ necessarily evolves toward focusing, providing the observational handle discussed around (11.254) [240, 7, 316].

Normalization, Limits, and Saturation. (i) *Normalization.* Any $\gamma \geq 0$ preserves the NCC (11.231); choosing $\gamma = 1$ matches the quadratic normalization from the temporal–sector action (see Section 6.1.13). (ii) *Decohered (GR) limit.* As $\bar{t}_{\mu\nu} \to 0$, one has $\mathcal{Q}_{\mu\nu}[\bar{t}] \to 0$ and $\bar{g}^{\mathrm{Lor}}_{\mu\nu} \to \bar{g}_{\mu\nu}$; thus (11.231) reduces to the standard NEC for $T^{\mathrm{matter}}_{\mu\nu}$ and (11.254) becomes the classical Raychaudhuri equation [7]. (iii) *Saturation.* Equality in (11.231) occurs iff the transverse coherence amplitudes vanish along the congruence, $\Xi_m := \bar{t}_{\mu\nu} k^\mu m^\nu = 0 = \Xi_{\bar{m}} := \bar{t}_{\mu\nu} k^\mu \bar{m}^\nu$ for some Newman–Penrose tetrad $\{k, \ell, m, \bar{m}\}$ (cf. Lemma 11.125); then only longitudinal (transport/pure–gauge) coherence survives and the condition reduces to the matter NEC alone.

Conclusion. Assuming matter obeys the NEC and $\gamma \geq 0$, the Relational Null Coherence Condition (11.231) is secured by operator–algebraic positivity and yields standard focusing theorems for $\bar{g}^{\mathrm{Lor}}$ with coherence–sensitive corrections, placing the Chronogeometric Einstein Equations (Definition 11.106) on the same energy–condition footing as in GR while opening observational avenues to probe $\bar{t}$ via null–congruence data.

11.7 Operator–Valued Einstein Equations with Unified Tensor

Instrumentation preamble (diagnostic realized reference configuration & tags). All statements in this section are made on a certified plateau $\mathfrak{P}$ with BRST–closed band tags (P_x, K_{IR}) commuting with the triad projectors $\{\Pi^{(\mathrm{corr})}, \Pi^{(\mathrm{vac})}, \Pi^{(\mathrm{spec})}\}$ and with the TT projector $\Pi^{[\mathrm{TT}]}{}_*\bar{\Sigma}$; observables descend to the physical space $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ with Σ–Nielsen flatness. Connections, curvatures and causal cones are those of $\bar{\Sigma}$ (Relational Levi–Civita); $\bar{\nabla}^\mu \bar{G}_{\mu\nu} \equiv 0$ and $\bar{\nabla}^\mu \bar{T}^{\mathrm{total}}_{\mu\nu} = 0$ are read on the same background (cf. Remark 11.108).

The semi–classical Chronogeometric Einstein law (Definition 11.106) reads

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\, \bar{\Sigma}_{\mu\nu} = \kappa\, \bar{T}^{\mathrm{total}}_{\mu\nu}, \qquad \text{equivalently} \quad \bar{G}_{\mu\nu} = \bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}\, \bar{T}^{\mathrm{total}}_{\rho\sigma},} \tag{11.255}$$

with the emergent coupling tensor $\bar{\mathcal{C}}$ defined in Definition 11.111 and scalarisation limits in Section 11.5.7. Since both geometry and matter are operator–valued in IQR, the fundamental law must be formulated at the operator level and reduce to (11.255) upon taking expectations in the Holo–State.

11.7.1 Formulation of the Operator Equation

Let the unified operator tensor (Chs. 6–7) be

$$\hat{\Sigma}_{\mu\nu}(x) := \hat{g}_{\mu\nu}(x) + \hat{t}_{\mu\nu}(x),$$

where $\hat{g}_{\mu\nu}$ arises from the distinguishability functional of the Gaiamiti sector and $\hat{t}_{\mu\nu}$ from the temporal–curvature functional (the coherence/chrono–temporal sector), cf. Definitions 5.1 and 5.17. The operator–valued curvature tensors $\hat{R}^\lambda{}_{\rho\mu\nu}[\hat{\Sigma}]$, $\hat{R}_{\mu\nu}[\hat{\Sigma}]$ and $\hat{R}[\hat{\Sigma}]$ are defined as operator–valued distributions by Hadamard point–splitting on $\mathfrak{P}$ and functional composition with the (quantum) Levi–Civita connection of $\hat{\Sigma}$ (normal–ordered where needed). The operator Einstein tensor is

$$\hat{G}_{\mu\nu}[\hat{\Sigma}] := \hat{R}_{\mu\nu}[\hat{\Sigma}] - \tfrac{1}{2}\, \hat{\Sigma}_{\mu\nu}\, \hat{R}[\hat{\Sigma}].$$

Causal response form (diagnostic realized reference configuration-covariant). Following Definition 11.109 and eqs. (11.213) and (11.214), the operator equation takes the retarded, diagnostic realized reference configuration-covariant bitensor form:

$$\boxed{\hat{G}_{\mu\nu}(x) = \int_{\mathcal{X}_q} d\mu_{\bar{\Sigma}}(x')\, \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \circ \Big[\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\rho}{}^{\rho'}\, \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\sigma}{}^{\sigma'}\, \hat{T}^{\text{total}}_{\rho'\sigma'}(x')\Big],} \tag{11.256}$$

where $d\mu_{\bar{\Sigma}}(x') := \sqrt{-\det \bar{\Sigma}(x')}\, d^d x'$, $\mathcal{U}_{\bar{\Sigma}}$ is the Levi–Civita parallel transporter of $\bar{\Sigma}$, and $A \circ B := \frac{1}{2}(AB+BA)$ denotes the Jordan product (self-adjointness). The retarded kernel

$$\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') = \mathbb{P}^{(\text{Ein})\alpha\beta}_{\mu\nu}\, \hat{\Delta}^{\text{ret}\,\gamma\delta}_{\alpha\beta}(x,x')\, \mathbb{J}_{\gamma\delta}{}^{\rho\sigma}$$

has support in $J^{+}_{\bar{\Sigma}}(x')$ (microcausality) and encodes the TT-typed graviton response in the radiative sector. In the local/spectral limit (Section 11.5.8 and Proposition 11.115), $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \to \kappa\, \Pi_{\mu\nu}{}^{\rho\sigma}\, \delta^{(d)}(x-x')\, \hat{\mathbf{1}}$, recovering the familiar local law.

Local symbolic form (including interaction/coherence terms). Suppressing parallel transport and density factors, the retarded bitensor law (11.256) can be written symbolically as

$$\boxed{\hat{G}_{\mu\nu}[\hat{\Sigma}](x) \;=\; \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x) \;\circ\; \hat{T}^{\text{total}}_{\rho\sigma}(x), \qquad A \circ B := \tfrac{1}{2}(AB+BA),} \tag{11.257}$$

where the *total* source includes the diagonal, interaction (mixing), and coherence/torsion pieces:

$$\boxed{\hat{T}^{\text{total}}_{\rho\sigma} \;:=\; \underbrace{\hat{T}^{(\Phi)}_{\rho\sigma} + \hat{T}^{(\Theta)}_{\rho\sigma}}_{\text{diagonal blocks}} \;+\; \underbrace{\hat{T}^{(\Phi\Theta)}_{\rho\sigma}\Big[\hat{\mathbf{G}}_{\Phi\Theta}\Big]}_{\text{off-diagonal interaction}} \;+\; \underbrace{\hat{T}^{(\tau)}_{\rho\sigma}\Big[\hat{K}^{(\tau)}, \hat{\mathcal{F}}^{(\tau)}\Big]}_{\text{coherence/torsion}}.} \tag{11.258}$$

Here $\hat{T}^{(\Phi\Theta)}$ encodes the mixing induced by the off–diagonal correlator blocks of the unified two–point kernel (cf. Section 6.1.1 and Lemma 11.146), and $\hat{T}^{(\tau)}$ collects the Chrono–Kymon contributions mapped into $\hat{t}_{[\mu\nu]} = \chi_\tau\, \hat{\mathcal{F}}^{(\tau)}_{\mu\nu}$ (cf. Sections 10.7 and 10.17.9). This is the operator–level analogue of the expectation–level decomposition in (11.264).

Vacuum placement. The cosmological (vacuum) channel may be kept on the geometric side, yielding the expectation–level form (11.269), or moved to the source as $-\frac{\Lambda_{\text{eff}}}{\kappa'}\, \hat{\Sigma}_{\rho\sigma}$. Both conventions are equivalent at the level of null contractions by Lemma 11.123. (For the precise diagnostic realized reference configuration–covariant bitensor structure, see (11.256).)

11.7.2 Consistency, Conservation, and Semiclassical Reduction

(i) Bianchi/cohomological consistency. On the diagnostic realized reference configuration background $(\bar{\Sigma}, \bar{\nabla})$, $\bar{\nabla}^{\mu}_{x} \mathbb{P}^{(\text{Ein})\alpha\beta}_{\mu\nu} = 0$ and the causal graviton kernel $\hat{\Delta}^{\text{ret}}$ is built from the $\bar{\Sigma}$–Lichnerowicz operator (Remark 11.108); together with Levi–Civita transport this yields

$$\bar{\nabla}^{\mu}_{x}\, \hat{G}_{\mu\nu}(x) = 0 \quad \Rightarrow \quad \bar{\nabla}^{\mu} \hat{T}^{\text{total}}_{\mu\nu}(x) = 0 \quad \text{(weakly on } \mathcal{H}_{\text{phys}}\text{, mod. BRST–exact).}$$

Equivalently, the cohomological EOMs vanish on $\mathfrak{P}$ "mod ζ–exact" as in Section 11.5.4.

(ii) State dependence and emergence. Taking the Holo–State expectation of (11.256) reproduces (11.255) with $\bar{\mathcal{C}} := \langle \hat{\mathcal{C}} \rangle$ (Definition 11.111); scalarisation and variation bounds are given in Section 11.5.7, and the GR limit in Section 11.5.8.

(iii) Ordering and microcausality. Non–commutativity is controlled by the Jordan product $\circ$ and by causal support of $\hat{\mathcal{C}}(\cdot;\cdot)$ in $J^{\pm}_{\bar{\Sigma}}$, guaranteeing that $\hat{G}_{\mu\nu}(x)$ depends only on sources in the past cone of x (the same microcausal cone used for scalar and spin–2 kernels in Chs. 6–8; cf. Remark 11.108).

(iv) Typed radiative sector. In the spin–2 sector, the TT–typed TLO and projector $\Pi^{[\mathrm{TT}]}{}_{*\bar{\Sigma}}$ (Ch. 11) act on (11.256), isolating physical graviton polarizations; non–TT observables are triad–mixed as in the polarization discussion of Ch. 11.

Weinberg–Witten applicability

The Weinberg–Witten (WW) no–go theorem [475] states that, *if* a quantum field theory (i) is formulated on a fixed Minkowski background with exact global Poincaré symmetry, and (ii) possesses a single, Lorentz–covariant, gauge–invariant, conserved local stress tensor $T^{\mu\nu}$, then it cannot contain interacting massless particles of spin $s > 1$. In the Chronogeometric/IQR framework, the hypotheses are not satisfied, and the theorem is therefore inapplicable:

1. **No fixed Minkowski background.** The dynamical "diagnostic realized reference configuration'' geometry is *emergent and state–dependent*: $\bar{\Sigma}_{\mu\nu}(x) = \langle \overset{\circ}{\boldsymbol{\Psi}} | \, \hat{\Sigma}_{\mu\nu}(x) \, | \overset{\circ}{\boldsymbol{\Psi}} \rangle$, so there is no global Poincaré frame or global Killing algebra supporting the WW assumptions. Causal structure, connections, and curvatures are those of $(\bar{\Sigma}, \bar{\nabla})$ (Relational Levi–Civita), with all readouts taken on the BRST/GNS physical space (diagnostic realized reference configuration instrumentation preamble; cf. Remark 11.108).

2. **No single local, gauge–invariant conserved $T^{\mu\nu}$.** The operative stress tensor is defined *relationally* with indices raised/lowered by $\bar{\Sigma}^{\mu\nu}$, and includes both matter and geometric contributions ($\hat{T}^{\mathrm{total}}_{\mu\nu} = \hat{T}^{(\Phi)}_{\mu\nu} + \hat{T}^{(\Theta)}_{\mu\nu}$; see Definition 9.358). The geometry–matter coupling is mediated by a *retarded bitensor kernel* with causal support, not by a single ultralocal coupling to a background–independent $T^{\mu\nu}$:

$$\hat{G}_{\mu\nu}(x) = \int d\mu_{\bar{\Sigma}}(x') \, \hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \;\circ\; \Big[\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\rho}{}^{\rho'} \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\sigma}{}^{\sigma'} \hat{T}^{\mathrm{total}}_{\rho'\sigma'}(x') \Big], \tag{11.259}$$

   (cf. eq. (11.256)). This relational kernel $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x')$ is state–dependent (Definition 11.111) and preserves microcausality on $J^{\pm}_{\bar{\Sigma}}$; such nonlocal bitensor couplings lie outside the WW hypothesis of a single local, gauge–invariant conserved tensor current on flat space.

3. **Gauge/BRST structure and physical polarizations.** Diffeomorphisms act as gauge symmetries; the physical graviton sector is the TT–typed cohomology on the diagnostic realized reference configuration, projected by $\Pi^{[\mathrm{TT}]}{}_{*\bar{\Sigma}}$ (Ch. 11; cf. Remark 11.108). Non–TT observables are triad–mixed and do not represent additional propagating

spin–2 modes. The operator identity (11.259) is BRST–consistent; its expectation reproduces the semi–classical equation with emergent coupling $\bar{\mathcal{C}} = \langle \hat{\mathcal{C}} \rangle$ (eq. (11.255) and Definition 11.111).

Spectral/GR limit and consistency. In the weak–field, low–coherence spectral channel one has $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \to \kappa\, \Pi_{\mu\nu}{}^{\rho\sigma}\, \delta^{(d)}(x-x')\, \hat{\mathbf{1}}$, so $\bar{G}_{\mu\nu} = \kappa\, \bar{T}^{\text{total}}_{\mu\nu}$ is recovered (Section 11.5.8 and Proposition 11.115). This agreement with low–energy GR and soft–theorem/EFT expectations [539, 403, 519] does not re–impose the WW hypotheses: the flat, globally Poincaré–invariant background and the existence of a single, background–independent, gauge–invariant local $T^{\mu\nu}$ are absent at the fundamental level. Hence the Chronogeometric TT graviton *evades* the WW obstruction in a manner consistent with (11.256) and with its GR limit.

11.7.3 The Einstein Tensor of the Unified Geometry

Instrumentation preamble (diagnostic realized reference configuration & tags). All statements in this subsection are made on a certified plateau $\mathfrak{P}$ with BRST–closed band tags (P_x, K_{IR}) commuting with the triad projectors and the TT projector, and all readouts descend to $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$ (Nielsen–flat law channel), cf. the preamble to §11.5.4. *Relational geometry.* Connections and curvatures are those of $\bar{\Sigma}$ (Relational Levi–Civita); index gymnastics use $\bar{\Sigma}_{\mu\nu}$ and $\bar{\Sigma}^{\mu\nu}$, and $\bar{\nabla}$ is the Levi–Civita connection of $\bar{\Sigma}$ (see Definition 11.103 and Remark 11.108).

Definition 11.138 (Einstein tensor of the unified geometry)**.** Given the relational Ricci tensor and scalar curvature of $\bar{\Sigma}$ (Definition 11.103), the *Einstein tensor* on $(\mathcal{X}_q, \bar{\Sigma})$ is

$$\boxed{\bar{G}_{\mu\nu}[\bar{\Sigma}] := \; \bar{R}_{\mu\nu}[\bar{\Sigma}] - \tfrac{1}{2}\, \bar{\Sigma}_{\mu\nu}\, \bar{R}[\bar{\Sigma}].} \tag{11.260}$$

Conservation via the contracted Bianchi identity. Because $(\bar{\Sigma}, \bar{\nabla})$ is torsion–free and metric–compatible, the curvature obeys the (second) Bianchi identity; contracting yields conservation of the Einstein tensor.

Proposition 11.139 (Relational Bianchi & conservation)**.** *With $\bar{\nabla}$ the Levi–Civita connection of $\bar{\Sigma}$,*

$$\boxed{\bar{\nabla}^{\mu}\, \bar{G}_{\mu\nu}[\bar{\Sigma}] \;\equiv\; 0,} \tag{11.261}$$

as a direct consequence of the Bianchi identities in Proposition 11.98.

This divergence–free structure fixes the geometric side of the law and matches the diagnostic realized reference configuration–level conservation of the total expectation stress tensor, $\bar{\nabla}_{\mu} \bar{T}^{\mu\nu}_{\text{total}} = 0$, used in the Chronogeometric Einstein equations (Definition 11.106 and Section 11.5.5).

Interpretation and placement in the dynamical stack. The tensor $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ captures the covariantly conserved, second–order content of the unified chronogeometry and therefore supplies the correct left–hand side of the field equations at both the semi–classical and operator levels: it appears in the diagnostic realized reference configuration law $\bar{G}_{\mu\nu} + \Lambda\,\bar{\Sigma}_{\mu\nu} = \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}$ (Definition 11.106 and Section 11.5.4), and in the operator–valued causal response relation (eq. (11.256)). Linearization about $\bar{\Sigma}$ produces the Lichnerowicz operator and TT–projected propagator (Remark 11.108), ensuring that the radiative (spin–2) sector is handled by the typed TT panel of Ch. 11 while non–TT observables are triad–mixed but remain orthogonal to TT as in Remark 11.108. The same causal cones $J^{\pm}_{\bar{\Sigma}}$ control the support of Green kernels across the scalar and spin–2 sectors, maintaining microcausal alignment with Chs. 6–8.

Diagnostic realized reference configuration visibility (optional). For diagnostics on $\mathfrak{P}$, deviations from the Einstein law can be summarized by the diagnostic realized reference configuration residual and visibility defined in §11.5.4, which are evaluated with the same tags and projectors that certify the plateau; $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ supplies the geometric input to those meters.

Relational connection and compatibility. Throughout this subsection the dynamical background is the unified tensor $\bar{\Sigma}_{\mu\nu}$ and $\nabla^{(\mathrm{rel})}$ denotes a *relational* affine connection chosen to be *metric–compatible* with $\bar{\Sigma}$ but allowed to carry torsion:

$$\nabla^{(\mathrm{rel})}_{\lambda}\bar{\Sigma}_{\mu\nu} = 0, \qquad \mathcal{T}^{\rho}{}_{\mu\nu} := 2\,\Gamma^{\rho}{}_{[\mu\nu]} \neq 0.$$

The antisymmetric piece of the temporal sector is modeled constitutively by the chrono–kymon field strength (Remark 11.133 and eq. (11.248)):

$$\bar{t}_{[\mu\nu]} \;=\; \chi_{\tau}\,\bar{\mathcal{F}}^{(\tau)}_{\mu\nu}, \qquad \bar{\mathcal{F}}^{(\tau)}_{\mu\nu} := 2\,\bar{\nabla}_{[\mu}\bar{K}^{(\tau)}_{\nu]},$$

where χ_{τ} is a constitutive coefficient and $\bar{\nabla}$ is the Levi–Civita connection of $\bar{\Sigma}$. Nonmetricity is set to zero (any nonmetric effects are absorbed in the constitutive definition of $\Gamma[\bar{\Sigma}]$), so that $\nabla^{(\mathrm{rel})}$ reduces to $\bar{\nabla}$ when $\mathcal{T} = 0$.

Proposition 11.140 (Relational Bianchi identity)**.** *Let $R^{\rho}{}_{\sigma\mu\nu}[\Gamma]$ be the curvature of the torsionful, metric–compatible $\Gamma = \Gamma[\bar{\Sigma}]$ with torsion $\mathcal{T}^{\rho}{}_{\mu\nu}$. Then the differential Bianchi identity takes the standard torsionful form*

$$\nabla^{(\mathrm{rel})}_{[\lambda} R^{\rho}{}_{|\sigma|\mu\nu]} \;-\; \mathcal{T}^{\eta}{}_{[\lambda\mu}\,R^{\rho}{}_{|\sigma|\nu]\eta} \;\equiv\; 0, \tag{11.262}$$

and the contracted identity implies a generalized divergence relation for an Einstein–type tensor $\mathbb{G}^{\mu}{}_{\nu}[\bar{\Sigma}]$ built from $R^{\rho}{}_{\sigma\mu\nu}[\Gamma]$:

$$\nabla^{(\mathrm{rel})}_{\mu}\,\mathbb{G}^{\mu}{}_{\nu}[\bar{\Sigma}] \;+\; \mathcal{C}_{\nu}[\mathcal{T}] \;\equiv\; 0, \tag{11.263}$$

where $\mathcal{C}_{\nu}[\mathcal{T}]$ is a covariant functional of torsion and curvature that vanishes identically when $\mathcal{T} = 0$. In the torsionless limit, $\mathbb{G}_{\mu\nu} \to \bar{G}_{\mu\nu}[\bar{\Sigma}]$ and (11.263) reduces to $\bar{\nabla}^{\mu}\bar{G}_{\mu\nu} = 0$ (cf. Proposition 11.139).

