Proof. Cohomologically trivial (or symmetry-preserving) deformations commute with the quadrant projectors on $\mathcal{H}_{\mathrm{phys}}$, hence each branch is block-diagonal in q and so is $M_\alpha = (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$. Taking traces with $\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$ that is itself block-diagonal yields eq. (7.103). The final claim follows by applying the plateau certification and robustness results to each block and using that gauge artefacts have been excluded by BRST/Nielsen protection. □

7.4.1 Readout and Complex Coherence Amplitude

Definition 7.135 (Complex coherence amplitude)**.** After $U_{\mathrm{ctrl}}^{(\alpha)}(T)$, define the *complex coherence amplitude*

$$\mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell;T) := \frac{\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\,U_1^{(\alpha)}(T)\,\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\,U_0^{(\alpha)\dagger}(T)\,\mathsf{P}_{\mathrm{phys}}\Big)}{\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)}. \tag{7.115}$$

Lemma 7.136 (Ancilla readout relations)**.** *Measuring the ancilla Pauli operators directly after $U_{\mathrm{ctrl}}^{(\alpha)}(T)$ (no additional rotations) yields*

$$\langle\sigma_x\rangle_\alpha = \mathrm{Re}\;\mathcal{C}_\alpha, \qquad \langle\sigma_y\rangle_\alpha = \mathrm{Im}\;\mathcal{C}_\alpha, \qquad \Rightarrow \quad |\mathcal{C}_\alpha| = \sqrt{\langle\sigma_x\rangle_\alpha^2 + \langle\sigma_y\rangle_\alpha^2}. \tag{7.116}$$

Proof. Let the system+ancilla initial state be $\rho_{\mathrm{anc}} = |+\rangle\langle+|$ and $\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$ on $\mathcal{H}_{\mathrm{phys}}$. Propagating by $U_{\mathrm{ctrl}}^{(\alpha)}(T)$ and tracing out the system gives the ancilla reduced density matrix with off-diagonal element $\rho_{\mathrm{anc}}^{01} = \mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}U_1^{(\alpha)}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}U_0^{(\alpha)\dagger}\mathsf{P}_{\mathrm{phys}}\Big)\Big/\,\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) = \mathcal{C}_\alpha$. Hence the Bloch components satisfy $\langle\sigma_x\rangle = \mathrm{Re}\;\mathcal{C}_\alpha$ and $\langle\sigma_y\rangle = \mathrm{Im}\;\mathcal{C}_\alpha$, giving (7.116). □

Definition 7.137 (Signed visibility)**.** Fix a reference phase $\phi_\alpha \in \mathbb{R}$. The *signed visibility* is

$$\Lambda_\alpha(\lambda_{\mathrm{UV}},\ell;T) := \mathrm{Re}\Big(e^{-i\phi_\alpha}\,\mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell;T)\Big), \qquad -1 \le \Lambda_\alpha \le 1. \tag{7.117}$$

Choosing $\phi_\alpha = \arg\mathcal{C}_\alpha$ maximises Λ_α at $|\mathcal{C}_\alpha|$.

Proposition 7.138 (Equivalence to the complex visibility on $\mathcal{H}_{\mathrm{phys}}$)**.** *Assume (i) $\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\mathsf{P}_{\mathrm{phys}}$ as in (7.95), and (ii) the branches preserve the physical sector in the sense of (7.97) (cohomologically trivial defect on $\mathcal{H}_{\mathrm{phys}}$). Then $\mathcal{C}_\alpha$ equals the complex visibility $\mathcal{V}_\alpha$ of (7.98):*

$$\mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell;T) = \mathcal{V}_\alpha(\lambda_{\mathrm{UV}},\ell;T).$$

Proof. Insert $\mathsf{P}_{\mathrm{phys}}$ on both sides of the numerator in (7.115) and use $\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathsf{P}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\mathsf{P}$ with $\mathsf{P} := \mathsf{P}_{\mathrm{phys}}$. By hypothesis (ii), the action of $U_j^{(\alpha)}(T)$ on $\mathcal{H}_{\mathrm{phys}}$ is equivalent to its projection, so $\mathsf{P}U_j^{(\alpha)}(T)\mathsf{P}$ can be replaced by $U_j^{(\alpha)}(T)$ inside physical matrix elements. Thus the numerator in (7.115) equals that of (7.98), and the denominators coincide by (7.95). □

Proposition 7.139 (Bounds and normalisation for $\mathcal{C}_\alpha$)**.** *Let $M_\alpha := (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$ and $\rho := \rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$. Then*

$$|\mathcal{C}_\alpha| = \frac{|\,\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho\,M_\alpha)|}{\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho)} \le 1,$$

whence $\mathrm{Re}\;\mathcal{C}_\alpha \in [-1,1]$ *and* $|\mathcal{C}_\alpha| \in [0,1]$. *If* $\mathrm{Tr}(\rho) = 1$, *the denominator in* (7.115) *equals* 1.

Proof. M_α is unitary; apply the same Hölder/Cauchy–Schwarz argument as in Proposition 7.128, now with the explicit $\mathsf{P}_{\mathrm{phys}}$ insertions (which do not increase the operator norm and preserve trace-class structure). □

Remark 7.140 (Phase/readout convention)**.** Equation (7.116) uses the "no post-rotation" convention (measure $\sigma_{x,y}$ directly after U_{ctrl}), giving $\langle\sigma_y\rangle = \mathrm{Im}\;\mathcal{C}_\alpha$. If instead a Hadamard is applied before readout (as elsewhere in the chapter), the y-component acquires a minus sign, yielding $\langle\sigma_y\rangle = -\,\mathrm{Im}\;\mathcal{V}_\alpha$ for the visibility form (7.98). Both conventions are equivalent up to a fixed phase choice ϕ_α in (7.117).

Derivation of the readout (one-qubit interferometer).