Proof sketch. Equation (11.262) is the first Bianchi identity for metric–compatible connections with torsion. Contracting on (ρ, λ) and rearranging produces (11.263). When $\mathcal{T} = 0$, $\nabla^{(\mathrm{rel})} \to \bar{\nabla}$ and $\mathcal{C}_\nu[\mathcal{T}] \to 0$, yielding the contracted Bianchi identity for $\bar{G}_{\mu\nu}[\bar{\Sigma}]$. □

Proposition 11.141 (Covariant conservation of the effective stress)**.** *Define the expectation–level field equations on* $(\mathcal{X}_q, \bar{\Sigma})$ *by*

$$\mathbb{G}_{\mu\nu}[\bar{\Sigma}] \;=\; \kappa\, T^{\mathrm{eff}}_{\mu\nu}, \qquad T^{\mathrm{eff}}_{\mu\nu} := \underbrace{\bar{T}^{(\Phi)}_{\mu\nu} + \bar{T}^{(\Theta)}_{\mu\nu}}_{\text{diagonal}} + \underbrace{T^{(\Phi\Theta)}_{\mu\nu}[\bar{\mathbf{G}}_{\Phi\Theta}]}_{\text{off–diagonal (mixing)}} + \underbrace{T^{(\tau)}_{\mu\nu}[\bar{K}^{(\tau)}, \bar{\mathcal{F}}^{(\tau)}]}_{\text{coherence/torsion}}, \tag{11.264}$$

where the mixed term $T^{(\Phi\Theta)}_{\mu\nu}$ *is induced by the off–diagonal correlator blocks of the unified two–point kernel (triadic propagator; cf. Section 10.19.6) and* $T^{(\tau)}_{\mu\nu}$ *collects the chrono–kymon contributions mapped into* $\bar{t}_{[\mu\nu]}$ *(Remark 11.133 and eq. (11.248)). Assume the chrono–kymon equations of motion (Maxwell/Proca–type on* $(\bar{\Sigma}, \bar{\nabla})$*) hold consistently with the constitutive map* $\bar{t}_{[\mu\nu]} = \chi_\tau\, \bar{\mathcal{F}}^{(\tau)}_{\mu\nu}$*. Then*

$$\nabla^{(\mathrm{rel})}_\mu\, T^{\mathrm{eff}\,\mu}{}_\nu \;=\; 0. \tag{11.265}$$

Proof sketch. Taking $\nabla^{(\mathrm{rel})}$ of (11.264) and using (11.263) shows that the torsion functional $\mathcal{C}_\nu[\mathcal{T}]$ generated from the geometric side is canceled by the divergence of $T^{(\tau)}_{\mu\nu}$ once the chrono–kymon equations and $\bar{t}_{[\mu\nu]} = \chi_\tau\, \bar{\mathcal{F}}^{(\tau)}_{\mu\nu}$ are imposed. The residual exchange between $\bar{T}^{(\Phi)}_{\mu\nu}$ and $\bar{T}^{(\Theta)}_{\mu\nu}$ is mediated by the off–diagonal correlator current in $T^{(\Phi\Theta)}_{\mu\nu}$ (relational diffeomorphism Ward identity for the mixed propagator), yielding (11.265). □

Remark 11.142 (Two equivalent placements of torsion effects)**.** Either (i) keep the Levi–Civita divergence $\bar{\nabla}_\mu \bar{G}^\mu{}_\nu = 0$ and absorb all contorsion/coherence terms into $T^{\mathrm{eff}}_{\mu\nu}$, or (ii) work with the natural derivative $\nabla^{(\mathrm{rel})}$ on the unified diagnostic realized reference configuration and use (11.263) together with (11.265). Both formulations are equivalent; the present choice emphasizes diagnostic realized reference configuration–covariance on $(\bar{\Sigma}, \bar{\nabla})$ and aligns with the operator–valued causal response law (eq. (11.256)) and with the scalarised, EP–safe sector used in 11.5.7.

11.7.4 What is Gravity in the IQR Framework?

Definition 11.143 (Gravity as a relational chronogeometric response)**.** In the IQR framework, *gravity* is the *state–relative, operator–valued response* of the unified *chronogeometric tensor* $\hat{\Sigma}_{\mu\nu} := \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ to physical and informational sources on the BRST/GNS physical sector.

(G0) Background (state dependence). The background chronogeometry is the Holo–State expectation

$$\bar{\Sigma}_{\mu\nu}(x) = \Big\langle \overset{\circ}{\mathbf{\Psi}} \Big|\, \hat{\Sigma}_{\mu\nu}(x) \,\Big|\overset{\circ}{\mathbf{\Psi}} \Big\rangle, \qquad \bar{g}^{\mathrm{Lor}}_{\mu\nu} := \bar{g}_{\mu\nu} + \tfrac{1}{2}\big(\bar{t}_{\mu\nu} + \bar{t}_{\nu\mu}\big), \tag{11.266}$$

which fixes the causal structure (cf. Section 5.4 and eq. (11.232)).

(G1) Operator response map (retarded, covariant). Let $\hat{T}^{\mathrm{nonvac}}_{\rho\sigma}$ collect the non–vacuum source (matter and coherence; the vacuum channel is placed on the geometric side in (G2)). Gravity is encoded by the retarded, type-(2,2) *operator response*

$$\hat{G}_{\mu\nu}(x) = \int_{\mathcal{M}} \mathrm{d}\mu_{\bar{\Sigma}}(x')\, \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\mu\nu}{}^{\mu'\nu'} \Big[\, \hat{\mathcal{C}}_{\mu'\nu'}{}^{\rho'\sigma'}(x; x') \;\circ\; \hat{T}^{\mathrm{nonvac}}_{\rho'\sigma'}(x') \,\Big], \tag{11.267}$$

where $\hat{G}_{\mu\nu}$ is the Einstein operator of $\hat{\Sigma}$, $A \circ B := \frac{1}{2}(AB + BA)$ is the Jordan product (ensuring self-adjointness), $\mathrm{d}\mu_{\bar{\Sigma}}(x') := \sqrt{-\det \bar{\Sigma}(x')}\,\mathrm{d}^d x'$ is the invariant measure, and

$$\mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\mu\nu}{}^{\mu'\nu'} := \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\mu}{}^{\mu'}\, \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\nu}{}^{\nu'}$$

is the Levi–Civita parallel transporter (of $\bar{g}^{\mathrm{Lor}}$) acting on each index; it vanishes unless $x' \in J^-_{\bar{g}^{\mathrm{Lor}}}(x)$ (retarded support). The operator–valued coupling kernel is

$$\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') = \mathbb{P}^{(\mathrm{Ein})\alpha\beta}_{\mu\nu}\ \hat{\Delta}^{\mathrm{ret}\,\gamma\delta}_{\alpha\beta}(x,x')\ \mathbb{J}_{\gamma\delta}{}^{\rho\sigma}, \tag{11.268}$$

with $\mathbb{P}^{(\mathrm{Ein})}$ the linearized Einstein (Lichnerowicz–type) map at x, $\hat{\Delta}^{\mathrm{ret}}$ the retarded (TT–projected) propagator of the Gaiamiti fluctuation about $\bar{\Sigma}$, and $\mathbb{J}$ the symmetric matter–to–geometry vertex (species–blind in the minimal case). Thus $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') : \mathrm{Sym}^2_{x'} \to \mathrm{Sym}^2_x$ is a causal bitensor superoperator, mapping the source at x' to the geometric response at x (cf. Definition 11.109 and eqs. (11.213), (11.214) and (11.256)).

(G2) Expectation level, vacuum placement, and scalarisation. Taking the Holo–State expectation $\bar{\mathcal{C}} := \langle \overset{\circ}{\boldsymbol{\Psi}} | \hat{\mathcal{C}} | \overset{\circ}{\boldsymbol{\Psi}} \rangle$, (11.267) becomes the c–number, diagnostic realized reference configuration–covariant bitensor equation

$$\bar{G}_{\mu\nu}(x) \ + \ \Lambda_{\mathrm{eff}}\, \bar{\Sigma}_{\mu\nu}(x) = \int_{\mathcal{M}} \mathrm{d}\mu_{\bar{\Sigma}}(x')\, \mathcal{U}_{\bar{\Sigma}}(x \leftarrow x')_{\mu\nu}{}^{\mu'\nu'}\ \bar{\mathcal{C}}_{\mu'\nu'}{}^{\rho'\sigma'}(x;x')\, \bar{T}^{\mathrm{nonvac}}_{\rho'\sigma'}(x'), \tag{11.269}$$

where the vacuum channel is carried geometrically by $\Lambda_{\mathrm{eff}} = \Lambda + \kappa'\varepsilon_\Lambda$ (Sections 17.1.2 and 17.1.4), so that null contractions of the vacuum term vanish (Lemmas 11.123 and 11.124). Equivalently, $\bar{T}^{\mathrm{total}} = \bar{T}^{\mathrm{nonvac}} - \frac{\Lambda_{\mathrm{eff}}}{\kappa'}\bar{\Sigma}$ moves the same content to the source side.

EP–safe scalarisation. In weak–field, low–coherence domains obeying Section 11.5.7, the expectation kernel is locally isotropic to leading order and reduces to a scalar multiple of the identity on Sym^2:

$$\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x;x') \simeq \kappa_{\mathrm{eff}}(x)\, \Pi_{\mu\nu}{}^{\rho\sigma}\, \delta_{\bar{\Sigma}}(x,x'), \qquad \Pi_{\mu\nu}{}^{\rho\sigma} := \tfrac{1}{2}\left(\delta_\mu{}^\rho \delta_\nu{}^\sigma + \delta_\mu{}^\sigma \delta_\nu{}^\rho\right), \tag{11.270}$$

where $\delta_{\bar{\Sigma}}$ is the covariant Dirac density (normalized with respect to $\mathrm{d}\mu_{\bar{\Sigma}}$) and the parallel transport inside $\mathcal{U}_{\bar{\Sigma}}$ is understood. Then (11.269) collapses to the local GR–like law

$$\bar{G}_{\mu\nu}(x) \ + \ \Lambda_{\mathrm{eff}}\, \bar{\Sigma}_{\mu\nu}(x) = \kappa_{\mathrm{eff}}(x)\, \bar{T}^{\mathrm{nonvac}}_{\mu\nu}(x), \qquad \kappa_{\mathrm{eff}} \to \kappa \ \text{ in the GR limit}, \tag{11.271}$$

consistent with Section 11.5.8 and Proposition 11.115.

Bianchi consistency. Applying $\bar{\nabla}^\mu$ to (11.271) and using $\bar{\nabla}^\mu \bar{G}_{\mu\nu} = 0 = \bar{\nabla}^\mu(\Lambda_{\mathrm{eff}}\bar{\Sigma}_{\mu\nu})$ yields $(\bar{\nabla}^\mu \kappa_{\mathrm{eff}})\, \bar{T}^{\mathrm{nonvac}}_{\mu\nu} + \kappa_{\mathrm{eff}}\, \bar{\nabla}^\mu \bar{T}^{\mathrm{nonvac}}_{\mu\nu} = 0$. Thus GR–like conservation follows when the variation controls of Section 11.5.7 suppress $\bar{\nabla}\kappa_{\mathrm{eff}}$ on the scales probed.

Remark 11.144 (On Λ, ε_Λ, and Λ_{eff} (cosmology sector))**.**

(i) **Definition.** In this chapter, the vacuum channel is carried geometrically by

$$\Lambda_{\mathrm{eff}} = \Lambda + \kappa'\varepsilon_\Lambda,$$

so that the expectation–level equation reads $\bar{G}_{\mu\nu} + \Lambda_{\mathrm{eff}}\bar{\Sigma}_{\mu\nu} = \cdots$ as in eq. (11.269). The *observational* cosmological constant corresponds to Λ_{eff}.

(ii) **Meaning of Λ (diagnostic realized reference configuration/bare cosmological term).** Λ is the chronogeometric (diagnostic realized reference configuration) cosmological constant that appears in the Einstein–Hilbert sector of the typed diagnostic realized reference configuration law. It is set by the diagnostic realized reference configuration/plateau choice and renormalization scheme, independent of the state-dependent residual ε_Λ. It has units L^{-2} and contributes as

$$\text{(geometric side)} \quad \Lambda\,\bar{\Sigma}_{\mu\nu} \quad \Longleftrightarrow \quad \text{(source side)} \quad T^{\mathrm{vac}}_{\mu\nu} = -(\Lambda/\kappa')\,\bar{\Sigma}_{\mu\nu},$$

which are equivalent placements at the expectation level used in this chapter.

(iii) **Diagnostic realized reference configuration vs. observed.** Λ is the diagnostic realized reference configuration (bare) cosmological term; the quantity compared to observations is $\Lambda_{\mathrm{eff}} = \Lambda + \kappa'\varepsilon_\Lambda$. Only if $\varepsilon_\Lambda = 0$ would $\Lambda_{\mathrm{eff}} = \Lambda$.

(iv) **Not the spectral cutoff.** The notation Λ_{eff} here is *not* the Chapter IV effective spectral cutoff $\Lambda^{[\mathrm{obs}]}_{\mathrm{eff}}(x, x'; \varepsilon)$. See the cross-chapter dictionary in Remark 4.575.

(v) **Null-silent vacuum.** The vacuum contribution is null-silent: $k^\mu k^\nu \bar{\Sigma}_{\mu\nu} = 0 \Rightarrow k^\mu k^\nu T^{\mathrm{vac}}_{\mu\nu} = 0$ (see Lemmas 11.123 and 11.124).

(G3) Axioms (covariance, causality, conservation, universality).

1. *Covariance & transport.* $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma}(x; x')$ is a bitensor on $(\mathcal{M}, \bar{\Sigma})$ and the response (11.267) is built with the Levi–Civita transporter $\mathcal{U}_{\bar{\Sigma}}$ and the invariant measure $\mathrm{d}\mu_{\bar{\Sigma}}$, ensuring full diffeomorphism covariance (cf. Definition 11.109).
2. *Causality & microcausality.* $\hat{\Delta}^{\mathrm{ret}}$ has retarded support, hence $\operatorname{supp}\hat{\mathcal{C}}(x; x') \subset J^-_{\bar{g}^{\mathrm{Lor}}}(x)$ (cf. eq. (11.268)), and BRST/GNS commutators vanish at $\bar{g}^{\mathrm{Lor}}$–spacelike separation.
3. *Self–adjointness & symmetry.* The kernel is symmetric on Sym^2: $\hat{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} = \hat{\mathcal{C}}_{\nu\mu}{}^{\rho\sigma} = \hat{\mathcal{C}}_{\mu\nu}{}^{\sigma\rho}$ and pair–Hermitian with respect to the $\bar{\Sigma}$–inner product (cf. §Section 11.5.7). With $A \circ B = \frac{1}{2}(AB+BA)$, $\hat{G}_{\mu\nu}$ is self–adjoint.
4. *Bianchi/consistency.* Since $\bar{\nabla}^\mu \bar{G}_{\mu\nu} = 0$ and $\bar{\nabla}^\mu_x \mathbb{P}^{(\mathrm{Ein})\alpha\beta}_{\mu\nu} = 0$, the expectation–level response with Λ_{eff} in (11.269) is compatible with source conservation modulo controlled exchange with slowly varying κ_{eff} (see Section 11.5.7 and the "Bianchi consistency" paragraph above). The vacuum channel is placed geometrically as $\Lambda_{\mathrm{eff}}\bar{\Sigma}_{\mu\nu}$, whose null contraction vanishes (Lemmas 11.123 and 11.124).
5. *Universality (scalarised limit).* In EP–tested regimes, $\bar{\mathcal{C}}_{\mu\nu}{}^{\rho\sigma} \propto \Pi_{\mu\nu}{}^{\rho\sigma}$ acts species–blind on $\bar{T}^{\mathrm{nonvac}}_{\rho\sigma}$, preserving universality of free fall (cf. Section 11.5.7 and Proposition 11.113).

(G4) Fluctuation channels and mixing. Small fluctuations of the unified tensor split as $\delta\hat{\Sigma}_{\mu\nu} = \hat{h}_{\mu\nu} \oplus \hat{\tau}_{\mu\nu}$ with $\hat{h}_{\mu\nu} := \delta\hat{g}_{\mu\nu}$ (metric channel) and $\hat{\tau}_{\mu\nu} := \delta\hat{t}_{\mu\nu}$ (temporal/coherence channel). The coherence channel is TT–silent, $\mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}[\hat{\tau}_{\mu\nu}] = 0$ (cf. Lemma 11.125 and Remark 11.133), and mixing with $\hat{h}_{\mu\nu}$ is captured by the off–diagonal two–point functions in the retarded kernel (11.268). In the spectral/GR limit this mixing is suppressed and $\hat{\mathcal{C}} \to \kappa\,\Pi\,\delta_{\bar{\Sigma}}$ (Section 11.5.8 and Proposition 11.115).

(G5) Perturbative state. Propagators and loop corrections are computed in the BRST/GNS physical sector using the interacting GNS vacuum associated with the Holo–State, denoted $|\Omega_{\Psi^\circ}\rangle$.

Remark 11.145 (What "push forward" means here)**.** Let G_{hh} be any linear kernel/operator acting on symmetric rank–2 fields (the full metric channel) and let $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ be the rig–compatible TT projector (cf. Definition 10.3). Denote by

$$i_{\mathrm{TT}}:\ \Gamma(S^2_{\mathrm{TT}}T^*)\hookrightarrow\Gamma(S^2T^*),\qquad P_{\mathrm{TT}}:=\Pi_{\bar\Sigma}^{[\mathrm{TT}]}:\ \Gamma(S^2T^*)\to\Gamma(S^2_{\mathrm{TT}}T^*)$$

the inclusion and projection (with $P_{\mathrm{TT}}\circ i_{\mathrm{TT}}=\mathrm{id}$ on the TT carrier). *Pushing forward* G_{hh} to the TT sector means taking the operator it *induces* on the TT subbundle:

$$G_{hh}^{[\mathrm{TT}]}\ :=\ P_{\mathrm{TT}}\circ G_{hh}\circ i_{\mathrm{TT}}\ \equiv\ \Pi_{\bar\Sigma}^{[\mathrm{TT}]}\ \circ\ G_{hh}\ \circ\ \Pi_{\bar\Sigma}^{[\mathrm{TT}]}. \tag{11.272}$$

In index (bitensor) form this is the "sandwich"

$$\big(G_{hh}^{[\mathrm{TT}]}\big)_{\mu\nu}{}^{\rho\sigma}(x,y)=\Pi_{\bar\Sigma\,\mu\nu}^{[\mathrm{TT}]\,\alpha\beta}(x)\,G_{hh\,\alpha\beta}{}^{\gamma\delta}(x,y)\,\Pi_{\bar\Sigma\,\gamma\delta}^{[\mathrm{TT}]\,\rho\sigma}(y).$$

Thus one obtains the TT graviton propagator/Green operator used in Lemma 11.146, Definition 10.182, and eq. (10.112). Heuristically, this is the "$4\to2$" reduction: from the full symmetric tensor fiber (10 components in $d{=}4$) down to the *two* physical TT helicities per momentum.

Remarks. (i) The same push–forward applies triad–resolved, because the weave triad projectors commute with typing: $G_{hh}^{[\mathrm{TT}],(a)}=\mathsf{P}^{(2)}_{(a)}\,\Pi_{\bar\Sigma}^{[\mathrm{TT}]}G_{hh}\Pi_{\bar\Sigma}^{[\mathrm{TT}]}\,\mathsf{P}^{(2)}_{(a)}$ (cf. Definition 10.2). (ii) Do not confuse this with the differential–geometric pushforward $f_*:TM\to TN$ of a map f: here "push forward" is the induced map on a *subspace* produced by inclusion–projection. (iii) On the certified plateau, properties like self–adjointness, positivity, and causal support that hold for G_{hh} descend to $G_{hh}^{[\mathrm{TT}]}$ by (11.272), and the resulting TT dynamics coincide with those built from the typed Peierls bracket (eq. (11.25)) and the canonical ETCR (Definition 11.8 and Proposition 11.4).

Lemma 11.146 (Kinematic push–forward of the fourfold inter–modal correlator)**.** *Let* $\mathbf{G}^{(2)}_{\Sigma;AB}(x,x')$ *denote the fourfold inter–modal correlator from Definition 6.4 and Section 6.1.1, with* $A,B\in\{0,1,p,s\}$ *(and implicit* $\mathbf{\Phi}/\mathbf{\Theta}$ *blocks as in Ch. Chapter 6). Let* $(\mathcal{S}_A)_{\mu\nu}$ *and* $(\mathcal{T}_A)_{\mu\nu}$ *be the constitutive maps that produce the rank–2 kinematic fields (metric channel* h *and temporal/coherence channel* τ*), with* $\mathcal{P}^{(2)}_{\bar g^{\mathrm{Lor}}}[\hat\tau]=0$ *(cf. Sections 10.3, 10.4 and 10.18.7). Then the* (h,τ) *two–point* bitensor *kernels are the push–forwards*

$$G_{hh\,\mu\nu}{}^{\rho\sigma}(x,x')=(\mathcal{S}_A)_{\mu\nu}(x)\ \mathbf{G}^{(2)}_{\Sigma;AB}(x,x')\ (\mathcal{S}_B^\dagger)^{\rho\sigma}(x'), \tag{11.273}$$

$$G_{h\tau\,\mu\nu}{}^{\rho\sigma}(x,x')=(\mathcal{S}_A)_{\mu\nu}(x)\ \mathbf{G}^{(2)}_{\Sigma;AB}(x,x')\ (\mathcal{T}_B^\dagger)^{\rho\sigma}(x'), \tag{11.274}$$

$$G_{\tau h\,\mu\nu}{}^{\rho\sigma}(x,x')=(\mathcal{T}_A)_{\mu\nu}(x)\ \mathbf{G}^{(2)}_{\Sigma;AB}(x,x')\ (\mathcal{S}_B^\dagger)^{\rho\sigma}(x'), \tag{11.275}$$

$$G_{\tau\tau\,\mu\nu}{}^{\rho\sigma}(x,x')=(\mathcal{T}_A)_{\mu\nu}(x)\ \mathbf{G}^{(2)}_{\Sigma;AB}(x,x')\ (\mathcal{T}_B^\dagger)^{\rho\sigma}(x'), \tag{11.276}$$

with modal indices A, B summed. Here $(\cdot)^\dagger$ is the formal adjoint with respect to the $\bar{g}^{\mathrm{Lor}}$–induced inner product on Sym^2 *and the invariant measure* $\mathrm{d}\mu_{\bar{\Sigma}}$*; it* includes *Levi–Civita parallel transport from x' to x, so the right index pair $(\rho\sigma)$ is compared at x before contraction. Consequently, the 2×2 kinematic kernel $\left(\begin{smallmatrix} G_{hh} & G_{h\tau} \\ G_{\tau h} & G_{\tau\tau}\end{smallmatrix}\right)$ used in Definition 10.182 and eq. (10.112) is the* kinematic reduction *(push–forward) of the* modal *fourfold object $\mathbf{G}^{(2)}_{\Sigma;AB}$ defined in Section 6.1.1.*

Proof sketch. Collect the constitutive maps into rectangular operators $\mathbb{S} := (\mathcal{S}_A)$ and $\mathbb{T} := (\mathcal{T}_A)$ mapping the modal sector to Sym^2. Then, by linearity of the push–forward on two–point functions,

$$\mathbf{G}_{(h,\tau)} = \begin{pmatrix} \mathbb{S} \\ \mathbb{T} \end{pmatrix} \mathbf{G}^{(2)}_{\Sigma} \begin{pmatrix} \mathbb{S}^\dagger & \mathbb{T}^\dagger \end{pmatrix},$$

with $\dagger$ the formal adjoint relative to the $\bar{g}^{\mathrm{Lor}}$ inner product and Levi–Civita transport from x' to x. Expanding the block product yields (11.273)–(11.276). Retarded/Hadamard/advanced variants follow componentwise, and causal support is preserved under push–forward. □

Remark 11.147 (Matrix shorthand, TT isolation, and projections)**.** Let $\mathbb{P}_{\mathrm{TT}} \equiv \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}$ denote the transverse–traceless (TT) projector on Sym^2 with respect to $\bar{g}^{\mathrm{Lor}}$. The absence of spin–2 content in the τ channel implies

$$\mathbb{P}_{\mathrm{TT}} \circ \mathbb{T} \equiv 0, \qquad \mathbb{T}^\dagger \circ \mathbb{P}_{\mathrm{TT}} \equiv 0,$$

hence the projected kernels satisfy

$$\mathbb{P}_{\mathrm{TT}} \circ G_{\tau\tau} \circ \mathbb{P}_{\mathrm{TT}} = 0, \qquad \mathbb{P}_{\mathrm{TT}} \circ G_{h\tau} \circ \mathbb{P}_{\mathrm{TT}} = 0, \qquad \mathbb{P}_{\mathrm{TT}} \circ G_{\tau h} \circ \mathbb{P}_{\mathrm{TT}} = 0. \tag{11.277}$$

Therefore no *new* TT basis directions arise from the τ sector; the TT radiative content is governed entirely by the hh block, through $\mathbb{P}_{\mathrm{TT}} \circ G_{hh} \circ \mathbb{P}_{\mathrm{TT}}$.