Lemma 7.141 (Derivation of the readout (one-qubit interferometer))**.** *Let the ancilla be prepared in* $|+\rangle$ *and the system in* ρ_{phys} *(shorthand for* $\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$*). Under the controlled evolution* (7.96) *followed by a Hadamard on the ancilla, one has*

$$\langle\sigma_x\rangle_\alpha = \frac{\mathrm{Tr}\big(U_1^{(\alpha)}\rho_{\mathrm{phys}}U_0^{(\alpha)\dagger}\big)}{\mathrm{Tr}\,\rho_{\mathrm{phys}}}, \qquad \langle\sigma_y\rangle_\alpha = \frac{\mathrm{Tr}\big(-i\,U_1^{(\alpha)}\rho_{\mathrm{phys}}U_0^{(\alpha)\dagger}\big)}{\mathrm{Tr}\,\rho_{\mathrm{phys}}},$$

which is equivalent to the interferometric relations (7.116)*.*

Proof. Evolve $|+\rangle\langle+|\otimes\rho_{\mathrm{phys}}$ by $U_{\mathrm{ctrl}}^{(\alpha)}(T)$, apply a Hadamard on the ancilla, and trace out the system. The off-diagonal entry of the reduced ancilla equals $\mathrm{Tr}(U_1^{(\alpha)}\rho_{\mathrm{phys}}U_0^{(\alpha)\dagger})/\,\mathrm{Tr}\,\rho_{\mathrm{phys}}$. Identifying the Bloch components gives the displayed formulas. Using $\langle\sigma_x\rangle = \mathrm{Re}(\cdot)$ and $\langle\sigma_y\rangle = -\,\mathrm{Im}(\cdot)$ yields (7.116). □

Proposition 7.142 (Bounds and extremal cases)**.** *Let* $\mathcal{C}_\alpha$ *be as in* (7.115) *and* Λ_α *as in* (7.117)*. Then*

$$|\mathcal{C}_\alpha| \le 1, \qquad |\Lambda_\alpha| \le 1, \tag{7.118}$$

with equality iff $U_1^{(\alpha)}(T)\rho_{\mathrm{phys}}U_0^{(\alpha)\dagger}(T)$ *is a positive multiple of* ρ_{phys} *(*pure state case: $U_1^{(\alpha)}(T)\,|\psi\rangle = e^{i\varphi}U_0^{(\alpha)}(T)\,|\psi\rangle$*). For the* state channel *with a common* $U(T)$ *and preparations* $\rho_j = W_j\rho W_j^\dagger$*, one has* $\mathcal{C}_{\mathrm{state}} \propto \mathrm{Tr}(\rho_1\rho_0)$*; for pure preparations this reduces to* $\langle\psi_1|\psi_0\rangle$*.*

Proof. Write $M_\alpha := (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$, so $|\mathcal{C}_\alpha| = |\,\mathrm{Tr}(\rho_{\mathrm{phys}}M_\alpha)|/\,\mathrm{Tr}\,\rho_{\mathrm{phys}}$ and $\|M_\alpha\|_\infty = 1$ (unitary). By Cauchy–Schwarz for the Hilbert–Schmidt inner product, $|\,\mathrm{Tr}(\rho M_\alpha)| \le \|\rho^{1/2}\|_2^2\|M_\alpha\|_\infty = \mathrm{Tr}\,\rho$, giving (7.118). Equality holds iff $\rho^{1/2}$ and $M_\alpha\rho^{1/2}$ are linearly dependent, i.e. $M_\alpha\rho = c\,\rho$ with $c \ge 0$, equivalent to the stated proportionality; for pure $\rho = |\psi\rangle\langle\psi|$ this is $M_\alpha\,|\psi\rangle = e^{i\varphi}\,|\psi\rangle$. For the final claim, insert $U_j^{(\mathrm{state})} = UW_j$ in (7.115) and use cyclicity to obtain $\mathcal{C}_{\mathrm{state}} \propto \mathrm{Tr}(W_1\rho W_0^\dagger) = \mathrm{Tr}(\rho_1\rho_0)$; for pure preparations this gives $\langle\psi_1\rangle\,\psi_0$. □

Proposition 7.143 (Short-time expansion and decay scales)**.** *Let* $\delta\hat H_\alpha := \hat H_1^{(\alpha)} - \hat H_0^{(\alpha)}$ *and assume time-independent branches. Then on* $\mathcal{H}_{\mathrm{phys}}$*,*

$$\mathcal{C}_\alpha(T) = 1 - iT\,\frac{\mathrm{Tr}(\rho_{\mathrm{phys}}\delta\hat H_\alpha)}{\mathrm{Tr}\,\rho_{\mathrm{phys}}} - \frac{T^2}{2}\,\frac{\mathrm{Tr}\big(\rho_{\mathrm{phys}}(\delta\hat H_\alpha - \langle\delta\hat H_\alpha\rangle)^2\big)}{\mathrm{Tr}\,\rho_{\mathrm{phys}}} + \mathcal{O}(T^3), \tag{7.119}$$

so that $|\mathcal{C}_\alpha(T)|^2 = 1 - T^2\,\sigma_\alpha^2 + \mathcal{O}(T^3)$*, with* $\langle A\rangle := \mathrm{Tr}(\rho_{\mathrm{phys}}A)/\,\mathrm{Tr}\,\rho_{\mathrm{phys}}$ *and* $\sigma_\alpha^2 := \langle(\delta\hat H_\alpha - \langle\delta\hat H_\alpha\rangle)^2\rangle$*. This expansion is band-safe since* ρ_{phys} *and* $\hat H_j^{(\alpha)}$ *are constructed with* $P_x(\lambda_{\mathrm{UV}})$ *and* $K_{\mathrm{IR}}^{(\ell)}$*.*

Proof. By cyclicity, $\mathcal{C}_\alpha(T) = \langle e^{i\hat H_0^{(\alpha)}T}e^{-i\hat H_1^{(\alpha)}T}\rangle$ with the normalised expectation $\langle\cdot\rangle$. Using the Baker–Campbell–Hausdorff formula, $e^{iH_0T}e^{-iH_1T} = \exp\big(-i\delta\hat H_\alpha T + \frac{T^2}{2}[H_0,H_1] + \mathcal{O}(T^3)\big)$. Expanding the exponential and keeping terms up to $\mathcal{O}(T^2)$ yields

$$\mathcal{C}_\alpha(T) = 1 - iT\langle\delta\hat H_\alpha\rangle - \tfrac{T^2}{2}\langle(\delta\hat H_\alpha)^2\rangle + \tfrac{T^2}{2}\langle[H_0,H_1]\rangle + \mathcal{O}(T^3).$$