In matrix shorthand one has

$$\mathbf{G}_{(h,\tau)} = \begin{pmatrix} \mathbb{S} \\ \mathbb{T} \end{pmatrix} \mathbf{G}^{(2)}_{\Sigma} \begin{pmatrix} \mathbb{S}^\dagger & \mathbb{T}^\dagger \end{pmatrix}, \qquad \mathbb{P}_{\mathrm{TT}}\, G_{\tau\tau}\, \mathbb{P}_{\mathrm{TT}} = 0,$$

with blocks given in Lemma 11.146. These 2×2 kernels are precisely the inputs that feed the coupling kernel $\hat{\mathcal{C}}$ (cf. Definition 11.109 and eq. (11.268)) and the E(2) polarization analysis (cf. Remarks 11.150 and 11.151).

Remark 11.148 (Change of modal basis)**.** Consider the (h, τ) doublet as a column vector $\left(\hat{h}, \hat{\tau}\right)^\top$. Under any admissible modal redefinition

$$\begin{pmatrix} \hat{h} \\ \hat{\tau} \end{pmatrix} \longmapsto U \begin{pmatrix} \hat{h} \\ \hat{\tau} \end{pmatrix}, \qquad U \in \mathrm{GL}(2) \text{ (unitary on the BRST/GNS physical sector)},$$

the data transform as

$$\mathbf{G}^{(2)}_{\Sigma} \;\mapsto\; U\, \mathbf{G}^{(2)}_{\Sigma}\, U^\dagger, \qquad \mathbb{S} \;\mapsto\; \mathbb{S}\, U^\dagger, \qquad \mathbb{T} \;\mapsto\; \mathbb{T}\, U^\dagger.$$

It follows that the assembled two–channel kernel

$$\mathbf{G}_{(h,\tau)} = \begin{pmatrix} \mathbb{S} \\ \mathbb{T} \end{pmatrix} \mathbf{G}_{\Sigma}^{(2)} \begin{pmatrix} \mathbb{S}^{\dagger} & \mathbb{T}^{\dagger} \end{pmatrix}$$

is invariant, and so are its TT/non–TT projections—particularly $\mathbb{P}_{\mathrm{TT}} \circ G_{hh} \circ \mathbb{P}_{\mathrm{TT}}$ and the null relations in (11.277). Hence the physical TT content and the mixing pattern are basis–independent.

Remark 11.149 (Change of modal basis: general $GL(n)$ form)**.** Let the typed/modal stack be the column vector of operators

$$\widehat{\mathbf{m}} := \big(\hat{m}_1, \dots, \hat{m}_n\big)^{\top},$$

with two–point (bitensor) kernel $\mathbf{G}_{\Sigma}^{(2)}$ on this stack. For any invertible modal redefinition

$$\widehat{\mathbf{m}} \;\longmapsto\; U\,\widehat{\mathbf{m}}, \qquad U \in GL(n) \;\; \text{(unitary on the BRST/GNS physical sector)},$$

the data transform by

$$\mathbf{G}_{\Sigma}^{(2)} \;\mapsto\; U\,\mathbf{G}_{\Sigma}^{(2)}\,U^{\dagger}, \qquad \mathbb{X} \;\mapsto\; \mathbb{X}\,U^{\dagger} \quad \text{for every row "selector" } \mathbb{X} \in \mathbb{C}^{1\times n} \text{ (e.g. } \mathbb{S}, \mathbb{T}).$$

Given any finite family of such selectors $\{\mathbb{X}_{\alpha}\}_{\alpha=1}^{r}$, form the assembled $r\times r$ kernel

$$\mathbf{G}_{(\mathbb{X})} \;:=\; \begin{pmatrix} \mathbb{X}_1 \\ \vdots \\ \mathbb{X}_r \end{pmatrix} \mathbf{G}_{\Sigma}^{(2)} \begin{pmatrix} \mathbb{X}_1^{\dagger} & \cdots & \mathbb{X}_r^{\dagger} \end{pmatrix}. \tag{11.278}$$

Then $\mathbf{G}_{(\mathbb{X})}$ is *basis–independent*: under $U \in GL(n)$ the factors on the left/right of $\mathbf{G}_{\Sigma}^{(2)}$ pick up $U^{\dagger}$ and cancel the U, $U^{\dagger}$ inside, so $\mathbf{G}_{(\mathbb{X})}$ is unchanged. In particular, for the (h,τ) selectors $\mathbb{S}, \mathbb{T}$ one recovers the invariance of

$$\mathbf{G}_{(h,\tau)} = \begin{pmatrix} \mathbb{S} \\ \mathbb{T} \end{pmatrix} \mathbf{G}_{\Sigma}^{(2)} \begin{pmatrix} \mathbb{S}^{\dagger} & \mathbb{T}^{\dagger} \end{pmatrix}.$$

Moreover, all TT/non–TT projections of the assembled blocks are invariant—for example,

$$G_{hh}^{[\mathrm{TT}]} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \circ G_{hh} \circ \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \quad \text{(cf. } \textit{Definition } 10.3, \textit{Lemma } 11.146, \textit{and eq. } (10.112))$$

is independent of the choice of modal basis. Hence the physical TT content and the mixing pattern are basis–independent within the entire admissible $GL(n)$ class.

Remark 11.150 (Triadic origin of extra GW polarizations)**.** In the IQR framework the observable metric response is sourced by three *flavours* of the graviton channel, $a \in \{\mathrm{spec}, \mathrm{vac}, \mathrm{corr}\}$ (the triadic split), and is obtained from the fourfold inter–modal correlator by the constitutive push–forward (Chs. Chapters 6 and 11, Section 6.1.1, Lemma 11.146, and Definition 11.143). Decomposing the observable perturbation in the E(2) polarization basis (Remark 11.151),

$$h_{ij}^{\mathrm{obs}}(x) = \sum_{A\in\{+,\times,x,y,b,L\}} h_A(x)\, e_{ij}^{A},$$

one finds:

1. **Tensor $(+,\times)$: spectral flavour only.** The TT amplitudes are governed solely by the spectral channel, because the τ-channel has no spin-2 content and the TT projector annihilates $\mathbb{T}$ (Lemma 11.146 and Remark 11.147):

$$(h_+, h_\times) \;\propto\; \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}\Big[(\mathcal{S}_A)\,\mathbf{G}^{(2,\mathrm{spec})}_{\Sigma;AB}\,(\mathcal{S}^\dagger_B)\Big]\,\mathcal{J}_h,$$

reproducing GR in the EP-safe scalarised limit (Section 11.5.7 and Proposition 11.113).

2. **Vector/scalar (x, y, b, L): triadic mixing.** Any non–TT amplitude is an *induced response* from off–diagonal mixing between the metric and temporal/coherence channels, sourced by the *vacuum* and/or *correlational* flavours:

$$h_A \;\propto\; e^{ij}_A\,\mathbb{P}_{\mathrm{nonTT}} \sum_{a\in\{\mathrm{vac,corr}\}} \Big[(\mathcal{S}_A)\,\mathbf{G}^{(2,a)}_{\Sigma;AB}\,(\mathcal{T}^\dagger_B)\Big]\,\mathcal{J}^{(a)}_\tau, \qquad \mathbb{P}_{\mathrm{nonTT}} := \mathbf{1} - \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}, \tag{11.279}$$

with $\mathcal{J}_h, \mathcal{J}_\tau$ the channel sources entering the response kernel (Definitions 11.109 and 11.143 and eq. (11.268)). Thus detections of x, y, b, L power in interferometer networks, PTA cross–correlations, or SGWB angular spectra would diagnose nonzero triadic weights together with nonvanishing off–diagonal blocks $G_{h\tau}, G_{\tau h}$ inherited from $\mathbf{G}^{(2,\mathrm{vac/corr})}_\Sigma$.

3. **Consistency with EP/PPN bounds.** In EP–tested (scalarised) domains the variation/aniso controls of Section 11.5.7 ensure $\|\mathbb{P}_{\mathrm{nonTT}} \circ G_{h\tau}\| \ll \|G^{\mathrm{TT}}_{hh}\|$, so $|h_{x,y,b,L}| \ll |h_{+,\times}|$; larger admixtures may occur in high–coherence or strong–field regimes, without introducing *extra* TT polarizations (cf. Remarks 11.147 and 11.151).

In short: *any observed extra GW polarizations in IQR trace back to triadic flavour content and metric–coherence mixing*, not to additional massless spin–2 degrees of freedom. The spectral flavour yields the GR tensor pair, while the vacuum/correlational flavours feed vector/scalar *responses* through the off–diagonal push–forward (11.279).

Remark 11.151 (E(2) polarization content and its realization in IQR)**.** In a local metric theory, plane–wave gravitational disturbances admit up to *six* independent polarizations (the E(2) classification): two tensor $(+,\times)$, two vector (x, y), and two scalar (breathing b and longitudinal L). In the IQR framework (Sections 4.8 and 11.5 and Chapters 6 and 11), the *metric response* can likewise exhibit up to six *observable* polarization templates. The *tensor* pair arises from the spectral channel (TT graviton), whereas possible *vector/scalar* components originate as *triadic admixtures* via the mixed propagator blocks $G_{h\tau}, G_{\tau h}$ (Remark Remark 11.150, Lemma 11.146). Throughout, the E(2) basis is understood in the local geometric–optics limit of $\bar{g}^{\mathrm{Lor}}$.

Local polarization basis and normalization. Let $\hat{n}$ be the propagation direction and $\{e_1, e_2, \hat{n}\}$ an orthonormal triad in a local Lorentz frame adapted to $\bar{g}^{\mathrm{Lor}}$. Define the six standard polarization tensors on the screen space,

$$\begin{aligned}
e^+_{ij} &:= e_{1i}e_{1j} - e_{2i}e_{2j}, & e^\times_{ij} &:= e_{1i}e_{2j} + e_{2i}e_{1j},\\
e^x_{ij} &:= e_{1i}\hat{n}_j + \hat{n}_i e_{1j}, & e^y_{ij} &:= e_{2i}\hat{n}_j + \hat{n}_i e_{2j},\\
e^b_{ij} &:= e_{1i}e_{1j} + e_{2i}e_{2j}, & e^L_{ij} &:= \hat{n}_i\hat{n}_j,
\end{aligned}$$

normalized so that $e^A_{ij} e^{B\,ij} = 2\,\delta^{AB}$. Any observable metric perturbation decomposes as

$$h^{\rm obs}_{ij}(x) = \sum_{A\in\{+,\times,x,y,b,L\}} h_A(x)\, e^A_{ij}, \qquad h_A := \tfrac{1}{2}\, h^{\rm obs}_{ij}\, e^{A\,ij}. \tag{11.280}$$

IQR realization (origin of each mode).

- *Tensor (two helicities).* The radiative TT modes are

$$\hat h^{[\mathrm{TT}],(\mathrm{spec})}_{\mu\nu} := \left(\mathsf{P}^{(2)}_{\rm spec}\, \Pi^{[\mathrm{TT}]}_{\bar\Sigma} \hat h\right)_{\mu\nu},$$

  with $\Pi^{[\mathrm{TT}]}_{\bar\Sigma}$ the rig–compatible TT projector (Definition 10.3) and $\mathsf{P}^{(2)}_{\rm spec}$ the spectral idempotent inside the TT block (provenance split; Definition 10.2). In the scalarized/weak-field limit (Section 11.5.7 and Proposition 11.115) these reduce to the GR tensor pair $(+,\times)$ in the standard TT polarization basis (cf. eq. (11.100)).

- *Vector/Scalar* (x,y,b,L). The coherence channel satisfies $\mathcal{P}^{(2)}_{\bar g^{\rm Lor}}[\hat\tau_{\mu\nu}] = 0$ (Section 10.18.7) but induces *non–TT metric responses* through off–diagonal mixing:

$$h^{\rm obs}_{ij} = \left(\mathcal{P}^{(2)}_{\bar g^{\rm Lor}} + \mathbb{P}_{\rm nonTT} \circ G_{h\tau} \circ \mathbb{J}_{\tau\to h}\right)[\text{sources}]_{ij}\,, \qquad \mathbb{P}_{\rm nonTT} := \mathbf{1} - \mathcal{P}^{(2)}_{\bar g^{\rm Lor}},$$

  with sources and vertex as in (11.267)–(11.268). Projecting (11.280) with $e^{x,y,b,L}$ yields the amplitudes $h_{x,y,b,L}$. Their magnitudes are controlled by the triadic weights and the state (Remark Remark 11.150); in EP–tested, scalarised domains the bounds of Section 11.5.7 ensure $|h_{x,y,b,L}| \ll |h_{+,\times}|$.

Summary. Chs. Chapters 4, 6 and 11 and Section 11.5 permit up to six *observable* polarization templates at the level of the metric response. The *radiative* massless content remains the standard TT pair from the spectral flavour; any *additional* vector/scalar responses arise via triadic mixing and are state- and regime-dependent, without introducing extra TT polarizations.

Remark 11.152 (What $E(2)$ means in this chapter)**.** Fix a future–pointing null direction k^μ (e.g. the propagation direction of a TT graviton mode) and choose a null partner ℓ^μ with $k\cdot\ell = -1$. The associated *screen* is the $(d-2)$–dimensional space orthogonal to $\{k,\ell\}$ with metric $q_{\mu\nu} = \bar g^{\rm Lor}_{\mu\nu} + k_\mu\ell_\nu + \ell_\mu k_\nu$ (cf. Remark 11.127). In $d=4$ the screen is 2–dimensional, and

$$E(2) \;:=\; \mathrm{Isom}(\mathbb{R}^2) \;\simeq\; \mathbb{R}^2 \rtimes SO(2)$$

is the Euclidean group of the screen: $SO(2)$ rotations about k and the (screen) translations. Equivalently, $E(2)$ is the *little group* of a null vector: the subgroup of the Lorentz group that leaves k^μ invariant. In our $\bar\Sigma$–based notation this is the symmetry that acts on the *screen* indices of polarization objects at fixed k.

Why it matters for TT graviton modes.

- The $SO(2)$ *rotation* part of $E(2)$ acts on the TT polarization basis $e^{(a,\lambda)}_{\mu\nu}(k)$ (eq. (11.100)) as a helicity rotation: the two TT modes furnish the $\lambda = \pm 2$ representation, i.e. under a screen rotation by angle θ, $e^{(\pm)} \mapsto e^{(\pm)} e^{\pm 2i\theta}$. This is the precise meaning of the "two tensor helicities."
- The $\mathbb{R}^2$ *translation* part (null rotations) corresponds to gauge transformations that shift non-TT (pure-gauge/longitudinal) pieces. In the *TT-projected* theory we work with $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \hat{h}_{\mu\nu}$ (Definition 10.3), so these translations act trivially on physical TT data.

Relation to our typed/triad structure. On the certified plateau, the radiative spin-2 content lives entirely in the TT carrier with helicities ± 2 (the $SO(2)$ sector above); vector/scalar screen representations do not appear in the gravitational wave channel because the τ–kairos sector is TT–null ($\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \hat{\tau}_{\mu\nu} = 0$; cf. eq. (10.139)), and the weave triad bookkeeping (Definition 10.2) is compatible with the same projector. Hence, within Chapter 12 the shorthand "$E(2)$" simply signals the screen–space symmetry behind helicity and polarization statements for TT modes.

Proposition 11.153 (E(2) completeness of the metric response in IQR)**.** *Fix a local Lorentz frame of $\bar{g}^{\mathrm{Lor}}$ and a plane–wave direction $\hat{n}$. Let $\{e_1, e_2, \hat{n}\}$ be an orthonormal triad and let $\{e^A_{ij}\}_{A\in\{+,\times,x,y,b,L\}}$ be the standard E(2) polarization tensors on the screen space (cf. Remark Remark 11.151). In the triadic response formalism (Section 10.17.6, Definition 10.182, and eq. (10.112)), the observable metric perturbation admits the full six–mode decomposition*

$$h^{\mathrm{obs}}_{ij}(x) = \sum_{A\in\{+,\times,x,y,b,L\}} h_A(x)\, e^A_{ij}, \qquad h_A := \tfrac{1}{2}\, h^{\mathrm{obs}}_{ij} e^{A\,ij}. \tag{11.281}$$

Moreover, writing $\mathbb{P}_{\mathrm{nonTT}} := \mathbf{1} - \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}$ and letting $\star$ denote the retarded convolution with Levi–Civita transport and invariant measure (eqs. (11.267) and (11.268)), one has

$$h_{+,\times} \;=\; \left(\mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}\, G^{\mathrm{ret}}_{hh}\right) \star \mathcal{J}_h, \qquad \textit{(spectral TT graviton)}, \tag{11.282}$$

$$(h_x, h_y, h_b, h_L) \;=\; \Big[\; \mathbb{P}_{\mathrm{nonTT}} \circ \left(G^{\mathrm{ret}}_{h\tau} \star \mathcal{J}_\tau \;+\; G^{\mathrm{ret}}_{hh} \star \mathcal{J}^{\mathrm{nonTT}}_h\right) \Big]_{\textit{projected}}, \tag{11.283}$$

where $\mathcal{J}_h$ and $\mathcal{J}_\tau$ are the metric and coherence source currents entering the operator coupling kernel $\hat{\mathcal{C}}$ (Definition 11.109 and eq. (11.268)), and $\mathcal{J}^{\mathrm{nonTT}}_h := \mathbb{P}_{\mathrm{nonTT}} \mathcal{J}_h$. "Projected" means contraction with $e^{A\,ij}$ as in (11.281).

Consequently:

- *The* radiative *massless spin–2 content is the usual TT pair from the spectral channel ($\mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}[\hat{\tau}] = 0$, Section 10.18.7).*
- *The* vector/scalar *metric responses arise as* triadic admixtures*. They are induced by the off-diagonal blocks $G_{h\tau}$ and $G_{\tau h}$ (push–forward of the fourfold correlator; Lemma Lemma 11.146), together with any non-TT part of $\mathcal{J}_h$.*

In EP–tested, scalarised domains (Section 11.5.7) one has $|h_{x,y,b,L}| \ll |h_{+,\times}|$; in high–coherence or strong–field regimes larger admixtures are possible without introducing extra TT polarizations.

Remark 11.154 (Phenomenology windows vs. weak-field expectations)**.** Within IQR none of the following effects is a fundamental no–go; each is *permitted* in suitable, state–dependent regimes governed by the operator kernel $\bar{\mathcal{C}}$ and the triadic weights (Definition 11.109 and Section 10.17.6). In EP–tested (scalarised) domains (Section 11.5.7) they are tightly bounded.

1. **Tensor speed deviations (non-luminal c_T at finite frequency).** The spectral TT graviton's dispersion follows from the pole of the TT block of the push–forward kernel (Lemma 11.146):

$$\det D^{\mathrm{TT}}(\omega, \mathbf{k}; \overset{\circ}{\mathbf{\Psi}}) = 0, \qquad G^{\mathrm{TT}}_{hh}(\omega, \mathbf{k}) = \left[D^{\mathrm{TT}}\right]^{-1}.$$

   Retarded support of $\hat{\mathcal{C}}$ enforces causality (Definition 11.109), so the *front* velocity is luminal with respect to $\bar{g}^{\mathrm{Lor}}$. The *phase/group* speed $c_T(\omega, \mathbf{k})$ can nevertheless acquire state/triadic self-energy dressings $\delta c_T^2(\overset{\circ}{\mathbf{\Psi}})$ through $\bar{\mathcal{C}}$. In scalarised regions $\delta c_T^2 = \mathcal{O}(\varepsilon_{\mathrm{aniso}} + \varepsilon_{\mathrm{grad}}) \ll 1$; in high-coherence or strong-field regimes larger (still causal) deviations are allowed.

2. **Vector/scalar GW power at detectors ("extra polarizations").** E(2) x, y, b, L components are *non-TT metric responses* induced by triadic mixing:

$$h_A \;\propto\; e_A^{ij}\, \mathbb{P}_{\mathrm{nonTT}}\Big[(\mathcal{S}_A)\, \mathbf{G}^{(2)}_{\Sigma}\, (\mathcal{T}_B^{\dagger})\Big]\mathcal{J}_\tau, \qquad A \in \{x, y, b, L\},$$

   i.e. via $G_{h\tau}, G_{\tau h}$ obtained by push–forward of the fourfold correlator (Section 6.1.1, Lemma 11.146, and Remark 11.151). In EP–tested regimes these amplitudes are suppressed by the scalarisation/variation bounds (Section 11.5.7); outside them (early universe, near compact objects) they can be appreciable.

3. **Multiple TT flavours (same two tensor basis states).** In $D = 4$ there are only two TT basis polarizations, but IQR allows distinct TT *flavours*—spectral, vacuum-dressed, correlational—each contributing to the *same* TT basis with different dispersion/damping,

$$G^{\mathrm{TT}}_{hh} = \sum_{a \in \{\mathrm{spec,vac,corr}\}} \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}} \circ \Big[(\mathcal{S})\, \mathbf{G}^{(2,a)}_{\Sigma}\, (\mathcal{S}^{\dagger})\Big] \circ \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}.$$

   Observable signatures include mild dispersion, birefringence, or phase beating of $(+, \times)$—not additional independent TT directions, consistent with $\mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}}[\hat{\tau}] = 0$ (no spin–2 in the τ channel; Section 10.18.7).

Bottom line. GR-like behavior (luminal front velocity, negligible non-TT power) is the *scalarised, weak-field expectation.* Departures are *allowed* and are controlled by the state-dependent triadic dressings and the operator kernel $\bar{\mathcal{C}}$, consistent with covariance, causality, and the relational NEC (Sections 11.5.7 and 11.6 and Definition 11.109).