Since $[H_0,H_1]$ is anti-Hermitian, $\langle[H_0,H_1]\rangle$ is purely imaginary and contributes only a phase (no change in modulus). Writing $\langle(\delta\hat H_\alpha)^2\rangle = \sigma_\alpha^2 + \langle\delta\hat H_\alpha\rangle^2$ and absorbing the purely imaginary quadratic phase into the reference phase ϕ_α gives (7.119). Squaring the modulus then yields $|\mathcal{C}_\alpha(T)|^2 = 1 - T^2\sigma_\alpha^2 + \mathcal{O}(T^3)$. □

Gauge/BRST robustness and regulator stability. Differentiating (7.115) with respect to a gauge-fixing parameter α_{gf} and using the Nielsen master identity (7.19) shows that $\partial_{\alpha_{\mathrm{gf}}}\mathcal{C}_\alpha$ is a sum of (i) ζ-exact insertions, which decouple on $\mathcal{H}_{\mathrm{phys}}$ by quartet/positivity Section 7.2.6 and eq. (7.12), and (ii) EOM insertions, which vanish on shell eqs. (6.333) and (6.334). Thus $\mathcal{C}_\alpha$ and any phase-fixed Λ_α are *gauge-parameter independent on shell* [117, 91]. Regularisation stability under admissible changes of P_x and $K_{\mathrm{IR}}^{(\ell)}$ follows from Section 7.3.7.

Proposition 7.144 (Gauge/BRST robustness and regulator stability for $\mathcal{C}_\alpha$)**.** *Differentiating* (7.115) *with respect to a gauge-fixing parameter* α_{gf} *and using the Nielsen master identity* (7.19) *yields*

$$\partial_{\alpha_{\mathrm{gf}}}\mathcal{C}_\alpha = \frac{\mathrm{Tr}\big(\mathsf{P}_{\mathrm{phys}}\,\mathsf{O}_{\zeta\text{-}exact}\,\mathsf{P}_{\mathrm{phys}}\big)}{\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})} + \frac{\mathrm{Tr}\big(\mathsf{P}_{\mathrm{phys}}\,\mathsf{O}_{\mathrm{EOM}}\,\mathsf{P}_{\mathrm{phys}}\big)}{\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})}.$$

On $\mathcal{H}_{\mathrm{phys}}$*,* ζ*-exact insertions decouple by quartet/positivity Section 7.2.6 and eq.* (7.12)*, and EOM insertions vanish on shell eqs.* (6.333) *and* (6.334)*. Hence*

$$\partial_{\alpha_{\mathrm{gf}}}\mathcal{C}_\alpha = 0 \quad \textit{on shell}, \qquad \partial_{\alpha_{\mathrm{gf}}}\Lambda_\alpha = 0 \quad \textit{on shell},$$

for any phase-fixed Λ_α *in* (7.117)*. Moreover, under admissible regularisation changes of* $P_x(\lambda_{\mathrm{UV}})$ *and* $K_{\mathrm{IR}}^{(\ell)}$*,* $\mathcal{C}_\alpha$ *is stable by the regulator robustness results in Section 7.3.7.*

Proof. Apply (7.19) to the operator insertions in (7.115) and insert $\mathsf{P}_{\mathrm{phys}}$ on both sides of each trace. Use BRST-closure of the preparation and band knobs, and invoke quartet/positivity Section 7.2.6 and eq. (7.12) to kill ζ-exact terms; EOM terms vanish on shell by eqs. (6.333) and (6.334). Regulator stability follows by the Lipschitz/IR-L^1 and gapped-projector arguments in Section 7.3.7. □

Phase choice and signed visibility. The reference phase ϕ_α in (7.117) can be fixed by any of the following equivalent prescriptions: (i) *centre phase* $\phi_\alpha = \arg\mathcal{C}_\alpha(\lambda_\star, \ell_\star; T)$ at the certified plateau centre (so $\Lambda_\alpha(\lambda_\star, \ell_\star; T) = |\mathcal{C}_\alpha|$); (ii) *echo phase* by inserting a symmetric echo to remove common-mode dynamical phase (useful when $U_{0,1}^{(\alpha)}$ share large identical pieces); (iii) *channel gauge* where ϕ_α is the continuous choice along any certified path in the plateau, minimising $\partial_u\phi_\alpha$ and $\partial_v\phi_\alpha$ (smooth-phase gauge). Any such choice leaves $|\mathcal{C}_\alpha|$ invariant and preserves the plateau metrics.

Proposition 7.145 (Phase choice and signed visibility)**.** *Let* Λ_α *be defined by* (7.117)*. The reference phase* ϕ_α *may be fixed by any of the following equivalent prescriptions without affecting* $|\mathcal{C}_\alpha|$ *or the plateau metrics:*

(i) Centre phase.
Set $\phi_\alpha = \arg\mathcal{C}_\alpha(\lambda_\star, \ell_\star; T)$ *at the certified plateau centre, so that* $\Lambda_\alpha(\lambda_\star, \ell_\star; T) = |\mathcal{C}_\alpha|$*.*

(ii) Echo phase.
Insert a symmetric echo to cancel common-mode dynamical phase when $U_{0,1}^{(\alpha)}$ *share large identical pieces; fix* ϕ_α *by the echo.*

(iii) Channel gauge.
Choose ϕ_α *continuously along any certified plateau path to minimise* $\partial_u\phi_\alpha$ *and* $\partial_v\phi_\alpha$ *(smooth-phase gauge).*

All choices are related by a constant phase shift on certified plateaus and leave $|\mathcal{C}_\alpha|$ *invariant.*

Integrated readouts and plateaus. Define the scale–box averaged $\overline{\mathcal{C}}_\alpha$ by replacing Λ_α with $\mathcal{C}_\alpha$ in eq. (7.73). The commutation of averaging with scale derivatives in the log chart eq. (7.74) and the oscillation bound eq. (7.76) imply that $|\overline{\mathcal{C}}_\alpha|$ and the phase-fixed $\overline{\Lambda}_\alpha$ inherit the plateau properties of Section 7.3.5 and the certification protocol of Section 7.3.9.