Radiative content. The *graviton* is the TT (spin–2) projection of the metric channel with respect to the unified background:

$$\hat{h}^{[\mathrm{TT}]}_{\mu\nu} \;:=\; \left(\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{h}\right)_{\mu\nu} \qquad (\text{cf. } \textit{Definition } 10.3),$$

and its dynamics are governed by the TT–sandwiched (pushed–forward) kernel

$$G^{[\mathrm{TT}]}_{hh} \;:=\; \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \;\circ\; G_{hh} \;\circ\; \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \tag{11.284}$$

See Lemma 11.146, Definition 10.182, and eq. (10.112); cf. [415, 502].

The *tau–kairos* sector is strictly non–TT at linear order,

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0 \quad (\text{Sections } 10.3,\ 10.4 \text{ and } 10.18.7),$$

so any *observed* vector/scalar GW responses arise only via triadic mixing in the off–diagonal blocks $G_{h\tau}$, $G_{\tau h}$ (Remark Remark 11.150).

Origin and symmetry. The unique long–range, massless radiative mode is the spin–2 graviton, identified as the geometric Goldstone excitation of the Gaiamiti sector's vacuum (Section 10.17.9); massive geometric scalars (apeiron) are radial (non–Goldstone) modes (Section 10.16). By contrast, the temporal/coherence channel $\hat{\tau}_{\mu\nu}$ is populated by *Tantrakyma* fluctuations via the constitutive map

$$\hat{t}_{[\mu\nu]} = \chi_\tau\,\hat{\mathcal{F}}^{(\tau)}_{\mu\nu}, \qquad \hat{\mathcal{F}}^{(\tau)}_{\mu\nu} := 2\,\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]},$$

with spin–1 *Chrono–Kymon* potential $\hat{K}^{(\tau)}_\mu$ (often $\hat{A}_\mu$) (Sections 10.7 and 10.17.9). This sector is non-radiative in the TT sense (Sections 10.3 and 10.4) but can seed non-TT *metric responses* through $G_{h\tau}, G_{\tau h}$.

Triadic factorization of sources. Curvature fluctuations admit a *triadic* resolution into correlational, vacuum, and spectral flavours:

$$\mathbf{G}^{(2)}_\Sigma = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \mathbf{G}^{(2,a)}_\Sigma, \qquad \hat{h}_{\mu\nu} = \sum_a \hat{h}^{(a)}_{\mu\nu},$$

separating entanglement–induced, vacuum–manifold, and energy–momentum–induced contributions (Sections 10.17.5 and 10.17.6). TT projection w.r.t. $\bar{g}^{\mathrm{Lor}}$ isolates the radiative content in each flavour while preserving the off–diagonal (h,τ) dressings at the response level (Definition 10.182 and Lemma 11.146). In particular, the observable TT block is

$$G^{\mathrm{TT}}_{hh} = \sum_a \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}} \circ \Big[(\mathcal{S})\,\mathbf{G}^{(2,a)}_\Sigma\,(\mathcal{S}^\dagger)\Big] \circ \mathcal{P}^{(2)}_{\bar{g}^{\mathrm{Lor}}},$$

and possible vector/scalar responses trace to $\mathbb{P}_{\mathrm{nonTT}} \circ G_{h\tau}$ (Remarks 11.150, 11.151).

Matter coupling and temporal torsion. The *Tantrakyma* field $\hat{\mathbf{\Theta}}$ furnishes the matter/coherence sector. Its fluctuations generate (i) *masses* via the operator mass matrix $\mathcal{M}_\Theta$ and projected propagators Δ_p (Sections 10.18.5 and 10.18.6); and (ii) a *temporal imprint* via

$$\hat{t}_{[\mu\nu]} = \chi_\tau \, \hat{\mathcal{F}}^{(\tau)}_{\mu\nu}, \qquad \hat{\mathcal{F}}^{(\tau)}_{\mu\nu} = 2\,\bar{\nabla}_{[\mu}\hat{K}^{(\tau)}_{\nu]},$$

sourced by the spin–1 Chrono–Kymon mode $\hat{K}^{(\tau)}_\mu = \delta\hat{\mathbf{\Theta}}^{(1)}_\mu$ (Sections 10.7 and 10.17.9). Thus, gravity in IQR is the joint, channel–resolved response of $\bar{\Sigma}_{\mu\nu}$ to energetic and coherence–informational sources.

Operational content (summary).

- *Causality:* propagation is governed by the $\bar{g}^{\mathrm{Lor}}$ light cone (equivalently, the $\bar{\Sigma}$ cone; Lemma 11.123) (Section 5.4.5); response kernels are retarded (Definition 11.109).
- *Radiation:* the TT block G^{TT}_{hh} carries exactly two tensor polarizations; any non-TT detector responses arise only via triadic mixing (Remark 11.150) (Sections 10.3, 10.4 and 10.17.8).
- *Background dependence:* amplitudes, phases, and effective ranges acquire triadic, state–dependent dressings through $\mathbf{G}^{(2,a)}_\Sigma$ and the Tantrakyma blocks $\mathbf{\Delta}^{(a)}_\Theta$ (Sections 10.17.6 and 10.18.7).

Bridge to Section 11.9. With gravity defined as a chronogeometric response, the operative regimes are controlled by the relative magnitude and anisotropy of $\bar{t}_{\mu\nu}$ versus $\bar{g}_{\mu\nu}$, the coherence scales entering $\mathcal{M}_\Theta$, and the triadic weights; these parameters organize the phenomenology in Section 11.9.

The world isn't stuff moving on a fixed stage. In this framework, the "stage" itself—the network of distances, clock rates, and cause-and-effect—is a fabric woven from relationships among everything that exists. We summarize that fabric by a single field, the **chronogeometric field** $\bar{\Sigma}_{\mu\nu}$. At the everyday, averaged (expectation) level it splits into a familiar symmetric metric $\bar{g}_{\mu\nu}$ that sets lengths and times, plus a tiny antisymmetric "coherence" piece $\bar{t}_{[\mu\nu]}$ that tracks subtle quantum-relational structure.

So what is gravity? It's how that fabric *responds* when the world is active. Put matter or light somewhere, build correlations, excite quantum fields—anything that counts as "total source"—and the fabric reshapes. Clocks tick a bit differently, straight paths curve, and light rays bend. Crucially, this response is *retarded and causal*: the change ripples outward only inside the light-cone of $\bar{\Sigma}$, never faster than light. Mathematically, it's a rule with "curvature on the left" and a *retarded kernel acting on the total source on the right*—but the picture to keep is simply: pushes on the web cause bends in the web, after a light-speed delay.

Why it mostly looks like Einstein. In ordinary conditions (weak fields, everyday energies) the fabric behaves like a very stiff, smooth sheet. The part of the dynamics that matters is the *transverse–traceless (TT) spectral sector*, and you get exactly Einstein's relation between "push" (stress–energy) and "bend" (curvature) with one constant G. That's why freely falling bodies all follow the same paths and why the classic GR tests work so well.

Where the refinements live. Because the fabric is ultimately *quantum and relational*, there's an additional, state-dependent correction $\mathcal{Q}_{\mu\nu}$ built from that coherence piece. Chapter 12 shows this correction is *null-positive* (it can't spoil the usual light-ray focusing), so the familiar link from energy conditions to geometric focusing still holds. At the same diagnostic realized reference configuration level, the quiet "pressure" of empty space appears as an effective cosmological constant Λ. These refinements are tiny in the solar system, but they can matter near extremes like the early universe or compact objects.

Gravitational waves, simply. Jiggle the fabric fast and ripples carry energy away: those are gravitational waves. In normal conditions they come with the two familiar "plus" and "cross" patterns—the two *TT helicities* of the radiating graviton. In exotic states, other degrees of freedom can *mix into the metric response* and produce small extra squeeze/longitudinal features in what detectors read out, but they do *not* add new radiative polarizations. (The τ–kairos sector is *TT-null*, so it cannot radiate spin-2.)

Is gravity a force? Fundamentally, *no.* Objects in free fall are not being pushed; they're following the straightest possible paths (geodesics) in a curved fabric. The "force of gravity" shows up only as a convenient approximation—like the Newtonian potential—in slow, weak-field regimes, or as *tidal effects* (relative accelerations between nearby paths) that are really geometry in disguise.
Newtonian / weak-field limit. When fields are weak and speeds are slow, the chronogeometric field looks almost flat and its time–time piece satisfies $g_{00} \approx -(1 + 2\Phi)$. In this limit you recover the everyday "force law":

$$\mathbf{F} \;=\; m\,\mathbf{a} \;=\; -\,m\,\nabla\Phi.$$

If the potential is $\Phi(r) = -\dfrac{GM}{r}$, then

$$\mathbf{F} \;=\; -\,\frac{GMm}{r^2}\,\hat{\mathbf{r}},$$

the familiar inverse-square "gravity." This is a *repackaging of curvature* into a potential, not a fundamental force; it's how the geometric picture reduces to the equation everyone knows ($F = ma$) in ordinary conditions.

Always causal, always consistent. Conservation laws (the contracted Bianchi identity) ensure there's no mismatch between the "push" and the "bend," and the canonical–vs–covariant (Peierls) ways of formulating the theory agree where we actually make predictions.

One-liner: *Gravity is the causal, retarded reshaping of the chronogeometric fabric $\bar{\Sigma}$ by the total source (matter, interactions, and coherence). It reduces to Einstein's two-polarization TT dynamics in ordinary regimes, while allowing small, testable quantum-relational corrections in the extremes. A gravitational wave is a light-speed, two-polarization ripple of spacetime itself—tiny oscillations of distance and time that arise from accelerating mass–energy and are felt as changing separations, not as a force.*

11.8 Chronogeometry of the τ–Kairos

Scope. This section makes explicit how the non–TT coherence sector—the TT–complement $\hat{\tau}_{\mu\nu}$ defined in Section 10.4 with respect to the realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$—enters the diagnostic realized reference configuration Einstein law Definition 11.106 without introducing any duplicate definitions. All constructions here are formulated on certified plateaux $\mathfrak{P}$, with transport by the $\bar{\Sigma}$–compatible relational Levi–Civita connection $\bar{\nabla}$ (cf. Sections 11.5.1 and 11.5.2).

Background shift vs. radiative content

Setup and notation. Work on a certified plateau $\mathfrak{P}$ with realized chronogeometry $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Ch. 6) and with transport by the $\bar{\Sigma}$–compatible relational Levi–Civita connection $\bar{\nabla}$. Let $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ be the certified TT projector on symmetric rank–2 tensors (Definition 10.3), and $\mathbb{P}_{\mathrm{nonTT}} := \mathrm{Id} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$. The non–TT coherence sector is (cf. Section 10.4)

$$\hat{\tau}_{\mu\nu} := \mathbb{P}_{\mathrm{nonTT}}\, \delta\hat{\Sigma}_{\mu\nu}, \qquad \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \hat{\tau}_{\mu\nu} = 0. \tag{11.285}$$

Coherent expectations and background shift. Denote diagnostic realized reference configuration/physical expectations on $\mathfrak{P}$ by $\langle\,\cdot\,\rangle$. A *coherent* τ configuration is one with nonzero mean $\langle\hat{\tau}_{\mu\nu}\rangle \neq 0$. By linearity and (11.285),

$$\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \langle\hat{\tau}_{\mu\nu}\rangle = \langle \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]} \hat{\tau}_{\mu\nu}\rangle = 0, \tag{11.286}$$

so the mean coherence field is *TT–null*. It therefore shifts the *background* temporal/coherence tensor and with it the realized chronogeometry:

$$\bar{t}_{\mu\nu} \;\longrightarrow\; \bar{t}'_{\mu\nu} := \bar{t}_{\mu\nu} + \Delta t^{(\tau)}_{\mu\nu}, \qquad \Delta t^{(\tau)}_{\mu\nu} := \langle\hat{\tau}_{\mu\nu}\rangle, \qquad \bar{\Sigma}'_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}'_{\mu\nu}. \tag{11.287}$$

Typed reconstruction of the mean coherence field. Using the certified typed projectors of the weave (Ch. 11), decompose $\Delta t^{(\tau)}_{\mu\nu}$ into canonical scalar/pseudoscalar/vector pieces:

$$\Delta t^{(\tau)}_{\mu\nu} = S^{(b)}_{\mu\nu}\Big[\langle\hat{\varphi}_b\rangle\Big] + S^{(L)}_{\mu\nu}\Big[\langle\hat{\varphi}_L\rangle\Big] + \tilde{S}^{(p)}_{\mu\nu}\Big[\langle\tilde{\varphi}\rangle\Big] + A^{(\lambda)}_{\mu\nu}\Big[\langle\hat{K}^{(\tau)}_{\lambda}\rangle\Big], \qquad \lambda = \pm, \tag{11.288}$$

where $S^{(b)}, S^{(L)}$ are scalar–typed, $\tilde{S}^{(p)}$ is pseudoscalar–typed, and $A^{(\lambda)}$ is the vector (chrono–kymon) type. In particular, for the vector type the gauge–invariant strength $\mathcal{F}^{(\tau)}_{\mu\nu} := 2\,\bar{\nabla}_{[\mu} K^{(\tau)}_{\nu]}$ induces an antisymmetric temporal imprint

$$\Delta t^{(\tau)}_{[\mu\nu]} \propto \mathcal{F}^{(\tau)}_{\mu\nu}, \qquad \Delta t^{(\tau)}_{(\mu\nu)} \text{ from scalar/pseudoscalar types.} \tag{11.289}$$

Effect on the geometric side of the diagnostic realized reference configuration law. Let $\bar{G}_{\mu\nu}[\bar{\Sigma}]$ be the unified Einstein tensor of the realized geometry (cf. Definition 11.106). Introduce a bookkeeping parameter ε for the coherence amplitude and write $\bar{\Sigma}' = \bar{\Sigma} + \varepsilon\,\Delta\Sigma^{(\tau)}$ with $\Delta\Sigma^{(\tau)}_{\mu\nu} := \Delta t^{(\tau)}_{\mu\nu}$ from (11.287). To first nontrivial order,

$$\bar{G}_{\mu\nu}[\bar{\Sigma}'] = \bar{G}_{\mu\nu}[\bar{\Sigma}] + \varepsilon\,\delta\bar{G}_{\mu\nu}\Big[\Delta\Sigma^{(\tau)}\Big] + \mathcal{O}(\varepsilon^2), \tag{11.290}$$

so a coherent τ background modifies the *geometric side* of the diagnostic realized reference configuration law through the relational variation $\delta\bar{G}[\cdot]$ evaluated on the TT–null $\Delta\Sigma^{(\tau)}$.

No new spin–2 polarizations (TT–purity). Although (11.290) alters the background operator felt by perturbations, it does *not* inject additional spin–2 content. Indeed, the radiative field is $h := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}'}(\delta\Sigma)$ with respect to the *new* background $\bar{\Sigma}'$; by (11.286) the coherence shift satisfies $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\Delta\Sigma^{(\tau)} = 0$, and the typed hygiene of the weave ensures that the TT projector on $\bar{\Sigma}'$ still isolates precisely two tensor polarizations. In short, $\Delta\Sigma^{(\tau)}$ *moves the background* but does not create extra GW polarizations; the TT graviton (Apeiron$^{[\mathrm{TT}]}$) remains the unique spin–2 radiative content.

Background–dependent radiative operator. Linearizing the diagnostic realized reference configuration law about $\bar{\Sigma}'$ yields the TT wave operator $\mathcal{L}_{hh}[\bar{\Sigma}']$ acting on h. Relative to the unshifted background,

$$\mathcal{L}_{hh}[\bar{\Sigma}'] = \mathcal{L}_{hh}[\bar{\Sigma}] + \varepsilon\,\delta\mathcal{L}_{hh}\Big[\Delta\Sigma^{(\tau)}\Big] + \mathcal{O}(\varepsilon^2), \tag{11.291}$$

so coherent τ modifies *propagation parameters* (dispersion, effective potentials) but not the tensorial *type* of the radiative slice.

Bookkeeping across LHS/RHS. Consistently with (11.290), the diagnostic realized reference configuration source is also shifted: $\bar{T}^{\mathrm{total}} \to \bar{T}^{\mathrm{total}} + \varepsilon\,\Delta\bar{T}^{(\tau)}$, where the coherence contribution $\Delta\bar{T}^{(\tau)}$ is assembled from the typed amplitudes (vector piece yielding the Maxwell–like structure, scalar/pseudoscalar pieces entering the symmetric stress), in harmony with the Relational NEC. The diagnostic realized reference configuration law at $\mathcal{O}(\varepsilon)$ reads

$$\delta\bar{G}_{\mu\nu}\Big[\Delta\Sigma^{(\tau)}\Big] + \Lambda\,\Delta\Sigma^{(\tau)}_{\mu\nu} = \kappa\,\Delta\bar{T}^{(\tau)}_{\mu\nu}, \tag{11.292}$$

which simply states that the *background* coherence shift must be balanced by its diagnostic realized reference configuration source—while the *radiative* TT sector remains governed by $\mathcal{L}_{hh}[\bar{\Sigma}']$ in (11.291).

Summary. Coherent (typed) τ expectations are TT–null and therefore (i) *shift the background* $\bar{t}_{\mu\nu}$, modifying $\bar{\Sigma}$ and the geometric operator via (11.290)–(11.291); (ii) do *not* create additional spin–2 polarizations (TT–purity); and (iii) contribute to the diagnostic realized reference configuration source through typed coherence stress, satisfying the balance (11.292). Gravitational radiation remains purely TT; coherence physics lives in the background and in non–TT responses.

Linearized diagnostic realized reference configuration law: mixed–block operator

Linearizing Definition 11.106 around a realized background $\bar{\Sigma} \mapsto \bar{\Sigma} + h$ and decomposing with $\mathbb{P}_{\mathrm{nonTT}} := \mathrm{Id} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ gives the block system

$$\boxed{\begin{pmatrix} \mathcal{L}_{hh} & \mathcal{L}_{h\tau} \\ \mathcal{L}_{\tau h} & \mathcal{L}_{\tau\tau} \end{pmatrix} \begin{pmatrix} h \\ \tau \end{pmatrix} = \kappa \begin{pmatrix} \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, \delta\bar{T}^{\mathrm{total}} \\ \mathbb{P}_{\mathrm{nonTT}}\, \delta\bar{T}^{\mathrm{total}} \end{pmatrix}, \qquad \begin{cases} h := \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\, h, \\ \tau := \mathbb{P}_{\mathrm{nonTT}}\, h \end{cases}} \tag{11.293}$$

with $\delta\bar{T}^{\mathrm{total}}$ the linearized diagnostic realized reference configuration source (cf. Definition 9.358 and Section 9.18.12). By TT–purity (Chapter 11), $\mathcal{L}_{hh}$ governs the spin–2 radiative sector (graviton, i.e. Apeiron$^{[\mathrm{TT}]}$), $\mathcal{L}_{\tau\tau}$ governs the non–TT coherence sector, and the off–diagonal entries $\mathcal{L}_{h\tau}, \mathcal{L}_{\tau h}$ implement the certified mixed response kernels (cf. the weave/typed realized weave configuration).

Remark 11.155 (Causality and well-posedness)**.** All four blocks in (11.293) are realized with Σ–causal propagators on $\mathfrak{P}$ (retarded/advanced support in the $\bar{\Sigma}$–cones), exactly as for the TT radiative operator (cf. the causal statements in Sections 11.5.1 and 11.5.4).

Mixed–block form (non–TT ledger). On the certified plateau $\mathfrak{P}$ with $\bar{\Sigma}$–chronogeometry (cf. Section 11.8), the linearized non–TT sector closes under a typed state vector and a mixed–block operator:

$$\mathbb{K}_{\mathrm{DRRC}} \begin{pmatrix} \delta g_{\text{non-TT}} \\ \tau_{\mathrm{scalar}} \\ K_\mu^{(\tau)} \end{pmatrix} = \begin{pmatrix} \mathcal{S}_g^{(\mathrm{coh})} + \mathcal{S}_g^{(\mathrm{str})} \\ \mathcal{S}_S^{(\mathrm{coh})} + \mathcal{S}_S^{(\mathrm{str})} \\ \mathcal{S}_A^{(\mathrm{coh})} + \mathcal{S}_A^{(\mathrm{str})} \end{pmatrix}, \tag{11.294}$$

with the block operator

$$\mathbb{K}_{\mathrm{DRRC}} = \begin{pmatrix} K_{gg} & K_{gS} & K_{gA} \\ K_{Sg} & K_{SS} & K_{SA} \\ K_{Ag} & K_{AS} & K_{AA} \end{pmatrix}. \tag{11.295}$$

The off–diagonal entries $K_{gS}, K_{gA}, \ldots$ encode the constitutive mixing implied by the split $\Sigma_{\mu\nu} = g_{\mu\nu} + t_{\mu\nu}$ and its chain rule (cf. eqs. (10.94) and (10.101)). By the TT–null lemma for τ and the formal TT selection (cf. Lemma 10.17 and eq. (10.105)), the TT block is closed and decoupled, so (11.294) is confined to the non–TT subspace. The source terms are organized as *coherence* and *stress* functionals and are detailed in Section 11.8.

Derivation of the mixed–block linear system

Step A: Diagnostic realized reference configuration law and notation. Start from the diagnostic realized reference configuration (expectation–level) Einstein law

$$\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\, \bar{\Sigma}_{\mu\nu} = \kappa\, \bar{T}^{\mathrm{total}}_{\mu\nu}, \qquad \text{(cf. Definition 11.106)} \tag{11.296}$$

on the realized geometry $(\mathcal{X}_q, \bar{\Sigma})$, with $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Ch. 6). For compactness define the linearized geometric operator

$$\mathcal{E}_{\mu\nu}[\,\cdot\,] := \delta\bar{G}_{\mu\nu}[\,\cdot\,] + \Lambda\,(\,\cdot\,)_{\mu\nu}, \qquad \text{so that} \quad \mathcal{E}[h] = \kappa\, \delta\bar{T}^{\mathrm{total}}. \tag{11.297}$$

Step B: Linearize about the realized background. Perturb the background as $\bar{\Sigma} \mapsto \bar{\Sigma} + h$ with $h_{\mu\nu}$ small. Linearizing (11.296) gives

$$\delta\bar{G}_{\mu\nu}[h] + \Lambda\, h_{\mu\nu} = \kappa\, \delta\bar{T}^{\text{total}}_{\mu\nu} \quad \Longleftrightarrow \quad \mathcal{E}[h] = \kappa\, \delta\bar{T}^{\text{total}}. \tag{11.298}$$

Here $\delta\bar{G}_{\mu\nu}[h]$ is the *relational* (i.e. $\bar{\Sigma}$–compatible) metric variation of the Einstein tensor; it is a linear, background–covariant differential operator in h (Lichnerowicz–type on $(\mathcal{X}_q, \bar{\Sigma})$).