Proposition 7.146 (Integrated readouts and plateaus)**.** *Define the scale–box average by replacing Λ_α with $\mathcal{C}_\alpha$ in eq. (7.73):*

$$\overline{\mathcal{C}}_{\alpha|B} := \frac{1}{\mu(B)}\int_B d\lambda_{\mathrm{UV}}\, d\ell\, dT\; \mathcal{C}_\alpha(\lambda_{\mathrm{UV}}, \ell; T).$$

Then averaging commutes with log-scale derivatives per eq. (7.74) and obeys the oscillation bound eq. (7.76). Consequently, $|\overline{\mathcal{C}}_\alpha|$ and the phase-fixed $\overline{\Lambda}_\alpha$ inherit the plateau properties of Section 7.3.5 and the certification protocol of Section 7.3.9.

Proof. Linearity of the trace and the admissibility of the knobs imply Gateaux differentiability under the integral; apply eqs. (7.74) and (7.76) to $\mathcal{C}_\alpha$ exactly as for visibilities, and invoke the same geometric/metric equivalence criteria from Section 7.3.5 together with the acceptance pipeline in Section 7.3.9. □

Quadrant preservation and diagnostic meaning. Because the branch differences in (7.97) are cohomologically trivial or symmetry-preserving, the holosymmetric probe does not alter quadrant membership. In Quadrant I, large $|\mathcal{C}_\alpha|$ on certified plateaus indicates high law/state coherence; sustained suppression signals genuine physical decoherence or IR effects consistent with unbroken laws, not gauge artefacts (cf. Sections 7.3 and 7.3.4).

Proposition 7.147 (Quadrant preservation and diagnostic meaning)**.** *Under (7.97), inter-branch differences are cohomologically trivial or symmetry-preserving on $\mathcal{H}_{\mathrm{phys}}$. Therefore the holosymmetric probe preserves quadrant membership:*

$$U_j^{(\alpha)}(T) = \bigoplus_q U_j^{(\alpha,q)}(T), \qquad \mathcal{C}_\alpha = \sum_q \frac{\mathrm{Tr}\big(\Pi^{(q)}\rho_{\mathrm{phys}}\Pi^{(q)}\, M_\alpha^{(q)}\big)}{\mathrm{Tr}(\rho_{\mathrm{phys}})},$$

with $M_\alpha^{(q)} = (U_0^{(\alpha,q)})^\dagger U_1^{(\alpha,q)}$ and $\Pi^{(q)}$ the quadrant projectors. In Quadrant I, certified plateaus imply large $|\mathcal{C}_\alpha|$ (high law/state coherence), whereas sustained suppression signals genuine physical decoherence or symmetry-allowed IR effects—consistent with unbroken laws and not gauge artefacts (cf. Sections 7.3 and 7.3.4).

Proof. Cohomological triviality/symmetry preservation makes each branch block-diagonal in the quadrant decomposition, hence no cross-quadrant interference. The decomposition of $\mathcal{C}_\alpha$ follows by inserting $\sum_q \Pi^{(q)} = \mathbb{I}$ and using cyclicity. The diagnostic statement follows from the certified plateau criteria and robustness guarantees in Section 7.3. □

7.4.2 Channel Realisations: Law vs. State

The two channels differ only in the *pair of branches* $U_{0,1}^{(\alpha)}(T)$; their design guarantees that the operational overlay leaves quadrant membership unchanged (branches differ by cohomologically trivial/symmetry-preserving deformations) [442, 117, 91]. Throughout, $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ are BRST-closed and band-safe eqs. (7.29), (7.30) and (7.33).

Law channel ($\alpha = \text{law}$). Let $H_0(t)$ be the Hamiltonian density generated by the symmetric law (Quadrant I) associated with the clean kinetic pairings and potentials of eqs. (6.333) and (6.334). Define

$$U_0^{(\text{law})}(T) = \mathcal{T}\exp\left[-i\int_0^T dt\, H_0(t)\right], \qquad U_1^{(\text{law})}(T) = \mathcal{T}\exp\left[-i\int_0^T dt\,\Big(H_0(t) + \zeta\,\Delta G(t)\Big)\right], \tag{7.120}$$

with $\Delta G(t)$ local and band-limited. Because $\zeta\,\Delta G$ is BRST-exact, the Slavnov identity and quartet mechanism imply that $U_1^{(\text{law})}$ and $U_0^{(\text{law})}$ produce identical physical matrix elements on $\mathcal{H}_{\text{phys}}$ (anomaly-free case), hence

$$\mathcal{C}_{\text{law}}(\lambda_{\text{UV}}, \ell; T) = 1 \quad \text{and} \quad \Lambda_{\text{law}}(\lambda_{\text{UV}}, \ell; T) = 1 \quad \text{on shell in Quadrant I}, \tag{7.121}$$

up to numerical/regulator tolerances. Any robust suppression $|\mathcal{C}_{\text{law}}| < 1$ signals *law-level incoherence* (e.g. a broken Slavnov identity/anomaly or a regulator pathology), and triggers the anomaly/regularisation checks of Sections 7.2.8 and 7.3.7. The *law visibility* is defined as

$$\Lambda_{\text{law}}(\lambda_{\text{UV}}, \ell; T) := \text{Re}\Big(e^{-i\phi_{\text{law}}}\,\mathcal{C}_{\text{law}}(\lambda_{\text{UV}}, \ell; T)\Big), \tag{7.122}$$

with ϕ_{law} fixed by a calibration at a certified plateau centre $(\lambda_\star, \ell_\star)$ (cf. Section 7.3.9).

Proposition 7.148 (On-shell unity of the law-channel coherence)**.** *Under the assumptions of (7.120) and anomaly freedom, the overlap operator $M_{\text{law}}(T) := (U_0^{(\text{law})})^\dagger U_1^{(\text{law})}$ acts as the identity on $\mathcal{H}_{\text{phys}}$. Consequently, $\mathcal{C}_{\text{law}} = 1$ and $\Lambda_{\text{law}} = 1$ on shell, as in (7.121).*

Proof. Write $U_1^{(\text{law})}$ in the interaction picture with respect to H_0: $U_1^{(\text{law})} = U_0\,\mathcal{T}\exp\Big(-i\int_0^T dt\,\zeta\,\Delta G_I(t)\Big)$, where $U_0 := U_0^{(\text{law})}$. Then $M_{\text{law}} = \mathcal{T}\exp\Big(-i\int_0^T dt\,\zeta\,\Delta G_I(t)\Big)$. Inside physical matrix elements, ζ-exact insertions decouple by quartet/positivity and the Slavnov identity; thus $\mathsf{P}_{\text{phys}}\,M_{\text{law}}\,\mathsf{P}_{\text{phys}} = \mathsf{I}_{\mathcal{H}_{\text{phys}}}$, proving the claim. □

Remark 7.149 (Diagnostic meaning of law-channel suppression)**.** If a certified plateau exhibits $|\mathcal{C}_{\text{law}}| < 1$ beyond tolerances, either (i) the BRST/Slavnov structure is anomalous, (ii) regulator admissibility fails, or (iii) the preparation strays off-shell. The triage proceeds via Sections 7.2.8 and 7.3.7.

State channel ($\alpha = \text{state}$). Fix a BRST-compatible reference Hamiltonian $H_{\text{ref}}(t)$ and two admissible preparations W_j (band-safe, BRST-compatible, quadrant-preserving). Realise the branches by *pushing* the preparations into the evolution,

$$U_j^{(\text{state})}(T) = U_{\text{ref}}(T)\,W_j, \qquad U_{\text{ref}}(T) := \mathcal{T}\exp\left[-i\int_0^T dt\, H_{\text{ref}}(t)\right], \tag{7.123}$$

so that the input remains $\rho_{\text{phys}}^{(\lambda_{\text{UV}},\ell)}$ and the channel difference resides in $W_{0,1}$ (equivalently to preparing $\rho_j = W_j \rho_{\text{phys}} W_j^\dagger$ with a common U_{ref}).

Proposition 7.150 (Coherence amplitude for the state channel)**.** *With* (7.123) *and* (7.115)*, one has*

$$\mathcal{C}_{\mathrm{state}}(\lambda_{\mathrm{UV}},\ell;T)=\frac{\mathrm{Tr}\Big(W_1\,\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\,W_0^{\dagger}\Big)}{\mathrm{Tr}\Big(\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)},$$

which is precisely eq. (7.109)*. In particular, for* $\rho_{\mathrm{phys}}=|\psi\rangle\langle\psi|$ *and* $W_j\,|\psi\rangle=|\psi_j\rangle$*,* $\mathcal{C}_{\mathrm{state}}=\langle\psi_1\rangle\,\psi_0$ *and* $|\mathcal{C}_{\mathrm{state}}|^2$ *is the (pure-state) fidelity.*

Proof. Insert $U_j^{(\mathrm{state})}=U_{\mathrm{ref}}W_j$ into (7.115) and use cyclicity plus unitarity of U_{ref} to cancel it, yielding the displayed expression and eq. (7.109). □

Definition 7.151 (State visibility)**.** Define the phase-fixed state visibility by

$$\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}},\ell;T):=\mathrm{Re}\Big(e^{-i\phi_{\mathrm{state}}}\,\mathcal{C}_{\mathrm{state}}(\lambda_{\mathrm{UV}},\ell;T)\Big),$$

with ϕ_{state} chosen by any of the prescriptions in Proposition 7.145.

Proposition 7.152 (Bounds and saturation)**.** *The bounds of Propositions 7.128 and 7.139 apply to* $\mathcal{C}_{\mathrm{state}}$ *and* Λ_{state}*. Equality* $|\mathcal{C}_{\mathrm{state}}|=1$ *holds iff* $W_1\rho_{\mathrm{phys}}W_0^{\dagger}$ *is a positive multiple of* ρ_{phys} *(pure-state case:* $W_1\,|\psi\rangle=e^{i\varphi}W_0\,|\psi\rangle$*).*

Remark 7.153 (Gauge/BRST protection and plateaus)**.** By Proposition 7.144 the quantities $\mathcal{C}_{\mathrm{state}}$ and Λ_{state} are gauge-parameter independent on shell and regulator-stable under admissible changes of $P_x, K_{\mathrm{IR}}^{(\ell)}$. Calibration of ϕ_{state} at $(\lambda_\star,\ell_\star)$ and certification follow Section 7.3.9.

State channel ($\alpha=$ state). Hold the *law* fixed to $H_0(t)$ for both branches, and seed a symmetry probe at the *state-preparation* stage by a unitary kick W generated by a conserved charge Q of the unbroken symmetry (Quadrant I):

$$\begin{aligned}\rho_0^{(\lambda_{\mathrm{UV}},\ell)}&\equiv\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)},\qquad \rho_1^{(\lambda_{\mathrm{UV}},\ell)}:=W\,\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\,W^{\dagger},\\ W&:=\exp(-i\epsilon Q),\quad \epsilon\ll 1,\quad [Q,H_0(t)]=0.\end{aligned}\tag{7.124}$$

Evolve both with the same $U_0(T):=\mathcal{T}\exp\Big[-i\int_0^T dt\,H_0(t)\Big]$ and implement

$$U_0^{(\mathrm{state})}(T)=U_0(T),\qquad U_1^{(\mathrm{state})}(T)=U_0(T),\tag{7.125}$$

with branch initial states ρ_0 and ρ_1, respectively.

Proposition 7.154 (Reduction to a preparation overlap)**.** *Inserting* (7.125) *into* (7.115) *and using* $[Q,H_0]=0$ *gives*

$$\mathcal{C}_{\mathrm{state}}(\lambda_{\mathrm{UV}},\ell;T)=\frac{\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\,W\,\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\,W^{\dagger}\,\mathsf{P}_{\mathrm{phys}}\Big)}{\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\Big)}.\tag{7.126}$$

Proof. Since $[Q,H_0]=0$, $U_0(T)$ commutes with W. In (7.115), the U_0 factors cancel by cyclicity and unitarity, leaving (7.126). □

Corollary 7.155 (Expectation in a symmetric state)**.** *If the prepared state is symmetric,* $[Q, \rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}] = 0$ *(up to IR smearing), then*

$$\mathcal{C}_{\mathrm{state}} = 1 + \mathcal{O}(\epsilon^2), \qquad \Lambda_{\mathrm{state}} = 1 + \mathcal{O}(\epsilon^2). \tag{7.127}$$

Proof. From $W\rho W^\dagger = \rho - i\epsilon[Q,\rho] - \frac{\epsilon^2}{2}[Q,[Q,\rho]] + \cdots$, the first nonzero term is $\mathcal{O}(\epsilon^2)$ when $[Q,\rho] = 0$ (modulo IR smearing), whence (7.127). □

Proposition 7.156 (Small-ϵ expansion for pure preparations)**.** *For* $\rho_{\mathrm{phys}} = |\psi\rangle\langle\psi|$,

$$\mathcal{C}_{\mathrm{state}} = \langle\psi|\, e^{-i\epsilon Q}\, |\psi\rangle + \mathcal{O}(\epsilon^3) = 1 - \tfrac{\epsilon^2}{2}\,\mathrm{Var}_\psi(Q) + \mathcal{O}(\epsilon^3), \tag{7.128}$$

where $\mathrm{Var}_\psi(Q) := \langle\psi|\, Q^2\, |\psi\rangle - \langle\psi|\, Q\, |\psi\rangle^2$. *This equality holds in the phase-fixed convention where the linear term* $\sim i\epsilon\langle Q\rangle_\psi$ *is removed by the reference phase (cf. (7.117)); equivalently it describes the short-*ϵ *behaviour of* $|\mathcal{C}_{\mathrm{state}}|$.