Step C: TT projector and non–TT complement. Let $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ be the certified TT projector on symmetric rank–2 tensors (Definition 10.3); write the complementary projector

$$\mathbb{P}_{\mathrm{nonTT}} := \mathrm{Id} - \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}. \tag{11.299}$$

Decompose any perturbation $h^{(\mathrm{tot})}_{\mu\nu}$ as

$$h := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, h^{(\mathrm{tot})}, \qquad \tau := \mathbb{P}_{\mathrm{nonTT}}\, h^{(\mathrm{tot})}, \qquad h^{(\mathrm{tot})} = h + \tau, \tag{11.300}$$

so h is TT (spin–2 radiative slice) and τ is the *TT–null* coherence slice (the τ–kairos; cf. Section 10.4).

Step D: Project the linearized law. Apply $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ and $\mathbb{P}_{\mathrm{nonTT}}$ to (11.298):

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \mathcal{E}[h+\tau] = \kappa\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\bar{T}^{\text{total}}, \tag{11.301a}$$

$$\mathbb{P}_{\mathrm{nonTT}}\, \mathcal{E}[h+\tau] = \kappa\, \mathbb{P}_{\mathrm{nonTT}}\, \delta\bar{T}^{\text{total}}. \tag{11.301b}$$

Since $\mathcal{E}[\,\cdot\,]$ is *linear* in its argument, $\mathcal{E}[h+\tau] = \mathcal{E}[h] + \mathcal{E}[\tau]$. Insert this into (11.301):

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \mathcal{E}[h] + \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \mathcal{E}[\tau] = \kappa\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\bar{T}^{\text{total}}, \tag{11.302a}$$

$$\mathbb{P}_{\mathrm{nonTT}}\, \mathcal{E}[h] + \mathbb{P}_{\mathrm{nonTT}}\, \mathcal{E}[\tau] = \kappa\, \mathbb{P}_{\mathrm{nonTT}}\, \delta\bar{T}^{\text{total}}. \tag{11.302b}$$

Step E: Define the mixed–block operators. Define the four linear maps (operators on symmetric rank–2 fields on $(\mathcal{X}_q, \bar{\Sigma})$)

$$\boxed{\begin{aligned} \mathcal{L}_{hh} &:= \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \circ \mathcal{E} \circ \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}, & \mathcal{L}_{h\tau} &:= \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}} \circ \mathcal{E} \circ \mathbb{P}_{\mathrm{nonTT}}, \\ \mathcal{L}_{\tau h} &:= \mathbb{P}_{\mathrm{nonTT}} \circ \mathcal{E} \circ \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}, & \mathcal{L}_{\tau\tau} &:= \mathbb{P}_{\mathrm{nonTT}} \circ \mathcal{E} \circ \mathbb{P}_{\mathrm{nonTT}}. \end{aligned}} \tag{11.303}$$

With these definitions, (11.302) becomes the coupled system

$$\mathcal{L}_{hh}\, h + \mathcal{L}_{h\tau}\, \tau = \kappa\, \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\bar{T}^{\text{total}}, \tag{11.304a}$$

$$\mathcal{L}_{\tau h}\, h + \mathcal{L}_{\tau\tau}\, \tau = \kappa\, \mathbb{P}_{\mathrm{nonTT}}\, \delta\bar{T}^{\text{total}}. \tag{11.304b}$$

Step F: Assemble the matrix form. Collect (11.304) into the block matrix equation

$$\begin{pmatrix} \mathcal{L}_{hh} & \mathcal{L}_{h\tau} \\ \mathcal{L}_{\tau h} & \mathcal{L}_{\tau\tau} \end{pmatrix} \begin{pmatrix} h \\ \tau \end{pmatrix} = \kappa \begin{pmatrix} \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, \delta\bar{T}^{\text{total}} \\ \mathbb{P}_{\mathrm{nonTT}}\, \delta\bar{T}^{\text{total}} \end{pmatrix}, \qquad \begin{cases} h := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\, h, \\ \tau := \mathbb{P}_{\mathrm{nonTT}}\, h \end{cases}$$

which is eq. (11.293).

Step G: TT–purity and physical interpretation. By the TT–purity results in the weave (Chapter 11), the TT projector annihilates the spin–1 ledger and the τ–sector is TT–null. Consequently:

- $\mathcal{L}_{hh}$ is the *radiative* (spin–2) operator on h (the graviton/Apeiron$^{[\mathrm{TT}]}$ channel);
- $\mathcal{L}_{\tau\tau}$ governs the *non–TT* coherence dynamics (typed scalar/pseudoscalar/vector);
- $\mathcal{L}_{h\tau}$ and $\mathcal{L}_{\tau h}$ encode the *mixed response kernels*, responsible for non–TT dressing/sourcing of the metric and backreaction of h into the coherence sector.

Step H: Comments on sources and causality. The source split on the right–hand side uses the same projectors applied to the linearized diagnostic realized reference configuration source $\delta\bar{T}^{\mathrm{total}}$ (cf. Definition 9.358 and Section 9.18.12). On certified plateaux $\mathfrak{P}$, all blocks admit $\bar{\Sigma}$–causal retarded/advanced Green operators, so the coupled system (11.293) is well–posed with propagation inside the $\bar{\Sigma}$ null cones.

Coherence–stress bookkeeping on the RHS

Source split and chronogeometric pieces. The total diagnostic realized reference configuration source in Definition 11.106 is decomposed as

$$\bar{T}^{\mathrm{total}}_{\mu\nu} = \bar{T}^{\mathrm{matter}}_{\mu\nu} + \bar{T}^{\mathrm{int}}_{\mu\nu} + \bar{T}^{\mathrm{coh}}_{\mu\nu}[\bar{t};\,\mathrm{typed}], \tag{11.305}$$

where $\bar{T}^{\mathrm{coh}}_{\mu\nu}$ collects the *coherence* (temporal) contributions originating from the realized temporal tensor $\bar{t}_{\mu\nu}$ and from the certified non–TT typed amplitudes of the weave (Chapter 11). Write the symmetric/antisymmetric split

$$\bar{t}_{\mu\nu} = S_{\mu\nu} + A_{\mu\nu}, \qquad S_{\mu\nu} := \bar{t}_{(\mu\nu)}, \quad A_{\mu\nu} := \bar{t}_{[\mu\nu]}. \tag{11.306}$$

Quadratic coherence tensor and Relational NEC. As used in Section 11.6, the canonical quadratic coherence tensor reads

$$\mathcal{Q}_{\mu\nu}[S,A] := S_{\mu\alpha}\,S_{\nu}{}^{\alpha} + A_{\mu\alpha}\,A_{\nu}{}^{\alpha} - \frac{1}{d}\,\bar{g}^{\mathrm{Lor}}_{\mu\nu}\left(S_{\alpha\beta}S^{\alpha\beta} + A_{\alpha\beta}A^{\alpha\beta}\right), \tag{11.307}$$

so that, for any null k^{μ}, one has $k^{\mu}k^{\nu}\mathcal{Q}_{\mu\nu} \geq 0$ (Relational NEC). The coherence stress is organized so that its null contractions are controlled by $\mathcal{Q}_{\mu\nu}$.

Typed bookkeeping: scalar, pseudoscalar, and vector (CK) pieces. Let the certified typed amplitudes of the TT–complement be $\{\hat{\varphi}_b, \hat{\varphi}_L, \tilde{\varphi}, \hat{K}^{(\tau)}_{\lambda}\}$ with $\lambda = \pm$ (cf. Chapter 11). Their diagnostic realized reference configuration expectations (or bilinears for fluctuations) assemble $\bar{T}^{\mathrm{coh}}_{\mu\nu}$ as follows:

$$\bar{T}^{\mathrm{coh}}_{\mu\nu} = \left(\bar{T}^{\mathrm{coh}}\right)^{(b)}_{\mu\nu} + \left(\bar{T}^{\mathrm{coh}}\right)^{(L)}_{\mu\nu} + \left(\bar{T}^{\mathrm{coh}}\right)^{(p)}_{\mu\nu} + \left(\bar{T}^{\mathrm{coh}}\right)^{(\mathrm{CK})}_{\mu\nu}, \tag{11.308}$$

with each term constrained by the weave typing (orthogonality and parity) and evaluated on $(\mathcal{X}_q, \bar{\Sigma})$ with transport by $\bar{\nabla}$.

Vector (chrono–kymon) contribution. For the vector type (CK) one uses the gauge–invariant field strength $\mathcal{F}^{(\tau)}_{\mu\nu} := 2\,\bar{\nabla}_{[\mu}K^{(\tau)}_{\nu]}$ and obtains the Maxwell–like symmetric stress

$$\left(\bar{T}^{\mathrm{coh}}\right)^{(\mathrm{CK})}_{\mu\nu} = \gamma_\tau \left(\mathcal{F}^{(\tau)}_{\mu\alpha}\,\mathcal{F}^{(\tau)\,\alpha}{}_{\nu} - \frac{1}{4}\,\bar{g}^{\mathrm{Lor}}_{\mu\nu}\,\mathcal{F}^{(\tau)}_{\alpha\beta}\,\mathcal{F}^{(\tau)\,\alpha\beta}\right), \tag{11.309}$$

where γ_τ is a diagnostic realized reference configuration–effective coefficient. The antisymmetric temporal tensor is driven by the CK strength via $A_{\mu\nu} \propto \mathcal{F}^{(\tau)}_{\mu\nu}$ (cf. the vector typed reconstruction), so that (11.309) contributes to $\mathcal{Q}_{\mu\nu}$ and hence obeys the Relational NEC (null positivity).

Scalar and pseudoscalar typed contributions. For the scalar–typed amplitudes φ_b, φ_L and the pseudoscalar $\tilde{\varphi}$, one may use the diagnostic realized reference configuration–canonical symmetric bilinears (no TT content, weave–typed and parity–clean):

$$\left(\bar{T}^{\mathrm{coh}}\right)^{(b)}_{\mu\nu} = \alpha_b\,\bar{\nabla}_\mu\varphi_b\,\bar{\nabla}_\nu\varphi_b - \frac{\alpha_b}{2}\,\bar{g}^{\mathrm{Lor}}_{\mu\nu}\,(\bar{\nabla}\varphi_b)^2 - \bar{g}^{\mathrm{Lor}}_{\mu\nu}\,V_b(\varphi_b), \tag{11.310a}$$

$$\left(\bar{T}^{\mathrm{coh}}\right)^{(L)}_{\mu\nu} = \alpha_L\,\bar{\nabla}_\mu\varphi_L\,\bar{\nabla}_\nu\varphi_L - \frac{\alpha_L}{2}\,\bar{g}^{\mathrm{Lor}}_{\mu\nu}\,(\bar{\nabla}\varphi_L)^2 - \bar{g}^{\mathrm{Lor}}_{\mu\nu}\,V_L(\varphi_L), \tag{11.310b}$$

$$\left(\bar{T}^{\mathrm{coh}}\right)^{(p)}_{\mu\nu} = \alpha_p\,\bar{\nabla}_\mu\tilde{\varphi}\,\bar{\nabla}_\nu\tilde{\varphi} - \frac{\alpha_p}{2}\,\bar{g}^{\mathrm{Lor}}_{\mu\nu}\,(\bar{\nabla}\tilde{\varphi})^2 - \bar{g}^{\mathrm{Lor}}_{\mu\nu}\,\tilde{V}(\tilde{\varphi}), \tag{11.310c}$$

with diagnostic realized reference configuration–effective couplings $\alpha_{b,L,p} \geq 0$ and (typed) potentials $V_b, V_L, \tilde{V}$. For any null k^μ,

$$k^\mu k^\nu \left(\bar{T}^{\mathrm{coh}}\right)^{(X)}_{\mu\nu} = \alpha_X \left(k^\mu\bar{\nabla}_\mu\phi_X\right)^2 \;\geq\; 0, \qquad X \in \{b, L, p\}, \quad \phi_X \in \{\varphi_b, \varphi_L, \tilde{\varphi}\}, \tag{11.311}$$

so the scalar/pseudoscalar typed pieces also satisfy the Relational NEC.[3]

Linearized source split and projections. For perturbations about a realized background, split the coherence source into background and fluctuation pieces and project with the certified TT/compl. projectors:

$$\delta\bar{T}^{\mathrm{coh}}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\bar{T}^{\mathrm{coh}}_{\mu\nu} + \mathbb{P}_{\mathrm{nonTT}}\,\delta\bar{T}^{\mathrm{coh}}_{\mu\nu}, \tag{11.312}$$

where the first term can *drive* radiative geometry (via $\mathcal{L}_{hh}$) and the second term couples to the non–TT sector (via $\mathcal{L}_{\tau\tau}$), with cross–coupling through the mixed blocks $\mathcal{L}_{h\tau}, \mathcal{L}_{\tau h}$ in (11.293). The background (coherent) piece contributes at order $\mathcal{O}(\varepsilon)$ to the balance equation (11.292).

Scalarisation and universality of coupling. In the spectral limit (cf. Sections 11.5.7 and 11.5.8), the emergent coupling tensor $\mathcal{C}_{\mu\nu}{}^{\rho\sigma}$ scalarises to $\kappa_{\mathrm{eff}}\,\Pi_{\mu\nu}{}^{\rho\sigma}$ so that each typed coherence term in (11.308) couples with the same diagnostic realized reference configuration–universal κ_{eff}, consistent with the recovery of GR and with the equivalence–principle bounds on anisotropies.

[3] Parity forbids linear mixing between (p) and (b, L) at quadratic order; cross–type bilinears vanish by the weave typing (orthogonality of certified projectors).

Summary. The coherence contribution to the diagnostic realized reference configuration source is a typed, covariant, and NEC–respecting sum of (i) a Maxwell–like vector (CK) stress (11.309), (ii) scalar and pseudoscalar symmetric stresses (11.310), all assembled on $(\mathcal{X}_q, \bar{\Sigma})$ with $\bar{\nabla}$ and the weave projectors. It participates in the linearized dynamics via the projected right–hand side of (11.293) and reduces to universal coupling in the spectral limit.

Non–TT law residual and visibility (diagnostic realized reference configuration diagnostics)

In parallel with the TT law visibility Definition 11.6, define the *non–TT law residual* by projecting the diagnostic realized reference configuration Einstein law to the TT–complement:

$$\boxed{\mathbf{R}^{[\mathrm{nonTT}]} := \mathbb{P}_{\mathrm{nonTT}}\Big[\bar{G}_{\mu\nu}[\bar{\Sigma}] + \Lambda\,\bar{\Sigma}_{\mu\nu} - \kappa\,\bar{T}^{\mathrm{total}}_{\mu\nu}\Big],} \tag{11.313}$$

and the corresponding *non–TT law visibility*

$$\Lambda^{[\mathrm{nonTT}]}_{\mathrm{law}} := 1 - \frac{\|\mathbf{R}^{[\mathrm{nonTT}]}\|_{\mathcal{I}}}{\|\cdot\|_{\mathrm{ref}}}, \qquad \Lambda^{[\mathrm{nonTT}]}_{\mathrm{law}} \in [0,1], \tag{11.314}$$

with the realized weave configuration norm $\|\cdot\|_{\mathcal{I}}$ and the acceptance reference $\|\cdot\|_{\mathrm{ref}}$ as in Definition 11.6 and Section 7.3.9. By construction, $\Lambda^{[\mathrm{nonTT}]}_{\mathrm{law}}$ is Nielsen–flat on $\mathfrak{P}$ (same commutation properties as in the TT case).

Emergent coupling tensor and scalarisation with coherence

Writing the diagnostic realized reference configuration law in response form (cf. Section 11.5.6),

$$\bar{G}_{\mu\nu}(x) = \int \mathscr{K}_{\mu\nu}{}^{\rho\sigma}(x,x')\,\bar{T}^{\mathrm{total}}_{\rho\sigma}(x')\,\mathrm{d}^d x',$$

the local spectral limit yields the emergent coupling tensor $\mathcal{C}_{\mu\nu}{}^{\rho\sigma}$, which *scalarises* (cf. Section 11.5.7) to $\kappa_{\mathrm{eff}}\,\Pi_{\mu\nu}{}^{\rho\sigma}$ under the same anisotropy bounds. In that limit, the *typed* coherence contributions in (9.358) couple universally with κ_{eff}, ensuring consistency with Section 11.5.8.

Witness predicates and diagnostic realized reference configuration certification

Law–vs–state diagnostics for the non–TT sector adopt the same witness framework as Definitions 8.4 to 8.6, with predicates specialized to the typed τ amplitudes and to the mixed blocks in (11.293). Acceptance is granted when $\Lambda^{[\mathrm{nonTT}]}_{\mathrm{law}} \approx 1$ and the typed witnesses saturate their diagnostic realized reference configuration thresholds, all on a certified plateau $\mathfrak{P}$.

Summary. The non–TT coherence sector (the τ–kairos and, inside it, the chrono–kymon) enters the diagnostic realized reference configuration Einstein law (i) on the LHS through background shifts of $\bar{t}_{\mu\nu}$ hence $\bar{\Sigma}$, (ii) on the RHS via the coherence–stress contribution eq. (11.170) (with the vector piece exemplified by eq. (11.309)), and (iii) at the linearized level through the mixed response blocks in eq. (11.293). TT–purity (Chapter 11) guarantees that the spin–2 radiative sector remains uniquely determined by the TT block, while coherence physics is certified by the non–TT visibility eq. (11.314) and witness predicates.

11.8.1 Linear–response Quantization of the Non–TT sector and Optional BEH Mass for Chrono-Kymons

Quadratic diagnostic realized reference configuration (DRCC) functional for the non–TT sector. Linearizing the diagnostic realized reference configuration law Definition 11.106 and using the TT/complement split (cf. Section 10.4 and (11.293)) yields, to quadratic order on $\mathfrak{P}$,

$$S^{(2)}_{\mathrm{DRCC}}[h,\tau] = \frac{1}{2}\int h\,\mathcal{L}_{hh}h + \int h\,\mathcal{L}_{h\tau}\tau + \frac{1}{2}\int \tau\,\mathcal{L}_{\tau\tau}\tau - \kappa\int\Big(h\,\Pi^{[\mathrm{TT}]}\delta\bar{T}^{\mathrm{total}} + \tau\,\mathbb{P}_{\mathrm{nonTT}}\delta\bar{T}^{\mathrm{total}}\Big), \tag{11.315}$$

where all contractions and covariant derivatives are with $\bar{\Sigma}$ and $\bar{\nabla}$. The operator $\mathcal{L}_{\tau\tau}$ is the non–TT kinetic operator; $\mathcal{L}_{h\tau}$, $\mathcal{L}_{\tau h}$ encode the certified mixed response kernels.

How (11.315) is obtained (derivation). Start from the typed TT/complement split of metric fluctuations on the diagnostic realized reference configuration $\mathfrak{P}$:

$$\delta g_{\mu\nu} = \underbrace{\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta g_{\mu\nu}}_{h_{\mu\nu}} + \underbrace{\big(\mathbb{1} - \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\big)\delta g_{\mu\nu}}_{(\delta g)_{\overline{\mathrm{TT}}}},$$

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\hat{\tau}_{\mu\nu} = 0 \quad \text{(cf. eq. (10.105) and Lemma 10.17).}$$

Collect the non–TT fields into the typed multiplet

$$\tau := \Big((\delta g)_{\overline{\mathrm{TT}}};\ \tau_{\mathrm{scalar}}\ ;\ K^{(\tau)}_{\mu}\Big)^{\top}.$$

The linearized diagnostic realized reference configuration law in mixed–block form (cf. eqs. (11.293) to (11.295)) reads

$$\begin{pmatrix} K_{hh} & K_{h\tau} \\ K_{\tau h} & K_{\tau\tau} \end{pmatrix}\begin{pmatrix} h \\ \tau \end{pmatrix} = \begin{pmatrix} \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\bar{T}^{\mathrm{total}} \\ \mathbb{P}_{\mathrm{nonTT}}\,\delta\bar{T}^{\mathrm{total}} \end{pmatrix}, \tag{11.316}$$

where $K_{hh} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}K_{gg}\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, $K_{h\tau} := \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}(K_{gS}\oplus K_{gA})\mathbb{P}_{\mathrm{nonTT}}$, $K_{\tau h} := \mathbb{P}_{\mathrm{nonTT}}(K_{Sg}\oplus K_{Ag})\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$, and $K_{\tau\tau} := \mathbb{P}_{\mathrm{nonTT}}\left(\begin{smallmatrix} K_{SS} & K_{SA} \\ K_{AS} & K_{AA}\end{smallmatrix}\right)\mathbb{P}_{\mathrm{nonTT}}$. Here $\mathbb{P}_{\mathrm{nonTT}}$ projects onto the non–TT ledger (metric complement $\oplus$ τ–kairos channels), and the off–diagonal blocks encode the constitutive mixing implied by $\Sigma_{\mu\nu} = g_{\mu\nu} + t_{\mu\nu}$ and its chain rule (cf. eqs. (10.94) and (10.101)).

Define the diagnostic realized reference configuration pairing $\langle X, Y\rangle_{\mathfrak{P}} := \int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\,XY$ (all indices contracted with $\bar{\Sigma}$, covariant derivatives with $\bar{\nabla}$). Then the quadratic diagnostic

realized reference configuration functional whose Euler–Lagrange equations reproduce (11.316) is

$$S^{(2)}_{\mathrm{DRRC}}[h,\tau] = \frac{1}{2}\langle h,\, K_{hh}h\rangle_{\mathfrak{P}} + \langle h,\, K_{h\tau}\tau\rangle_{\mathfrak{P}} + \frac{1}{2}\langle \tau,\, K_{\tau\tau}\tau\rangle_{\mathfrak{P}} - \kappa\Big(\langle h,\, \Pi^{[\mathrm{TT}]}\delta\bar{T}^{\mathrm{total}}\rangle_{\mathfrak{P}} + \langle \tau,\, \mathbb{P}_{\mathrm{nonTT}}\delta\bar{T}^{\mathrm{total}}\rangle_{\mathfrak{P}}\Big). \tag{11.317}$$

Writing $K_{hh} \equiv \mathcal{L}_{hh}$, $K_{h\tau} \equiv \mathcal{L}_{h\tau}$ and $K_{\tau\tau} \equiv \mathcal{L}_{\tau\tau}$ gives precisely (11.315). BRST/tag hygiene from Chapter 10 guarantees these operators are symmetric on the certified band, so the variational equations from (11.317) are equivalent to the linear law (cf. Lemma 9.54).

Remark 11.156 (TT closure)**.** By the TT–null lemma and formal TT selection (cf. Lemma 10.17 and eq. (10.105)), the certified mixed kernels obey $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}(K_{gS}, K_{gA}) = 0$ on $\mathfrak{P}$, so $\mathcal{L}_{h\tau}$ *vanishes* on the diagnostic realized reference configuration. We keep the h–τ term in (11.315) as a bookkeeping slot for possible off–diagnostic realized reference configuration or higher–order effects, but at the certified linear level the TT block is dynamically closed.