Proof. Expand $e^{-i\epsilon Q} = 1 - i\epsilon Q - \frac{\epsilon^2}{2}Q^2 + \mathcal{O}(\epsilon^3)$. The overlap is $1 - i\epsilon\langle Q\rangle_\psi - \frac{\epsilon^2}{2}\langle Q^2\rangle_\psi + \cdots$. Removing the linear phase via $\phi_{\mathrm{state}} = \epsilon\langle Q\rangle_\psi$ (or taking modulus) gives the stated form with $\mathrm{Var}_\psi(Q)$. □

Definition 7.157 (State visibility)**.** The *state visibility* is

$$\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; T) := \mathrm{Re}\Big(e^{-i\phi_{\mathrm{state}}}\, \mathcal{C}_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; T)\Big)\,. \tag{7.129}$$

The phase ϕ_{state} may be fixed by any of the prescriptions in Proposition 7.145.

Proposition 7.158 (Design constraints and robustness)**.** *Consider the holosymmetric operational overlay with branches* $U_{0,1}^{(\alpha)}(T)$ *acting on the physical sector, band-limited by* $P_x(\lambda_{\mathrm{UV}})$ *and* $K_{\mathrm{IR}}^{(\ell)}$. *Then:*

(i) Quadrant preservation.
In the law channel, branch differences are BRST-exact (cohomologically trivial); in the state channel, the symmetry generator Q *commutes with* H_0. *Hence the overlay is block-diagonal in the quadrant decomposition and does not alter quadrant membership [442, 117, 91]. Equivalently,* $U_j^{(\alpha)}(T) = \bigoplus_q U_j^{(\alpha,q)}(T)$ *and no cross-quadrant interference occurs (cf. (7.97) and Definition 7.114 and eq. (7.103)).*

(ii) Nielsen/BRST protection.
Differentiating the visibility/coherence definitions with respect to the gauge-fixing parameter and invoking the Nielsen identity (Section 7.2.9 and eq. (7.19)) shows that the derivative reduces to ζ*-exact and EOM insertions. The former decouple on* $\mathcal{H}_{\mathrm{phys}}$ *by quartet/positivity (Section 7.2.6 and eq. (7.12)); the latter vanish on shell by eqs. (6.333) and (6.334). Thus visibilities are gauge-parameter independent on shell, consistent with eq. (7.66) and the BRST invariance results proved above.*

(iii) Regularisation stability.
Replacing $(P_x, K_{\mathrm{IR}}^{(\ell)})$ *by any admissible* $(\tilde{P}_x, \tilde{K}_{\mathrm{IR}}^{(\ell)})$ *perturbs the readouts by at most* $\varepsilon_{\mathrm{reg}}$ *as certified in Section 7.3.7. Quantitatively, writing* $\rho := \rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$ *and* $M_\alpha := (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$,

$$\Big|\mathcal{C}_\alpha - \tilde{\mathcal{C}}_\alpha\Big| = \left|\frac{\mathrm{Tr}(P\,\rho\,P\,M_\alpha)}{\mathrm{Tr}(P\,\rho\,P)} - \frac{\mathrm{Tr}\Big(\tilde{P}\,\rho\,\tilde{P}\,M_\alpha\Big)}{\mathrm{Tr}\Big(\tilde{P}\,\rho\,\tilde{P}\Big)}\right| \;\le\; \varepsilon_{\mathrm{reg}},$$

with $P := P_x K_{\mathrm{IR}}^{(\ell)}$ and $\tilde{P} := \tilde{P}_x \tilde{K}_{\mathrm{IR}}^{(\ell)}$, where $\varepsilon_{\mathrm{reg}}$ is controlled by the admissibility norms (IR L^1 closeness and UV-projector gap) and the Lipschitz constants cited in Section 7.3.7. The same bound transfers to Λ_α by continuity.

(iv) Plateau certification.
Both channels inherit the scale-dependence and plateau metrics of Section 7.3; readouts are to be certified via the acceptance pipeline in Section 7.3.9. Hence any reported Λ_α (or $\mathcal{C}_\alpha$) is accompanied by a certified plateau neighbourhood and uncertainty budget.

Proof. (i) Follows from the cohomological triviality/symmetry-preserving hypotheses and the quadrant-compatibility of the overlay (Definition 7.114); cf. the block-diagonal form implied by (7.97). (ii) Is the standard Nielsen/BRST argument using Sections 7.2.6 and 7.2.9 and eqs. (7.12) and (7.19) and on-shell EOM eqs. (6.333) and (6.334) (consistent with eq. (7.66)). (iii) Use the triangle inequality and the regulator-stability estimates in Section 7.3.7; the trace functional is Lipschitz on the admissible class, and the denominator remains bounded away from zero on certified bands. (iv) Is immediate from the plateau geometry and certification results cited. □

7.4.3 Embedding of UV/IR Knobs and Sector Projectors

Every operator in eqs. (7.96) and (7.129) is band-limited and IR-smoothed by the functor $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$ of eq. (7.40):

$$U_j^{(\alpha)}(T) \;\mapsto\; U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) := \mathcal{T}\exp\!\left[-i\int_0^T dt \int d^d x\, K_{\mathrm{IR}}^{(\ell)}(x)\, \mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}})\right], \tag{7.130}$$

where $\mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}}) := \mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}[\mathcal{H}_j^{(\alpha)}(t,x)]$ is built from fields projected by $P_x(\lambda_{\mathrm{UV}})$ and averaged with $K_{\mathrm{IR}}^{(\ell)}$ (cf. Section 7.3.1). By construction, $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ are BRST-closed and ghost-number 0 eq. (7.30), so the embedding preserves the Slavnov identities and the decoupling properties on $\mathcal{H}_{\mathrm{phys}}$ [114, 117, 91].

Definition 7.159 (Band/IR functorial embedding)**.** Let $\mathcal{A}$ be the $*$-algebra of (densitised) local Hamiltonian densities admissible for the dynamics. The functor $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)} : \mathcal{A} \to \mathcal{A}$ acts by

$$\mathcal{H}(t,x) \;\mapsto\; \Big(\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}\mathcal{H}\Big)(t,x) := \int d^d y\, K_{\mathrm{IR}}^{(\ell)}(x-y)\, \Big(P_y(\lambda_{\mathrm{UV}})\, \mathcal{H}(t,y)\, P_y(\lambda_{\mathrm{UV}})\Big),$$

with $K_{\mathrm{IR}}^{(\ell)} \in L^1(\mathbb{R}^d)$ real and even, and $P_y(\lambda_{\mathrm{UV}})$ a local UV projector of eq. (7.29). Then $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$ is completely positive, $*$-preserving, and norm-contracting on $\mathcal{A}$.

Lemma 7.160 (BRST closure and sector naturality)**.** *If $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = 0$ and $[\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}] = 0$ as in eq. (7.30), then for any $\mathcal{H} \in \mathcal{A}$,*

$$[\hat{Q}_{\mathrm{BRST}}, \mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}\mathcal{H}] = \mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}\Big([\hat{Q}_{\mathrm{BRST}}, \mathcal{H}]\Big),$$
$$\mathsf{P}_{\mathrm{phys}}\, \mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}(\cdot)\, \mathsf{P}_{\mathrm{phys}} = \mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}\Big(\mathsf{P}_{\mathrm{phys}}(\cdot)\mathsf{P}_{\mathrm{phys}}\Big).$$

Hence $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$ is BRST-natural and respects the physical/sector projectors.

Proposition 7.161 (Well-posed unitary band evolution)**.** *Assume for each branch j: (i) $\mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})$ is essentially self-adjoint on a common, band-stable core $\mathcal{D}$; (ii) $t \mapsto \mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})$ is strongly continuous on $[0,T]$; (iii) $K_{\mathrm{IR}}^{(\ell)} \in L^1(\mathbb{R}^d)$ and $\sup_t \|\mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})\|$ is locally bounded in $(\lambda_{\mathrm{UV}},\ell)$. Then the time-ordered exponential in (7.130) exists and defines a unitary propagator $U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)$ on $\overline{\mathcal{D}}$, depending strongly continuously on T.*

Proof. Young's inequality implies $\|K_{\mathrm{IR}}^{(\ell)} * \cdot\| \le \|K_{\mathrm{IR}}^{(\ell)}\|_{L^1}\|\cdot\|$, preserving essential self-adjointness and the core $\mathcal{D}$. Strong continuity in t is inherited from the integrand; Kato's existence/uniqueness theorem for time-dependent self-adjoint generators then yields a unitary, strongly continuous evolution [115]. □

Proposition 7.162 (Preservation of BRST compatibility under embedding)**.** *Suppose the unembedded branches satisfy $[\hat{Q}_{\mathrm{BRST}}, U_j^{(\alpha)}(T)] = \zeta X_j^{(\alpha)}$ with $\mathsf{P}_{\mathrm{phys}}\zeta X_j^{(\alpha)}\mathsf{P}_{\mathrm{phys}} = 0$. Then the embedded propagators satisfy*

$$[\hat{Q}_{\mathrm{BRST}}, U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)] = \zeta\, \widetilde{X}_j^{(\alpha)}(\lambda_{\mathrm{UV}},\ell), \qquad \mathsf{P}_{\mathrm{phys}}\, \widetilde{X}_j^{(\alpha)}\, \mathsf{P}_{\mathrm{phys}} = 0,$$

so BRST cohomological triviality persists on $\mathcal{H}_{\mathrm{phys}}$.

Proof. Differentiate the Dyson series for $U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)$; by Lemma 7.160 the commutator with $\hat{Q}_{\mathrm{BRST}}$ pushes through $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$. Each time-ordered term becomes BRST-exact with the same physical-sector nullification; summing the series gives the claim. □

Proposition 7.163 (Quadrant/block structure under embedding)**.** *Let $\mathcal{H}_{\mathrm{phys}} = \bigoplus_q \mathcal{H}_{\mathrm{phys}}^{(q)}$ and suppose the unembedded branches are block-diagonal, $U_j^{(\alpha)}(T) = \bigoplus_q U_j^{(\alpha,q)}(T)$. Then the embedded propagators remain block-diagonal:*

$$U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) = \bigoplus_q U_j^{(\alpha,q)}(T;\lambda_{\mathrm{UV}},\ell), \qquad M_\alpha(T;\lambda_{\mathrm{UV}},\ell) = \bigoplus_q M_\alpha^{(q)}(T;\lambda_{\mathrm{UV}},\ell),$$

with $M_\alpha := (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$. Consequently, eq. (7.103) holds for the embedded objects.

Proof. $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with the quadrant projectors on $\mathcal{H}_{\mathrm{phys}}$ (ghost number 0, BRST-closed), so $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$ preserves the block decomposition and hence so do the Dyson series and their adjoints. □

Proposition 7.164 (Gateaux derivatives in UV/IR knobs)**.** *Assume $(\lambda_{\mathrm{UV}},\ell) \mapsto P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ are (piecewise) C^1 in the admissible sense, with $\partial_{\lambda_{\mathrm{UV}}} P_x$ bounded and $\partial_\ell K_{\mathrm{IR}}^{(\ell)} \in L^1$. Then the map $(\lambda_{\mathrm{UV}},\ell) \mapsto U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)$ is Gateaux differentiable in the strong operator topology and*

$$\partial_{\lambda_{\mathrm{UV}}} U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) = -i\int_0^T dt\; U_j^{(\alpha)}(T,t)\left(\int d^dx\, K_{\mathrm{IR}}^{(\ell)}(x)\, \partial_{\lambda_{\mathrm{UV}}} \mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}})\right) U_j^{(\alpha)}(t,0),$$

$$\partial_\ell U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) = -i\int_0^T dt\; U_j^{(\alpha)}(T,t)\left(\int d^dx\, (\partial_\ell K_{\mathrm{IR}}^{(\ell)})(x)\, \mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}})\right) U_j^{(\alpha)}(t,0),$$

with $U_j^{(\alpha)}(t',t)$ the embedded propagator from t to t'. Moreover, the derivatives obey the Lipschitz bound

$$\left\|\partial_{\lambda_{\mathrm{UV}}} U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)\right\| \le T\, \|\partial_{\lambda_{\mathrm{UV}}} \mathcal{H}_j^{(\alpha)}\|_{\mathrm{op}} \|K_{\mathrm{IR}}^{(\ell)}\|_{L^1},$$
$$\left\|\partial_\ell U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)\right\| \le T\, \|\mathcal{H}_j^{(\alpha)}\|_{\mathrm{op}} \|\partial_\ell K_{\mathrm{IR}}^{(\ell)}\|_{L^1}.$$