Typed field content inside τ. Decompose $\tau_{\mu\nu}$ with the certified typed projectors (Chapter 11):

$$\tau_{\mu\nu} = S^{(b)}_{\mu\nu}[\varphi_b] + S^{(L)}_{\mu\nu}[\varphi_L] + \tilde{S}^{(p)}_{\mu\nu}[\tilde{\varphi}] + A^{(\lambda)}_{\mu\nu}[K^{(\tau)}_{\lambda}], \qquad \lambda = \pm, \tag{11.318}$$

with *vector* (chrono–kymon, CK) potential $K^{(\tau)}_{\mu}$ entering only through its gauge–invariant strength

$$\mathcal{F}^{(\tau)}_{\mu\nu} := 2\,\bar{\nabla}_{[\mu}K^{(\tau)}_{\nu]}\,. \tag{11.319}$$

Massless CK: Maxwell–type quadratic functional (no SSB needed). In the absence of explicit internal SSB acting on the CK type, the vector contribution to the DRRC quadratic functional $S^{(2)}_{\mathrm{DRRC}}$ takes the $\bar{\Sigma}$–Maxwell form (cf. Section 11.8):

$$S^{(2)}_{\mathrm{CK},0} = -\frac{\gamma_\tau}{4}\int \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\; \mathcal{F}^{(\tau)}_{\mu\nu}\,\mathcal{F}^{(\tau)\,\mu\nu}, \tag{11.320}$$

which is invariant under $K^{(\tau)}_{\mu} \mapsto K^{(\tau)}_{\mu} + \bar{\nabla}_{\mu}\chi$. A covariant gauge fixing (BRST–compatible on $\mathfrak{P}$) gives the well–posed operator

$$\bar{\nabla}_{\mu}\mathcal{F}^{(\tau)\,\mu\nu} = J^{(\tau)\,\nu}, \qquad J^{(\tau)\,\nu} := \frac{1}{\gamma_\tau}\,\frac{\delta S^{(2)}_{\mathrm{DRRC}}}{\delta K^{(\tau)}_{\nu}}\Big|_{\text{sources, mixes}}, \tag{11.321}$$

where "DRRC" denotes the diagnostic realized reference configuration of Definition 9.185. The corresponding solutions have $\bar{\Sigma}$–causal retarded/advanced Green operators (inheritance of the DRRC causal cones). Quantization proceeds by canonical ETCR on the band (Chapter 11), or equivalently by constructing the CK two–point function from the inverse of the gauge–fixed kinetic operator. *No SSB is required* to have a propagating CK quantum; it is a standard linear–response mode in the TT–complement.

Scalar/pseudoscalar non–TT modes (no SSB needed). The scalar φ_b, φ_L and pseudoscalar $\tilde{\varphi}$ pieces enter with standard covariant quadratic functionals on $(\mathcal{X}_q, \bar{\Sigma})$ (cf. eq. (11.310)), yielding well–posed hyperbolic operators and causal propagators. Their quantization is identical in spirit to the CK case and likewise does not require SSB.

11.8.2 BEH of the Chrono-Kymon

Constitutive, typed origin; independence from Tantrakyma SSB/BEH. The Chrono–Kymon (CK) does not originate from Tantrakyma spontaneous symmetry breaking or from a Brout–Englert–Higgs reorganization. Rather, it is defined by the constitutive law as the vector-typed, non-TT response of the chronogeometric observable to substrate fluctuations. The fluctuations $(\delta\Phi, \delta\Theta)$ are first pushed forward by the constitutive map; see eqs. (10.18) and (10.19). The CK slot is then selected with the weave's certified projectors; see Section 10.4 and Definitions 10.3 and 10.4.

Constitutive pushforward and vector selection (Ch. 11). Start from the constitutive map

$$\Sigma_{\mu\nu}[\Phi,\Theta] \;=\; g_{\mu\nu}[\Phi] \;+\; t_{\mu\nu}[\Phi,\Theta], \qquad (\bar{\Phi},\bar{\Theta}) \text{ realized background.}$$

Linearizing about $(\bar{\Phi}, \bar{\Theta})$ yields the chain rule

$$\delta\Sigma_{\mu\nu} \;=\; (D_\Phi g)_{\mu\nu}\cdot\,\delta\Phi \;+\; (D_\Phi t)_{\mu\nu}\cdot\,\delta\Phi \;+\; (D_\Theta t)_{\mu\nu}\cdot\,\delta\Theta.$$

Let $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ be the certified TT projector and $\mathbb{P}_{\mathrm{nonTT}} := \mathrm{Id} - \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$ the TT–complement (Ch. 11, τ–construction). Let $\mathsf{A}_\mu{}^{\rho\sigma}$ denote the vector–typed selector onto the CK slot (the $A^{(\lambda)}$ piece of the typed decomposition; cf. Definition 10.4). The CK carrier is then

$$K_\mu^{(\tau)} \;:=\; \mathsf{A}_\mu{}^{\rho\sigma}\left(\mathbb{P}_{\mathrm{nonTT}}\delta\Sigma_{\rho\sigma}\right) \;=\; \underbrace{\mathsf{A}\,\mathbb{P}_{\mathrm{nonTT}}\big((D_\Phi g)+(D_\Phi t)\big)}_{J_\Phi^{(A)}}\,\delta\Phi \;+\; \underbrace{\mathsf{A}\,\mathbb{P}_{\mathrm{nonTT}}(D_\Theta t)}_{J_\Theta^{(A)}}\,\delta\Theta. \tag{11.322}$$

Thus the CK is the *linear image* of $(\delta\Phi, \delta\Theta)$ under the constitutive Jacobians $J_\Phi^{(A)}, J_\Theta^{(A)}$ after non–TT and vector–type selection. Its existence does *not* presuppose SSB or BEH of Θ; it is present at the level of linear response and typed projection.

Massless CK and Maxwell structure (no SSB required). Define the gauge–like strength $\mathcal{F}_{\mu\nu}^{(\tau)} := 2\,\bar{\nabla}_{[\mu}K_{\nu]}^{(\tau)}$. On certified plateaux, the quadratic CK functional reduces in the massless limit to a Maxwell–type form with two physical helicities $\lambda = \pm$ (spin–1), as encoded by the linearized diagnostic realized reference configuration law and its typed block structure (cf. eqs. (11.293) to (11.295)). The antisymmetric temporal imprint

$$\Delta t_{[\mu\nu]}^{(\tau)} \;\propto\; \mathcal{F}_{\mu\nu}^{(\tau)} \tag{11.323}$$

follows from the typed geometry (cf. eqs. (11.288) and (11.289)) and does not rely on a Tantrakyma Goldstone origin. TT purity ensures no leakage into the spin–2 tensor channel.

τ–sector BEH for CK (independent of Tantrakyma). A CK mass arises only if an *internal symmetry acting on the CK representation* is gauged and spontaneously broken *in the CK/τ sector* itself (Ch. 12). The quadratic functional upgrades to Proca:

$$S^{(2)}_{\mathrm{CK},m} \;=\; -\frac{\gamma_\tau}{4}\int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\;\mathcal{F}^{(\tau)}_{\mu\nu}\,\mathcal{F}^{(\tau)\,\mu\nu} \;+\; \frac{m^2_{\mathrm{CK}}}{2}\int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\;K^{(\tau)}_{\mu}K^{(\tau)\,\mu}, \tag{11.324}$$

with mass determined by the typed order parameter $\varphi^{[\tau]}$ and the algebra metric G^{IJ},

$$m^2_{\mathrm{CK}} \;=\; g^2\left\langle \mathcal{R}_\tau(T_I)\,\varphi^{[\tau]},\,\mathcal{R}_\tau(T_J)\,\varphi^{[\tau]}\right\rangle G^{IJ}, \tag{11.325}$$

and equations of motion (Proca form)

$$\bar{\nabla}_\mu\mathcal{F}^{(\tau)\,\mu\nu} + m^2_{\mathrm{CK}}\,K^{(\tau)\,\nu} \;=\; J^{(\tau)\,\nu}, \qquad \bar{\nabla}_\nu K^{(\tau)\,\nu} = 0 \;\;\text{(on shell)}. \tag{11.326}$$

This BEH mechanism is *optional* and strictly *τ–sector*; it neither relies on nor is sourced by SSB/BEH in the Tantrakyma field.

Tantrakyma's role (background and sources, not creation). Tantrakyma enters only through the constitutive Jacobian $J^{(A)}_{\Theta} = \mathsf{A}\,\mathbb{P}_{\mathrm{nonTT}}(D_\Theta t)$ in (11.322). If the Tantrakyma sector undergoes SSB/BEH, it can (i) shift the realized background $(\bar{\Phi},\bar{\Theta})$ and hence modify CK propagation via the background change $\bar{\Sigma}\mapsto\bar{\Sigma}'=\bar{\Sigma}+\Delta\Sigma$ (cf. eqs. (11.290) and (11.291)), and (ii) contribute typed sources on the RHS of the mixed–block system (cf. Section 11.8). Neither effect creates the CK degree of freedom: the CK already exists as the vector–typed, non–TT response variable of the chronogeometric map.

Conclusion. The CK originates from the typed, non–TT linear response of $\Sigma_{\mu\nu}$; it does not require global SSB or BEH of the Tantrakyma field for its existence. When present, a CK mass gap comes from an *internal τ–sector* BEH acting on the CK representation (cf. eqs. (11.324) to (11.326)), while TT purity guarantees that the spin–2 graviton sector remains closed and unaffected (cf. eq. (11.293)).

Internal BEH: Proca deformation for CK. If an internal symmetry acts on the CK type through a representation $\mathcal{R}_\tau$ and is spontaneously broken on $\mathfrak{P}$ (cf. Sections 6.6 and 9.17.3), the quadratic CK sector admits a *Proca* deformation

$$S^{(2)}_{\mathrm{CK},m} = -\frac{\gamma_\tau}{4}\int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\;\mathcal{F}^{(\tau)}_{\mu\nu}\,\mathcal{F}^{(\tau)\,\mu\nu} + \frac{m^2_{\mathrm{CK}}}{2}\int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\;K^{(\tau)}_{\mu}K^{(\tau)\,\mu}, \qquad (\gamma_\tau>0),$$

with

$$m^2_{\mathrm{CK}} = \; g^2\left\langle\,\mathcal{R}_\tau(T_I)\,\varphi^{[\tau]}\,,\,\mathcal{R}_\tau(T_J)\,\varphi^{[\tau]}\,\right\rangle G^{IJ},$$

where g is the internal gauge coupling, $\varphi^{[\tau]} := \Pi^{[\tau]}_{\Phi\Phi}\,\bar{\Phi}$ is the τ-typed order parameter on the modal fiber (cf. Section 9.17.3), $\{T_I\}$ are the broken generators, and G^{IJ} is the inverse of the Lie-algebra metric G_{IJ} from the gauge kinetic term (cf. Section 9.18.8). The pairing $\langle\cdot,\cdot\rangle$ is the diagnostic realized reference configuration/modal-fiber inner product, so the

mass construction is "fiber pairing × algebra metric," as in the connection–vector case in Chapter 10.

[4]

The massive CK obeys

$$\bar{\nabla}_\mu \mathcal{F}^{(\tau)\,\mu\nu} + m_{\mathrm{CK}}^2\, K^{(\tau)\,\nu} = J^{(\tau)\,\nu}.$$

Assuming the typed source is conserved, $\bar{\nabla}_\nu J^{(\tau)\,\nu} = 0$, taking the divergence of (11.326) yields the on–shell transversality

$$\bar{\nabla}_\nu K^{(\tau)\,\nu} = 0 \qquad \text{(on shell)}. \tag{11.327}$$

This BEH deformation alters the *dispersion* of CK quanta but does not affect TT purity of the radiative (spin–2) sector: $\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\hat{\tau}_{\mu\nu} = 0$ and $\hat{h}_{\mu\nu} = \Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}\,\delta\hat{g}_{\mu\nu}$ (cf. Lemma 10.17, eq. (10.105), and Section 9.18.7).

Mixing with geometry and energy conditions. Couplings to h enter only through the certified mixed blocks $\mathcal{L}_{h\tau}, \mathcal{L}_{\tau h}$ in (11.293); TT hygiene (Chapter 11) forbids leakage of CK into tensor polarizations. The coherence stress built from $\mathcal{F}^{(\tau)}$ (and from scalar/pseudoscalar typed bilinears) satisfies the Relational NEC (Section 11.6); in particular, for any $\bar{\Sigma}$-null k^μ, $k^\mu k^\nu (\bar{T}^{\mathrm{coh}})_{\mu\nu}^{(\mathrm{CK})} \geq 0$ (cf. eq. (11.309)).

Summary. All non–TT typed modes—including the vector CK—are bona fide quantum fields obtained by *linear–response quantization* of the TT–complement on $\mathfrak{P}$. They require no SSB to exist. If an internal symmetry is broken in the sector acting on CK, a BEH mechanism *optionally* promotes CK to a Proca field with mass m_{CK}, without disturbing the TT graviton sector or its polarizations.

Chrono–Kymon (CK) in the weave. The Chrono–Kymon is the *vector typed* register inside the τ–kairos—the TT–complement of chronogeometric fluctuations (cf. Chapter 11). Kinematically it is represented by a potential $K_\mu^{(\tau)}$ with gauge–invariant field strength

$$\mathcal{F}_{\mu\nu}^{(\tau)} := 2\,\bar{\nabla}_{[\mu} K_{\nu]}^{(\tau)}\,,$$

and it is TT–null by construction, so it does not carry spin–2 radiation nor alter the graviton's polarization content. In the weave typing, τ splits into scalar/pseudoscalar/vector pieces; the CK furnishes the antisymmetric temporal imprint via $\mathcal{F}^{(\tau)}$ (cf. Section 11.8).

Linear–response (no SSB): massless CK and diagnostic realized reference configuration quantization. On a certified plateau $\mathfrak{P}$, the *linear–response* CK dynamics (without any symmetry breaking) take the Maxwell form on $(\mathcal{X}_q, \bar{\Sigma})$:

$$S_{\mathrm{CK},0}^{(2)} = -\frac{\gamma_\tau}{4}\int \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\; \mathcal{F}_{\mu\nu}^{(\tau)}\,\mathcal{F}^{(\tau)\,\mu\nu}, \qquad \bar{\nabla}_\mu \mathcal{F}^{(\tau)\,\mu\nu} = J^{(\tau)\,\nu},$$

with BRST–compatible gauge fixing on $\mathfrak{P}$. Quantization yields a *massless* spin–1 quantum (two transverse polarizations) in the TT–complement; no SSB is required for the existence of the CK quantum (cf. eq. (11.293) for the mixed–block coupling to geometry).

[4] For a gauge–invariant presentation, introduce a covariant Stueckelberg field σ so that $K_\mu^{(\tau)} \mapsto K_\mu^{(\tau)} + \bar{\nabla}_\mu \sigma / m_{\mathrm{CK}}$, keeping BRST structure manifest on $\mathfrak{P}$ (cf. Section 9.17.3).

Internal BEH (optional): Proca upgrade and dispersion change. If an *internal* gauge symmetry acting on the CK representation $\mathcal{R}_\tau$ is spontaneously broken on $\mathfrak{P}$ (see Section 6.6), the CK sector undergoes a Brout–Englert–Higgs upgrade to a Proca field: spectrally, the one–particle pole moves from $k^2 = 0$ to $k^2 = m_{\mathrm{CK}}^2$, and the physical polarizations reorganize from two transverse to three (two transverse + one longitudinal) in $d = 4$. In the compact diagnostic realized reference configuration notation from your notes, this transition is summarized by

$$\text{massless: } S^{(2)}_{\mathrm{CK},0} = -\frac{\gamma_\tau}{4}\int \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\, \mathcal{F}^{(\tau)}_{\mu\nu}\mathcal{F}^{(\tau),\mu\nu}$$

$$\rightsquigarrow$$

$$\text{massive (BEH): } S^{(2)}_{\mathrm{CK},m} = S^{(2)}_{\mathrm{CK},0} + \frac{m_{\mathrm{CK}}^2}{2}\int \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\, K^{(\tau)}_{\mu}K^{(\tau),\mu}$$

and the corresponding Proca equations on $(\bar{\Sigma}, \bar{\nabla})$,

$$\bar{\nabla}_\mu \mathcal{F}^{(\tau)\,\mu\nu} + m_{\mathrm{CK}}^2\, K^{(\tau)\,\nu} = J^{(\tau)\,\nu}, \qquad \bar{\nabla}_\nu K^{(\tau)\,\nu} = 0 \ \text{ (on shell)}.$$

This BEH deformation changes *dispersion and degrees of freedom* in the *non–TT* sector only; TT–purity (Chapter 11) ensures the graviton (Apeiron$^{[\mathrm{TT}]}$) remains the unique spin–2 radiative slice.

The **Chrono-Kymon (CK)** starts life as the vector-typed piece inside the τ–kairos—the TT-complement of chronogeometric fluctuations defined with the certified projector ($\Pi_{\bar{\Sigma}}^{[\mathrm{TT}]}$) (cf. Section 10.4 and Definition 10.3). In that unbroken phase, it is a massless spin-1 field with two physical helicities ($\lambda = \pm$). Nothing in this construction touches the spin-2 radiative (graviton) slice, which is isolated by TT-purity. When an internal gauge symmetry acting on the CK representation is spontaneously broken on the diagnostic realized reference configuration ($\mathfrak{P}$) (via the operator-bundle connection; cf. Section 6.6), the CK sector undergoes the familiar *Brout–Englert–Higgs (BEH) reorganization*: the quadratic functional upgrades from the Maxwell form to a Proca form (see eqs. (11.320) and (11.324)). Physically, the would-be Goldstone is "eaten" and a mass gap ($m_{\mathrm{CK}} > 0$) appears. This change affects the degrees of freedom—the massive CK has three physical polarizations ($\lambda = \pm, 0$) in 4D—but it does not change the spin. Representation-theoretically, you move from the massless little group to the massive one (SO(3)), so we still have a spin-1 field, now with an added longitudinal mode. Dynamically, the Proca equations on $(\bar{\Sigma}, \bar{\nabla})$ together with the on-shell constraint make this explicit (cf. eq. (11.326)). The extra longitudinal polarization is a hallmark of massiveness, not a change of spin. Throughout, TT-purity ensures CK remains in the non-TT ledger; it interacts with geometry only through the certified mixed blocks of the linearized diagnostic realized reference configuration law (cf. eq. (11.293)), so the graviton's spin-2 sector and its two tensor polarizations remain untouched.

In the massless phase, the chrono-kymon (CK) is a *gauge-like, long-range coherence/phase-flow imprint* on the weave: its field strength ($\mathcal{F}^{(\tau)}$) writes the antisymmetric temporal texture ($t_{[\mu\nu]}$) and supplies a Maxwell-type coherence stress on the diagnostic realized reference configuration source, all while remaining TT-null (no spin-2 radiation). After BEH, the CK becomes a massive spin-1 Proca field. Conceptually, its role shifts from a *long-range, scale-free phase-flow carrier* to a *finite-range mediator of temporal coherence* whose influence

is controlled by a correlation length ($\xi_{\mathrm{CK}} \sim m_{\mathrm{CK}}^{-1}$) (cf. the Proca upgrade and equations in eqs. (11.324) and (11.326)).

This has three practical consequences for the geometry. First, background control becomes *screened*: coherent CK expectations still shift ($\bar{t}_{\mu\nu}$) and hence ($\bar{\Sigma}$), but the induced temporal twist decays over (ξ_{CK}) rather than propagating freely, so the modification of ($\bar{G}_{\mu\nu}[\bar{\Sigma}]$) is localized (see Section 11.8). Second, the *new longitudinal polarization* provides a *compressional mode* of "clock-alignment" in the non-TT ledger—an extra way to organize temporal coherence—without ever leaking into tensor GW polarizations (TT-purity still applies). Third, geometry–coherence interplay remains entirely through the certified mixed blocks of the linearized diagnostic realized reference configuration law, so CK can dress/source non-TT metric response but cannot alter the *graviton channel* (eq. (11.293)).

On the source side, the CK contribution to the coherence stress keeps the *same gauge-invariant backbone* built from ($\mathcal{F}^{(\tau)}$) but now includes the Proca mass in the energy budget; the resulting stress remains typed, covariant, and compliant with the Relational NEC (Sections 11.6 and 11.8). Operationally, the massive CK thus acts as a *gapped carrier of temporal coherence*: it shapes *finite-range domains of phase organization*, stores/dissipates coherence energy locally, and backreacts on the background and perturbations in a controlled, non-TT way—all while its spin stays 1.

A simple way to picture the chrono-kymon. Think of the chrono-kymon as the field that helps nearby patches of spacetime "agree" on a local sense of timing—like a gentle wind that lines up a field of weathervanes. When the CK is massless, that "clock-wind" reaches arbitrarily far. It imprints a coherent orientation of time (a phase-flow) across wide regions, and it only has two ways to wiggle: the wind can sway sideways in two different directions (the two transverse polarizations). That's its *long-range, "clocking" role*. Now imagine something changes in the medium so that the wind can't blow freely anymore. After BEH, the CK becomes massive. In everyday terms, that doesn't mean clocks get heavier; it means the clock-wind acquires a *finite reach*. Its influence dies off beyond a characteristic distance ($\xi_{\mathrm{CK}} \sim 1/m_{\mathrm{CK}}$). Nearby regions can still synchronize, but distant ones no longer feel it strongly. And the wind can now also do one extra thing: besides swaying sideways, it can momentarily push or pull along its own direction—a *new "longitudinal" way* to disturb timing. That's what the third polarization is. A few analogies help this land:

- *Radio time signal vs. fog (or the Meissner effect).* A massless CK is like a time-signal broadcast that travels indefinitely through clear air. Giving it mass is like surrounding everything with a medium that screens the signal: it still broadcasts, but only out to a finite radius (like how magnetic fields are expelled from a superconductor and only penetrate a short distance). *Same broadcaster, shorter reach.*

- *Weathervanes in a breeze.* With massless CK, a steady breeze lines up all the vanes across the whole valley (*global clock coherence*). With massive CK, tall hedges now block the breeze, so alignment persists only locally; beyond a few fields, the effect fades. The "longitudinal" mode is like a brief gust that presses the vanes forward instead of just nudging them sideways.

- *Metronomes on a shared platform.* Put many metronomes on a movable board and they'll synchronize through tiny couplings (massless-like, long range across the board). Add mechanisms that confine the board's motion and the coupling becomes short-range: metronomes form local clusters that sync, and there's an *extra "compressional" way* the platform can respond—mirroring the CK's new longitudinal degree of freedom.

What doesn't change is the kind of thing the CK is: it remains a *spin-1 vector field* (an oriented "clock-wind"), not a spin-2 gravitational wave. BEH doesn't turn it into something else; it just adds a *gap* (so the effect is finite-range) and unlocks that *extra longitudinal wiggle*. The graviton sector stays pristine and separate; the CK continues to live in the *non-TT ledger*, acting as a *gapped carrier of temporal coherence*—organizing timing locally rather than globally.

Coupling, causality, and certification on the diagnostic realized reference configuration. The CK couples to geometry exclusively through the certified mixed blocks $\mathcal{L}_{h\tau}, \mathcal{L}_{\tau h}$ in the linearized diagnostic realized reference configuration law eq. (11.293), allowing CK to *dress* non–TT metric features without leaking into tensor polarizations. Its coherence imprint enters the RHS bookkeeping via the Maxwell/Proca–like term (vector piece in Section 11.8), while null–positivity is guaranteed by the Relational NEC (Section 11.6). Diagnostic realized reference configuration certification proceeds via typed correlator poles (existence of CK quanta, massless or massive) and witness predicates for actual *production* (which requires sources, mixing, or non–adiabatic background evolution, not BEH alone).

11.8.3 The Chrono-Kymon as a Unified Dark Sector Candidate

Massless Phase (Pre-BEH): Dark Radiation In its massless phase, the CK is a gauge-like, long-range coherence or phase-flow imprint on the weave. Its Maxwell-type stress is traceless, and if isotropically excited on the diagnostic realized reference configuration, it behaves as an extra **dark radiation** component. This contribution sits in the coherence-stress term built from the vector-typed piece $\mathcal{F}^{(\tau)}$ (cf. eqs. (11.235) and (11.248)) and contributes to the right-hand side (RHS) of the diagnostic realized reference configuration Einstein law (cf. Definition 11.106), while consistently obeying the Relational Null Energy Condition (NEC) (cf. Section 11.6). Critically, the CK remains Transverse–Traceless (TT)-null (cf. Section 10.4), ensuring it never contaminates the spin-2 gravitational wave (GW) polarizations. Conceptually, this phase is a long-range "clock-wind" that can subtly modify cosmic expansion and perturbation history without coupling to visible-sector Standard Model (SM) fields.

Broken Phase (After Internal BEH): Vector Dark Matter Once the **Brout–Englert–Higgs (BEH)** mechanism imparts a Proca mass ($m_{\mathrm{CK}} > 0$) to the CK (cf. eqs. (11.324) and (11.326)), its solutions—which possess three physical polarizations while retaining spin-1—redshift on average like pressureless matter. This dynamical behavior makes the CK a natural candidate for **vector dark matter (DM)**. The field's correlation length ($\xi_{\mathrm{CK}} \sim m_{\mathrm{CK}}^{-1}$) sets the characteristic size of coherent domains. The massive CK field remains "dark" because its universal coupling is exclusively through gravity—entering the RHS of Definition 11.106—and through any hidden-sector charges sharing its internal symmetry, bypassing direct coupling

to SM fields. The internal gauge-theoretic origin of this BEH upgrade is framed by the operator-bundle connection (cf. Section 6.6).

Dark Energy Potentiality The CK's Maxwell/Proca stress tensor does not generically yield the necessary equation of state ($w \simeq -1$) for **dark energy (DE)**. For it to mimic DE, the diagnostic realized reference configuration must sustain a nearly homogeneous, slowly varying CK background whose energy density is dominated by the potential or mass term, while the field strength $\mathcal{F}^{(\tau)}$ remains small enough to suppress anisotropic stress (cf. eq. (11.235)). In typed terms, the vector-typed contribution to the background coherence stress tensor $\bar{T}^{\mathrm{coh}}_{\mu\nu}$ must approximate an isotropic fluid and pass the Relational-NEC and diagnostic realized reference configuration diagnostics (cf. Section 11.6). Achieving this behavior is model-building–possible but significantly more constrained than the robust DM case.

Structural Consistency and Hygiene The Chrono-Kymon remains consistent with the structure of the unified theory through rigorous adherence to internal checks:

- The CK contribution always enters on the **RHS** of the field equations as coherence stress (cf. Definition 11.106), and influences the left-hand side (LHS) exclusively through background shifts of the temporal texture $\bar{t}_{\mu\nu}$; these background effects are detailed in the TT/complement framework (cf. Section 10.4).
- Causality, BRST symmetry, and Nielsen hygiene on a certified plateau ensure that the massive pole (if present) is physical and gauge-parameter independent; the massless case remains well-posed with Σ-causal Green functions (cf. Definition 9.62 and eq. (11.326)).
- In the low-energy (spectral/GR) limit, the emergent coupling scalarises and becomes universal (cf. Sections 11.5.7 and 11.5.8), so the CK's gravitational interaction is consistent with a dark sector coupling rule.

The overarching conclusion is that the Chrono-Kymon is a viable dark sector candidate: the BEH mechanism determines whether the field naturally inhabits the dark-radiation or vector–dark-matter corner of the cosmological landscape, while TT-purity keeps the spin-2 graviton channel uncontaminated (cf. eq. (11.293)).

11.8.4 BEH of the Gaiaton

Two complementary lenses; one physical mode. There is no contradiction between Chapters 10 and 11. The *Gaiaton* is a single *spin–0* scalar mode that appears (i) in Chapter 10 as the *radial (apeiron) scalar* of the Gaiamiti sector produced by global SSB (mass from the typed Hessian curvature), and (ii) in Chapter 11 as the *scalar piece of the τ–kairos*, namely the *non–TT scalar response* of the chronogeometric observable $\Sigma_{\mu\nu}$ to the same substrate fluctuations, obtained by linear response and typed projection. Formally, the two views are related by pushing forward the substrate fluctuations into chronogeometric fluctuations via the constitutive map and then selecting the non–TT scalar slot with the weave projectors (cf. Section 10.4 and Definitions 10.3 and 10.4).

Constitutive pushforward and typed selection (Ch. 10 → Ch. 11). Start from the constitutive map (Ch. 11)

$$\Sigma_{\mu\nu}[\Phi,\Theta] \;=\; g_{\mu\nu}[\Phi] \;+\; t_{\mu\nu}[\Phi,\Theta], \qquad \text{with background } (\bar\Phi,\bar\Theta).$$

Linearizing about $(\bar\Phi,\bar\Theta)$ gives the chain rule (Ch. 11)

$$\delta\Sigma_{\mu\nu} \;=\; (D_\Phi g)_{\mu\nu}\cdot\delta\Phi \;+\; (D_\Phi t)_{\mu\nu}\cdot\delta\Phi \;+\; (D_\Theta t)_{\mu\nu}\cdot\delta\Theta.$$

Let $\Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ be the certified TT projector and $\mathbb{P}_{\mathrm{nonTT}} := \mathrm{Id} - \Pi_{\bar\Sigma}^{[\mathrm{TT}]}$ the TT–complement (Ch. 11, τ–construction). Let S denote the scalar typed idempotent on symmetric rank–2 tensors (Ch. 11; cf. Definition 10.4). The *τ–kairos scalar* field used in Chapter 11 is

$$\tau_{\mathrm{scalar}} \;:=\; S\,\mathbb{P}_{\mathrm{nonTT}}\,\delta\Sigma \;=\; \underbrace{S\,\mathbb{P}_{\mathrm{nonTT}}\Big((D_\Phi g)+(D_\Phi t)\Big)}_{J_\Phi}\,\delta\Phi \;+\; \underbrace{S\,\mathbb{P}_{\mathrm{nonTT}}(D_\Theta t)}_{J_\Theta}\,\delta\Theta. \tag{11.328}$$

Thus τ_{scalar} is the *linear pushforward* of $(\delta\Phi,\delta\Theta)$ under the *constitutive Jacobians*

$$J_\Phi \;:=\; S\,\mathbb{P}_{\mathrm{nonTT}}\Big((D_\Phi g)+(D_\Phi t)\Big), \qquad J_\Theta \;:=\; S\,\mathbb{P}_{\mathrm{nonTT}}(D_\Theta t). \tag{11.329}$$

All typed/TT hygiene (orthogonality, TT–nullity, band causality) is inherited from the weave/realized weave configuration (Chs. 10–11; cf. Definition 9.116 and Proposition 9.202).

Origin of the Gaiaton in Chapter 10 (substrate/Hessian viewpoint). Let $\bar\Phi$ minimize the (effective) Gaiamiti potential. Decompose the Gaiamiti fluctuation into *tangential* NG directions and the *radial (apeiron)* direction using the typed projectors (Ch. 10):

$$\delta\Phi \;=\; \sum_a \pi^a\, v_a^{\mathrm{NG}} \;+\; H_{\mathrm{G}}\, v_{\mathrm{rad}}, \qquad v_{\mathrm{rad}} \;\propto\; \Pi_{\Phi\Phi}^{[S]}\,\bar\Phi. \tag{11.330}$$

The *typed Hessian* (curvature) of the potential restricted to the scalar slot gives the radial mass,

$$m_{\mathrm{G}}^2 \;\in\; \mathrm{spec}\Big(\Pi_{\Phi\Phi}^{[S]}\Big[\delta^2\mathcal{U}_{\Phi\Phi}\Big|_{\bar\Phi}\Big]\,\Pi_{\Phi\Phi}^{[S]}\Big)\,. \tag{11.331}$$

The *gapped radial scalar* H_{G} is the *Gaiaton* (Ch. 10 SSB result). NG directions are massless prior to internal gauging and may be eaten by connection–borne vectors only after gauging (BEH) in the relevant sector (cf. Section 9.17.3).

Detection of the same mode in Chapter 11 (response/spectral viewpoint). Insert the above decomposition into the pushforward:

$$\tau_{\mathrm{scalar}} \;=\; J_\Phi\Big(\sum_a \pi^a\, v_a^{\mathrm{NG}} + H_{\mathrm{G}}\, v_{\mathrm{rad}}\Big) \;+\; J_\Theta\,\delta\Theta \;=\; \underbrace{(J_\Phi v_{\mathrm{rad}})}_{\neq 0}\,H_{\mathrm{G}} \;+\; (\text{NG and } \Theta \text{ pieces}). \tag{11.332}$$

On the certified band, the τ–scalar block $K_\tau^{(0)}$ is analyzed with the *spin–0 Riesz selector* (Ch. 11, Definitions 10.68 and 10.70):

$$\mathsf{P}^{(0)}_{\text{spec}} = \sum_{m\in\mathfrak{S}_0} \frac{1}{2\pi i}\oint_{\zeta_m} \left(K_\tau^{(0)} - z\right)^{-1} dz, \qquad \text{realized masses } m_{0,\eta} \text{ from the enclosed poles/bands.} \tag{11.333}$$

Because τ_{scalar} is a linear image of $(\delta\Phi, \delta\Theta)$, its two–point function factorizes as

$$G_{\tau\tau} \;=\; J\, G_{\text{sub}}\, J^{*}, \qquad J := (J_\Phi, J_\Theta), \tag{11.334}$$

so the poles of $G_{\tau\tau}$ are inherited from the substrate correlators G_{sub}. In particular, the *radial* Φ *pole* at $p^2 = m_{\text{G}}^2$ appears in $G_{\tau\tau}$ with nonzero residue precisely when $J_\Phi v_{\text{rad}} \neq 0$ (ensured by typed construction and orthogonality). This is exactly what the Riesz selector isolates as the *Gaiaton channel* on the τ side. NG contributions are treated by the typed/BRST machinery: they remain massless before internal gauging, or are eaten in the τ–scalar BEH completion; in all cases, TT purity precludes leakage into the TT sector (cf. Lemma 10.17 and eq. (10.105)).

Reconciliation in one line. The Gaiaton is *not* created twice. Chapter 10 *identifies* the radial scalar H_{G} as a gapped substrate mode (mass from the typed Hessian). Chapter 11 *detects the same mode* in the τ–kairos by pushing substrate fluctuations through the constitutive Jacobian $J = (J_\Phi, J_\Theta)$ and then projecting to the non–TT scalar ledger; the scalar Riesz projector picks out the same pole in the τ–scalar correlator:

$$\begin{array}{rcl} \text{Gaiamiti radial mode } (H_{\text{G}}) & \xrightarrow{\text{constitutive } J} & \\ \tau\text{–scalar response } (\tau_{\text{scalar}}) & \xrightarrow{\text{Riesz/typed}} & \text{Gaiaton channel (Ch. 11)} \end{array}$$

All steps respect TT purity and typed orthogonality; the graviton (TT Goldstone-like branch) remains disjoint from the scalar (apeiron/Gaiaton) branch throughout (cf. Definition 10.3 and Proposition 9.202).

Internal BEH: τ–scalar (Gaiaton) completion. We apply BEH to the *τ–scalar multiplet* (the gaiaton slot) rather than to the Gaiamiti field of Chapter 10. Let $\mathcal{R}_\tau^{(S)}$ be the internal representation acting on the τ–scalar typed space, with gauge fields $\mathcal{B}_\mu^I$ and Lie–algebra metric $G_{IJ}^{(\tau)}$ in the kinetic term (cf. Section 9.17.3). Write the typed order parameter $\varphi^{[S]} := \Pi_{\Phi\Phi}^{[S]}\,\bar{\Phi}$ and parameterize the scalar fiber as $\Phi = \exp\!\big(\pi^I T_I\big)\big(\varphi^{[S]} + H_{\text{G}}\big)$, where π^I are the τ–scalar NG coordinates and H_{G} is the *radial* (gaiaton) fluctuation.

Vector masses from τ–sector SSB. If the τ–scalar symmetry is broken on $\mathfrak{P}$, the $\mathcal{B}_\mu^I$ acquire a BEH mass matrix built as "fiber pairing × algebra metric":

$$(\,M^2_{\tau\text{-vec}}\,)_{IJ} = g_\tau^2 \left\langle \mathcal{R}_\tau^{(S)}(T_I)\,\varphi^{[S]}\,,\, \mathcal{R}_\tau^{(S)}(T_J)\,\varphi^{[S]} \right\rangle, \qquad (\,G^{(\tau)}\,)^{IK} G^{(\tau)}_{KJ} = \delta^I{}_J, \tag{11.335}$$

and the NG coordinates π^I are eaten. A Stueckelberg presentation keeps BRST structure manifest if desired.

Surviving scalar (the gaiaton). The radial mode H_{G} survives as the physical **gaiaton**. Its quadratic diagnostic realized reference configuration functional is the typed τ–scalar corner of the non–TT block (cf. eqs. (11.293) and (11.294)):

$$\begin{aligned} S^{(2)}_{\text{Gaiaton}} = \frac{1}{2}\int \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\,\Big[H_{\mathrm{G}}\,\mathcal{K}_{SS}\,H_{\mathrm{G}} + 2\,H_{\mathrm{G}}\,\mathcal{K}_{Sg}\,(\delta g)_{\overline{\mathrm{TT}}}\Big] \\ - \kappa\int \sqrt{-\det \bar{g}^{\mathrm{Lor}}}\,\Big[H_{\mathrm{G}}\,\mathcal{J}_S + (\delta g)_{\overline{\mathrm{TT}}}\,\mathcal{J}_g\Big], \end{aligned} \tag{11.336}$$

with $\mathcal{K}_{SS}$ the τ–scalar kinetic operator and $\mathcal{K}_{Sg}$ the certified scalar–metric mixed kernel; sources are the scalar/complement projections of $\delta\bar{T}^{\mathrm{total}}$ (cf. Section 11.8). The gaiaton mass is set by the typed diagnostic realized reference configuration potential curvature,

$$m^2_{\text{Gaiaton}} = \left.\frac{\partial^2 \mathcal{V}_\Phi}{\partial \|\varphi^{[S]}\|^2}\right|_{\varphi^{[S]}=\langle\varphi^{[S]}\rangle}, \tag{11.337}$$

and covariant expansion generates the expected couplings $H_{\mathrm{G}}\,\mathcal{B}^I_\mu\mathcal{B}^{J\,\mu}$ with coefficients fixed by $\mathcal{R}^{(S)}_\tau$ and $\varphi^{[S]}$.

Placement in the mixed–block system and TT hygiene. This BEH completion refines the scalar corner (K_{SS}) and its sources in eq. (11.295), may induce controlled scalar–vector off–diagonals (K_{SA}, K_{AS}), and leaves the TT block closed: by Lemma 10.17 and eq. (10.105) the gaiaton and the $\mathcal{B}^I_\mu$ live entirely in the *non–TT ledger*. Couplings to the TT graviton h appear only through the certified mixed blocks $\mathcal{L}_{h\tau}, \mathcal{L}_{\tau h}$ (cf. eq. (11.293)); no extra spin–2 polarizations are created.

Remark 11.157 (Minimal $U(1)$ snapshot)**.** For $U(1)$ with charge $q_{\tau S}$: $m^2_{\mathcal{B}} = g^2_\tau q^2_{\tau S}\|\varphi^{[S]}\|^2$ and $S^{(2)}_{\text{Gaiaton}} = \frac{1}{2}\int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\big[(\bar{\nabla}H_{\mathrm{G}})^2 - m^2_{\text{Gaiaton}}H^2_{\mathrm{G}}\big] + \int\sqrt{-\det\bar{g}^{\mathrm{Lor}}}\,\alpha\,H_{\mathrm{G}}\,\mathcal{B}_\mu\mathcal{B}^\mu$, with $\alpha = g^2_\tau q^2_{\tau S}\|\varphi^{[S]}\|$ up to typed normalizations. This resides entirely in the non–TT subspace and respects TT purity.

The gaiaton is a *spin-0* (Lorentz-scalar) mode both *before* and *after* internal BEH in the τ–scalar sector. BEH changes its mass and couplings but *not* its spin (typed τ–kairos context from Ch. 11: cf. Definitions 10.4 and 10.15 and Section 10.4; TT purity from Lemma 10.17 and eq. (10.105)). Its scalar identity and diagnostic realized reference configuration mass input are already fixed in the global-SSB summary of Ch. 10 (cf. Section 9.17.3).

Setup (typed τ–scalar sector). Let the τ–scalar typed space carry an internal representation $\mathcal{R}^{(S)}_\tau$ (typed projectors and triad per Ch. 11, cf. Definitions 10.4 and 10.15). On the diagnostic realized reference configuration $\mathfrak{P}$ (with realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$ and $\bar{\nabla}$), introduce the typed order parameter

$$\varphi^{[S]} := \Pi^{[S]}_{\Phi\Phi}\,\bar{\Phi} \quad \text{and the } \textit{radial} \text{ fluctuation } H_{\mathrm{G}} \quad \text{so that} \quad \Phi = \exp\Big(\pi^I T_I\Big)\Big(\varphi^{[S]} + H_{\mathrm{G}}\Big),$$

with π^I the *typed NG coordinates* (Ch. 10: cf. Section 9.17.3; see also the Ch. 10 gauging scope and completion for context Sections 9.17.3 to 9.17.4). The gaiaton is, by definition, the *radial* scalar H_{G} in the τ–scalar slot of the non–TT ledger (TT-orthogonality from Ch. 11: Lemma 10.17 and eq. (10.105); typed τ construction from Section 10.4).

Pre–BEH: quadratic functional and scalar character. The non–TT block yields the scalar corner (cf. eqs. (11.293) to (11.295))

$$S^{(2)}_{\text{Gaiaton}} = \tfrac{1}{2}\langle H_{\text{G}},\, \mathcal{K}_{SS} H_{\text{G}}\rangle_{\mathfrak{P}} + \langle H_{\text{G}},\, \mathcal{K}_{Sg}(\delta g)_{\overline{\text{TT}}}\rangle_{\mathfrak{P}} + \cdots ,$$

where all pairings use $\bar{\Sigma}$ and $\bar{\nabla}$ (cf. Section 11.8). Under local Lorentz (with respect to $\bar{\Sigma}$), H_{G} transforms as a *scalar*:

$$H_{\text{G}}(x) \mapsto H'_{\text{G}}(x) = H_{\text{G}}(x), \qquad \Rightarrow \quad \text{Pauli–Lubanski: } W_\mu\, |H_{\text{G}}(p)\rangle = 0,$$

so the one–particle states created by H_{G} are spin–0. (Equivalently, the two-point $G_{SS}(x,y)$ is a scalar bisolution of $\mathcal{K}_{SS}$; no spin projectors other than the scalar one appear.)

BEH in the τ–scalar sector (not in Gaiamiti; cf. Section 9.17.3). Gauge the *τ–scalar* symmetry with fields $\mathcal{B}^I_\mu$ and algebra metric $G^{(\tau)}_{IJ}$:

$$D_\mu \Phi := \bar{\nabla}_\mu \Phi - g_\tau\, \mathcal{B}^I_\mu\, \mathcal{R}^{(S)}_\tau(T_I)\, \Phi.$$

Expanding the kinetic term $\langle D_\mu\Phi, D^\mu\Phi\rangle$ about $\varphi^{[S]}$ gives

$$\underbrace{\tfrac{1}{2}(\bar{\nabla} H_{\text{G}})^2}_{\text{scalar kinetic}} + \underbrace{\tfrac{1}{2}\,\mathcal{B}^I_\mu (M^2_{\tau\text{-vec}})_{IJ}\, \mathcal{B}^{J\mu}}_{\text{vector masses}} + \underbrace{\alpha_{IJ}\, H_{\text{G}}\, \mathcal{B}^I_\mu \mathcal{B}^{J\mu}}_{\text{typed } HBB \text{ coupling}} + \underbrace{(\partial_\mu \pi^I + \cdots)\mathcal{B}^\mu_I}_{\text{mixing}},$$

with

$$(M^2_{\tau\text{-vec}})_{IJ} = g_\tau^2 \left\langle \mathcal{R}^{(S)}_\tau(T_I)\, \varphi^{[S]},\, \mathcal{R}^{(S)}_\tau(T_J)\, \varphi^{[S]} \right\rangle, \qquad \alpha_{IJ} \propto g_\tau^2 \left\langle \mathcal{R}^{(S)}_\tau(T_I)\, \varphi^{[S]},\, \mathcal{R}^{(S)}_\tau(T_J)\, H_{\text{G}} \right\rangle,$$

(fiber pairing $\times$ algebra metric; cf. Section 9.18.8). In unitary gauge the NG coordinates π^I are eaten, and one obtains the *BEH-completed* quadratic piece

$$\begin{aligned} S^{(2)}_{\text{Gaiaton, BEH}} = {} & \tfrac{1}{2}\langle H_{\text{G}},\, \mathcal{K}_{SS} H_{\text{G}}\rangle_{\mathfrak{P}} - \tfrac{1}{2} m^2_{\text{Gaiaton}} \langle H_{\text{G}}, H_{\text{G}}\rangle_{\mathfrak{P}} \\ & + \tfrac{1}{2}\langle \mathcal{B}_\mu, (M^2_{\tau\text{-vec}})\mathcal{B}^\mu\rangle + \langle H_{\text{G}},\, \alpha_{IJ}\, \mathcal{B}^I_\mu \mathcal{B}^{J\mu}\rangle + \cdots , \end{aligned} \tag{11.338}$$

with

$$m^2_{\text{Gaiaton}} = \left.\frac{\partial^2 \mathcal{V}_\Phi}{\partial \|\varphi^{[S]}\|^2}\right|_{\varphi^{[S]} = \langle \varphi^{[S]}\rangle} \qquad \text{(typed DRRC curvature; cf. Section 9.17.3).}$$

Here "DRRC" refers to the diagnostic realized reference configuration of Definition 9.185.

Spin after BEH: unchanged (still 0). The Lorentz transformation on H_{G} is untouched by internal gauging:

$$H_{\text{G}}(x) \mapsto H_{\text{G}}(x) \quad \text{(scalar under local Lorentz)}, \qquad \mathcal{B}^I_\mu(x) \mapsto \Lambda_\mu{}^\nu\, \mathcal{B}^I_\nu(x) \quad \text{(vector)}.$$

Thus the Pauli–Lubanski operator (built from $\bar{\Sigma}$'s local Lorentz generators) still annihilates the one–particle gaiaton states:

$$W_\mu\, |H_{\text{G}}(p)\rangle_{\text{BEH}} = 0,$$

and the Källén–Lehmann representation of the τ–scalar two–point remains purely *scalar*,

$$G_{SS}(p) = \frac{Z_S}{p^2 - m^2_{\text{Gaiaton}} + i0} + \int_{4m_{\mathcal{B}}^2}^{\infty} d\mu^2 \, \frac{\rho_S(\mu^2)}{p^2 - \mu^2 + i0},$$

with $Z_S \in (0, 1]$ and *no* spin-1/2/2 projectors (contrast eq. (11.293) for the TT sector). Couplings $H_{\text{G}}\,\mathcal{B}\mathcal{B}$ renormalize m^2_{Gaiaton} and Z_S but do not change the Lorentz *type*. In particular, TT hygiene enforces

$$\Pi^{[\text{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0, \qquad \Pi^{[\text{TT}]}_{\bar{\Sigma}}\,(\text{any functional of } H_{\text{G}}) = 0,$$

so no spin–2 content is ever created (cf. Lemma 10.17 and eq. (10.105)).

Conclusion. *Before* BEH, the gaiaton H_{G} is a scalar (spin–0) governed by the τ–scalar corner $\mathcal{K}_{SS}$. *After* BEH in the τ–scalar sector, NG modes are eaten and τ–vectors become massive, while the same H_{G} survives with updated (m, Z) and scalar interactions (e.g. $H\mathcal{B}\mathcal{B}$). Its Lorentz spin remains 0 throughout; only its mass/couplings change. The TT graviton sector stays closed and pure by Lemma 10.17 and eq. (10.105).

Gaiaton after τ–sector BEH: NG removal and spin conservation. Consider the τ–scalar typed space in representation $\mathcal{R}^{(S)}_{\tau}$ with typed projectors as in Ch. 11 (cf. Definition 10.4 and Section 10.4). On the diagnostic realized reference configuration $\mathfrak{P}$ with realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$ and connection $\bar{\nabla}$, introduce the typed order parameter and radial fluctuation

$$\varphi^{[S]} := \Pi^{[S]}_{\Phi\Phi}\,\bar{\Phi}, \qquad \Phi = \exp\!\big(\pi^I T_I\big)\big(\varphi^{[S]} + H_{\text{G}}\big),$$

where π^I are τ–scalar NG coordinates (Ch. 10; cf. Section 9.17.3). The *gaiaton* is the radial scalar H_{G} in the τ–scalar slot of the non–TT ledger; TT orthogonality and purity follow from Ch. 11 (cf. Lemma 10.17 and eq. (10.105)).

(i) NG removal via the τ–vector EOM. Gauge the τ–scalar symmetry with gauge fields $\mathcal{B}^I_\mu$ and algebra metric $G^{(\tau)}_{IJ}$ (cf. Section 9.17.3). The BEH mass matrix is

$$\begin{aligned} (M^2_{\tau\text{-vec}})_{IJ} &= g_\tau^2 \left\langle \mathcal{R}^{(S)}_{\tau}(T_I)\,\varphi^{[S]}\,,\, \mathcal{R}^{(S)}_{\tau}(T_J)\,\varphi^{[S]} \right\rangle, \\ (M^2_{\tau\text{-vec}})^I{}_J &:= G^{(\tau)\,IK}(M^2_{\tau\text{-vec}})_{KJ} \quad \text{(cf. Section 9.18.8)}. \end{aligned} \tag{11.339}$$

The τ–vector Proca/BEH equation of motion reads

$$\bar{\nabla}_\mu \mathcal{F}^{I\,\mu\nu} + (M^2_{\tau\text{-vec}})^I{}_J\,\mathcal{B}^{J\,\nu} = J^{I\,\nu}_{(\tau)}, \qquad \mathcal{F}^I_{\mu\nu} := 2\bar{\nabla}_{[\mu}\mathcal{B}^I_{\nu]}. \tag{11.340}$$

Taking $\bar{\nabla}_\nu$ of (11.340) and using $\bar{\nabla}_\nu \mathcal{F}^{I\,\mu\nu}$ antisymmetry gives

$$(M^2_{\tau\text{-vec}})^I{}_J\,\bar{\nabla}_\nu \mathcal{B}^{J\,\nu} = \bar{\nabla}_\nu J^{I\,\nu}_{(\tau)} \;\Rightarrow\; \bar{\nabla}_\nu \mathcal{B}^{I\,\nu} = 0 \quad \text{on shell if} \quad \bar{\nabla}_\nu J^{I\,\nu}_{(\tau)} = 0. \tag{11.341}$$

Thus the NG coordinates are removed (eaten) by the vector fields. Equivalently, in a Stueckelberg presentation, the mass term $\frac{1}{2}\,G^{(\tau)}_{IJ}(M\mathcal{B}_\mu - \bar{\nabla}_\mu\sigma)^I(M\mathcal{B}^\mu - \bar{\nabla}^\mu\sigma)^J$ is gauge-fixed by $\sigma = 0$ (unitary gauge), reproducing (11.341). The dynamics remain in the non–TT block of the mixed system (cf. eqs. (11.293) and (11.294)), preserving TT closure.

(ii) Spin of the gaiaton is unchanged (Pauli–Lubanski test). The gaiaton H_{G} is a scalar density of weight 0 relative to $\bar{\Sigma}$. Let Q_ω be the Noether charge for an infinitesimal local Lorentz transformation with parameter $\omega^{\mu\nu} = -\omega^{\nu\mu}$. The typed Peierls bracket (equal-time limit agreeing with ETCR on $\mathfrak{P}$; cf. Section 11.8.1) gives the field variation

$$\delta_\omega H_{\mathrm{G}}(x) = \{H_{\mathrm{G}}(x), Q_\omega\}_{\mathrm{P}} = -\tfrac{1}{2}\,\omega^{\mu\nu}\left(x_\mu \bar{\nabla}_\nu - x_\nu \bar{\nabla}_\mu\right) H_{\mathrm{G}}(x), \tag{11.342}$$

which contains no intrinsic (spin) term (Peierls map and its equal-time limit: [155]; Noether–Lorentz generators on fields: [14, 82]). Passing to momentum space, the Lorentz generators act purely orbitally on the one-particle space created by H_{G}. The Pauli–Lubanski vector

$$W_\mu := -\tfrac{1}{2}\,\epsilon_{\mu\nu\rho\sigma}\, M^{\nu\rho} P^\sigma \tag{11.343}$$

therefore annihilates these states:

$$W_\mu\,|H_{\mathrm{G}}(p)\rangle = 0 \;\Rightarrow\; W^2\,|H_{\mathrm{G}}(p)\rangle = -m^2_{\text{Gaiaton}}\, s(s+1)\,|H_{\mathrm{G}}(p)\rangle = 0, \tag{11.344}$$

so $s = 0$ both before and after BEH (Pauli–Lubanski Casimir and Wigner classification: [482, 14, 255]). The scalar two–point admits the Källén–Lehmann form without non-scalar projectors,

$$G_{SS}(p) = \frac{Z_S}{p^2 - m^2_{\text{Gaiaton}} + i0} + \int_{4m^2_{\tau\text{-vec}}}^{\infty} d\mu^2\, \frac{\rho_S(\mu^2)}{p^2 - \mu^2 + i0}, \qquad Z_S \in (0,1], \tag{11.345}$$

consistent with the spectral representation for scalar channels ([14, 82, 255]).

TT hygiene and placement. All constructions above lie in the τ–kairos (Ch. 11; cf. Definition 10.4 and Section 10.4) and the non–TT ledger. TT purity is preserved:

$$\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\hat{\tau}_{\mu\nu} = 0, \qquad \hat{h}_{\mu\nu} = \Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}\,\delta\hat{g}_{\mu\nu} \quad \text{(cf. Lemma 10.17 and eq. (10.105))}. \tag{11.346}$$

The BEH completion of the τ–scalar sector refines the scalar corner in the mixed–block operator (cf. eqs. (11.294) and (11.295)) and modifies masses/couplings, but not the gaiaton's spin.

Identity and degrees of freedom. The *Chrono–Kymon (CK)* is the vector–typed piece of the τ–kairos, i.e. the TT–complement of chronogeometric fluctuations selected by the certified projector $\Pi^{[\mathrm{TT}]}_{\bar{\Sigma}}$ (cf. Section 10.4 and Definition 10.3). In the unbroken phase it is a massless spin–1 field with two physical helicities $\lambda = \pm$. When an internal gauge symmetry acting on the CK representation is spontaneously broken on the diagnostic realized reference configuration $\mathfrak{P}$ (via the operator–bundle connection), the CK sector undergoes the Brout–Englert–Higgs (BEH) reorganization and upgrades from the Maxwell form to a Proca form (cf. eqs. (11.324) and (11.326)). The resulting massive CK is still spin–1 but now exhibits three physical polarizations $\lambda = \pm, 0$; the new longitudinal polarization reflects massiveness, not a change of spin. The *Gaiaton* is the scalar–typed (radial) piece of the τ–kairos defined by the typed scalar projector of the weave (Ch. 11; cf. Definitions 10.4 and 10.15 and Section 10.4). Before BEH in the τ–scalar sector it is a spin–0 radial mode;

after τ–scalar BEH (distinct from the Gaiamiti completion of Ch. 10), the Nambu–Goldstone directions in the scalar slot are eaten by τ–sector vectors while the radial Gaiaton survives as a spin–0 scalar. In both cases BEH modifies masses and couplings but not Lorentz spin (cf. Ch. 10 Section 9.17.3).

Background imprint. The CK imprints an *antisymmetric* temporal texture through its gauge–invariant strength $\mathcal{F}^{(\tau)}_{\mu\nu} = 2\,\bar{\nabla}_{[\mu}K^{(\tau)}_{\nu]}$, yielding $\Delta t^{(\tau)}_{[\mu\nu]} \propto \mathcal{F}^{(\tau)}_{\mu\nu}$ in the typed mean (cf. eqs. (11.288) and (11.289)). By contrast, scalar maps $S^{(\cdot)}[\varphi]$ generate a *symmetric* shift $\Delta t^{(\tau)}_{(\mu\nu)}$ associated with the Gaiaton (no antisymmetric twist). Both enter the background shift $\bar{\Sigma} \mapsto \bar{\Sigma}' = \bar{g} + \bar{t}'$ and modify the geometric and radiative operators at first order as in eqs. (11.290) and (11.291), while remaining TT–null (cf. eqs. (10.105), (11.285) and (11.286) and Lemma 10.17).

Range and the effect of BEH. In the massless phase the CK mediates *long–range* coherence of phase–flow (Maxwell–like propagation). After BEH it becomes a Proca field with *finite range* set by the correlation length $\xi_{\mathrm{CK}} \sim m_{\mathrm{CK}}^{-1}$ and gains a longitudinal polarization (cf. eqs. (11.324) and (11.326)). The Gaiaton's range is controlled by its scalar mass m_{G} obtained from the typed curvature of the diagnostic realized reference configuration potential, $m_{\mathrm{G}}^2 = \partial^2\mathcal{V}_\Phi/\partial\|\varphi^{[S]}\|^2|_{\mathrm{DRRC}}$ (cf. Section 9.17.3). After τ–scalar BEH the τ–sector vectors acquire a mass matrix

$$(M^2_{\tau\text{-vec}})_{IJ} = g_\tau^2 \left\langle \mathcal{R}^{(S)}_\tau(T_I)\,\varphi^{[S]}\,,\, \mathcal{R}^{(S)}_\tau(T_J)\,\varphi^{[S]} \right\rangle G^{(\tau)\,IJ},$$

while the Gaiaton remains a scalar with updated m_{G} determined by the same typed curvature (cf. Section 9.18.8).

Placement in the mixed–block system. Within the linearized diagnostic realized reference configuration law (cf. eq. (11.293)), the CK occupies the vector corner K_{AA} and mixes constitutively through K_{Ag}, K_{AS}; the Gaiaton occupies the scalar corner K_{SS} and mixes via K_{Sg}, K_{SA} (cf. eqs. (10.94), (10.101), (11.294) and (11.295)). All entries lie strictly in the non–TT ledger; the TT block remains closed by TT–purity (cf. Lemma 10.17 and eq. (10.105)).

Coupling to geometry. Both CK and Gaiaton alter the *background* felt by TT waves through the typed coherence shift $\Delta\Sigma^{(\tau)}$, thereby modifying dispersion/effective potentials via eqs. (11.290) and (11.291). Neither generates additional spin–2 polarizations; the graviton channel is isolated by the certified TT projector (cf. Definition 10.3, Lemma 10.17, and eq. (10.105)).

Source and energy structure. The CK coherence stress is built from $\mathcal{F}^{(\tau)}_{\mu\nu}$ (and includes $m^2_{\mathrm{CK}}K^{(\tau)}_\mu K^{(\tau)\mu}$ when massive) and remains typed and covariant; the Gaiaton stress arises from $(\bar{\nabla}H_{\mathrm{G}})^2$ and the curvature of $\mathcal{V}_\Phi$. In both cases the stress satisfies the Relational NEC on the diagnostic realized reference configuration (cf. Sections 11.6 and 11.8).

Summary. The CK is a *vector phase–flow carrier* whose BEH transition converts long–range coherence into finite–range mediation while preserving spin–1. The Gaiaton is a *scalar background–stiffness controller* whose BEH occurs in the τ–scalar sector: it remains spin–0 as nearby τ–vectors become massive and its own mass/couplings shift. In all cases the TT graviton sector (two tensor polarizations) remains unaffected by construction (cf. eq. (11.293) and Lemma 10.17).

A simple way to picture the gaiaton. The gaiaton is a *rate–stiffness dial* for the chronogeometric medium. In its massless/light regime it behaves like a gentle, uniform change to the medium's "elasticity," subtly adjusting how quickly disturbances propagate without twisting time (its imprint is *symmetric*, not antisymmetric). It does not radiate spin–2 waves; it quietly shifts the background against which those waves travel. After BEH in the τ–scalar sector, the scalar Nambu–Goldstone directions are eaten by nearby τ–vectors, which become massive, while the *radial* gaiaton remains a scalar. What changes is not its identity but its *reach and couplings*: its mass (m_{G}) (set by the typed curvature of ($\mathcal{V}_\Phi$)) fixes a scalar correlation length ($\xi_{\mathrm{G}} \sim m_{\mathrm{G}}^{-1}$), and it now couples locally to the massive τ–vectors (terms like $\langle H_{\mathrm{G}}, \mathcal{B}_\mu \mathcal{B}^\mu \rangle$). The role is still to regulate background "stiffness" and dispersion—not to carry phase-flow or create tensor polarizations.

- *Drum-head tension.* The gaiaton acts like a global tensioner on a drum skin: increasing tension raises the pitch and speeds surface waves; relaxing it lowers the pitch. Pre-BEH, tension can drift smoothly; post-BEH, tension adjustments remain but also couple to added hardware (the now-massive τ–vectors).

- *Index of refraction.* It is an index field for the chronogeometric medium: higher index slows signals, lower index speeds them. BEH makes this index modulator interact with short-range "access points" (massive τ–vectors) but does not change it into a vector; it stays a scalar knob.

- *Metronome tempo knob.* If the CK is a "clock–wind" aligning directions, the gaiaton is the "tempo knob" setting how fast the beat runs. After BEH, the tempo knob still sets the beat, while additional damped linkages (massive vectors) limit how far that adjustment propagates.

Bottom line. The CK is a *vector phase–flow carrier* (twist, antisymmetric imprint) that becomes finite–range and gains a longitudinal mode after BEH but remains spin–1. The gaiaton is a *scalar stiffness/rate controller* (symmetric imprint) that remains spin–0 before and after BEH; BEH chiefly localizes its influence and introduces scalar–vector couplings, without touching the graviton's TT sector.

11.8.5 Gaiaton as the Dark Matter and Energy Candidate

Post–BEH validity of Proposition 10.153. Yes. After completing the τ–scalar BEH (which eats the τ–scalar NG directions and gives mass to the τ–sector vectors), the *radial* scalar H_{G}—the Gaiaton—remains a spin–0 field in the non–TT ledger with updated mass and

typed couplings (cf. Section 10.8 and the τ–scalar BEH completion in Ch. 12). The dark–sector proposition remains valid with the replacements $\mathcal{V}_\Phi \to \mathcal{V}_\Phi^{(\tau\text{–BEH})}$ (the gauge–invariant, Nielsen–stable effective potential on the certified plateau) and with the inclusion of the induced scalar–vector couplings from the BEH completion (cf. Section 9.17.3 and Definition 10.68).

Low–energy post–BEH scalar sector (unitary gauge). On a certified plateau $\mathfrak{P}$ with realized chronogeometry $(\mathcal{X}_q, \bar{\Sigma})$ and Levi–Civita $\bar{\nabla}$, the quadratic-plus-interaction scalar sector for the Gaiaton takes the form

$$\begin{aligned} S_{\mathrm{G}} = \int \sqrt{-\det \bar{g}^{\mathrm{Lor}}} \Big[& \tfrac{1}{2}\, \bar{\nabla}_\mu H_{\mathrm{G}}\, \bar{\nabla}^\mu H_{\mathrm{G}} - \mathcal{V}_\Phi^{(\tau\text{–BEH})}(H_{\mathrm{G}}) \\ & + \tfrac{1}{2}\, \mathcal{B}^I_\mu (M^2_{\tau\text{–vec}})_{IJ}\, \mathcal{B}^{J\mu} + \alpha_{IJ}\, H_{\mathrm{G}}\, \mathcal{B}^I_\mu \mathcal{B}^{J\mu} + \dots \Big], \end{aligned} \tag{11.347}$$

where $(M^2_{\tau\text{–vec}})_{IJ} = g_\tau^2 \langle \mathcal{R}_\tau^{(S)}(T_I)\, \varphi^{[S]},\, \mathcal{R}_\tau^{(S)}(T_J)\, \varphi^{[S]} \rangle\, G^{(\tau)\, IJ}$ is the τ–vector mass matrix generated by τ–scalar BEH (cf. Ch. 12), and α_{IJ} are the typed $H\mathcal{B}\mathcal{B}$ coefficients fixed by $\mathcal{R}_\tau^{(S)}$ and $\varphi^{[S]}$ (cf. the scalar corner refinement of eqs. (11.294) and (11.295)). Physical observables extracted from (11.347) on $\mathfrak{P}$ are gauge–parameter independent by Nielsen identities, exactly as in Chs. 10–11.

Dark energy channel (post–BEH). Let H_{G} be spatially coherent on cosmological slices and define $\rho_H = \frac{1}{2}\dot{H}_{\mathrm{G}}^2 + \mathcal{V}_\Phi^{(\tau\text{–BEH})}$, $p_H = \frac{1}{2}\dot{H}_{\mathrm{G}}^2 - \mathcal{V}_\Phi^{(\tau\text{–BEH})}$ (with overdots taken along the diagnostic realized reference configuration flow; cf. the scalar typed stress entry $S_{\mu\nu}[\hat{\varphi}_A]$ in Definitions 10.4 and 10.13). The equation–of–state parameter is $w_H = (p_H/\rho_H) = (K - V)/(K + V)$ with $K = \frac{1}{2}\dot{H}_{\mathrm{G}}^2$, $V = \mathcal{V}_\Phi^{(\tau\text{–BEH})}$. In the slow–roll/quintessence regime,

$$\epsilon_V := \frac{M_{\mathrm{P}}^2}{2}\Big(\frac{\partial_H \mathcal{V}_\Phi^{(\tau\text{–BEH})}}{\mathcal{V}_\Phi^{(\tau\text{–BEH})}}\Big)^2 \ll 1, \qquad \eta_V := M_{\mathrm{P}}^2\, \frac{\partial_H^2 \mathcal{V}_\Phi^{(\tau\text{–BEH})}}{\mathcal{V}_\Phi^{(\tau\text{–BEH})}} \ll 1, \tag{11.348}$$

and any energy transfer to massive τ–vectors is negligible on Hubble times, $\Gamma_{H\to\mathcal{B}\mathcal{B}} \ll H$ (or kinematically forbidden if $m_{\mathrm{G}} < 2m_{\mathcal{B}}$), one has $w_H \simeq -1 + 2K/V \approx -1$ (cf. Section 10.8). Hence item (1) of Proposition 10.153 remains valid post–BEH, with $\mathcal{V}_\Phi \to \mathcal{V}_\Phi^{(\tau\text{–BEH})}$ and with the slow–roll conditions (11.348) evaluated on the BEH–completed effective potential.

Dark matter channel (post–BEH). Near a minimum, write $\mathcal{V}_\Phi^{(\tau\text{–BEH})} = \frac{1}{2}m_{\mathrm{G}}^2 H_{\mathrm{G}}^2 + \mathcal{O}(H_{\mathrm{G}}^3)$. When $H \lesssim m_{\mathrm{G}}$ the field undergoes coherent oscillations; averaged over many periods, $\langle w_H \rangle \simeq 0$ for a quadratic minimum, yielding a pressureless condensate (*misalignment*). Post–BEH viability requires:

$$\begin{aligned} &\text{(i) stability:} && \Gamma_{H\to\mathcal{B}\mathcal{B}} \ll H_0 \ \ \text{(or forbidden if } m_{\mathrm{G}} < 2m_{\mathcal{B}}), \\ &\text{(ii) weak portals:} && |\alpha_{IJ}\langle \mathcal{B}^I_\mu \mathcal{B}^{J\mu} \rangle| \ll \rho_H, \end{aligned} \tag{11.349}$$

together with the usual abundance/misalignment bounds (initial displacement, onset epoch), all read on the certified band with the scalar Riesz selector (Definition 10.68). Under (11.349), item (2) of Proposition 10.153 remains valid post–BEH.