Proof. Differentiate the Dyson series term-by-term; boundedness of the variational kernels and Young's inequality control the series uniformly in order, permitting interchange of limit and sum. The norm estimates follow by Grönwall-type bounds and $\|K * \cdot\| \le \|K\|_{L^1}\|\cdot\|$. □

Corollary 7.165 (Stability of readouts in UV/IR knobs)**.** *Let $\mathcal{C}_\alpha$ and Λ_α be defined as in eqs. (7.115) and (7.117). Under the hypotheses of Proposition 7.164, the maps $(\lambda_{\mathrm{UV}}, \ell) \mapsto \mathcal{C}_\alpha$ and $(\lambda_{\mathrm{UV}}, \ell) \mapsto \Lambda_\alpha$ are Gateaux differentiable and locally Lipschitz on certified bands. In particular,*

$$\left|\partial_{\lambda_{\mathrm{UV}}} \mathcal{C}_\alpha\right| \le \frac{T\,\|K_{\mathrm{IR}}^{(\ell)}\|_{L^1}}{\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})}\ \mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}\mathsf{P}_{\mathrm{phys}}\Big)\,\|\partial_{\lambda_{\mathrm{UV}}}\mathcal{H}_j^{(\alpha)}\|_{\mathrm{op}},$$

and similarly with ∂_ℓ and $\|\partial_\ell K_{\mathrm{IR}}^{(\ell)}\|_{L^1}$.

Proposition 7.166 (Heisenberg embedding and observable band-limiting)**.** *Let $\hat{O}$ be a (quasi)local observable with finite band norm on the admissible class. Define the embedded Heisenberg evolution*

$$\hat{O}_{j,\mathrm{H}}^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) := U_j^{(\alpha)\dagger}(T;\lambda_{\mathrm{UV}},\ell)\,\hat{O}\,U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell).$$

Then $\hat{O}_{j,\mathrm{H}}^{(\alpha)}$ is band-limited/IR-smoothed (belongs to the image of $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$ up to conjugation) and preserves BRST/sector naturality as in Lemma 7.160. Consequently, any readout functional built from $\hat{O}_{j,\mathrm{H}}^{(\alpha)}$ inherits the gauge/BRST robustness and regularisation stability established earlier.

Remark 7.167 (Ordering of IR averaging and time-ordering)**.** Equation (7.130) places the IR averaging inside the time-ordered exponential. If one first forms unembedded $U_j^{(\alpha)}(T)$ and then applies the (completely positive) band map on the propagator level, the two procedures coincide on $\mathcal{H}_{\mathrm{phys}}$ up to $\mathcal{O}(\|K_{\mathrm{IR}}^{(\ell)}\|_{L^1}\,\varepsilon_{\mathrm{reg}})$ in the admissible topology, by the CP-contractivity of $\mathcal{B}^{(\lambda_{\mathrm{UV}},\ell)}$ and the regulator robustness estimates of Section 7.3.7.

Scale derivatives (Duhamel formulas). The $(\lambda_{\mathrm{UV}}, \ell)$-dependence of the embedded branches is entirely through the knobs. Differentiating the time-ordered exponential gives band-safe Duhamel identities:

$$\partial_{\ln\lambda_{\mathrm{UV}}} U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) = -i\int_0^T dt \int d^dx\, K_{\mathrm{IR}}^{(\ell)}(x)\, U_j^{(\alpha)}(T,t)\,\Big(\partial_{\ln\lambda_{\mathrm{UV}}}\mathcal{H}_j^{(\alpha)}\Big)(t,x;\lambda_{\mathrm{UV}})\,U_j^{(\alpha)}(t,0), \tag{7.131}$$

$$\partial_{\ln\ell} U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell) = -i\int_0^T dt \int d^dx\,\Big(\partial_{\ln\ell}K_{\mathrm{IR}}^{(\ell)}(x)\Big)\,U_j^{(\alpha)}(T,t)\,\mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}})\,U_j^{(\alpha)}(t,0), \tag{7.132}$$

with $U_j^{(\alpha)}(t_2,t_1)$ the band/IR-smoothed propagator. These formulas yield explicit expressions for $D_\lambda\Lambda_\alpha, D_\ell\Lambda_\alpha$ used in the plateau metrics (Sections 7.3.2 and 7.3.4); operator-norm bounds on the integrands give Lipschitz control of the visibilities in the knobs (sufficient conditions in Section 7.3.7).

Proposition 7.168 (Duhamel identities and assumptions)**.** *Assume the hypotheses of Proposition 7.161 and, in addition, (i) $(\lambda_{\mathrm{UV}},\ell) \mapsto \mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})$ is (piecewise) C^1 in the strong operator topology with $\partial_{\ln\lambda_{\mathrm{UV}}}\mathcal{H}_j^{(\alpha)}$ bounded on the scan window, and (ii) $\partial_{\ln\ell}K_{\mathrm{IR}}^{(\ell)} \in L^1(\mathbb{R}^d)$. Then (7.131)–(7.132) hold as strong operator identities on the common core.*

Proof. Write the Dyson series for $U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)$ using the embedded densities. Differentiate term-by-term; boundedness of the variational kernels and Young's inequality control each term uniformly, legitimising exchange of $\partial_{\ln\lambda_{\mathrm{UV}}}$ or $\partial_{\ln\ell}$ with the infinite sum. Collect the insertions in the interaction picture to obtain (7.131)–(7.132). □

Lemma 7.169 (Heisenberg form of the kernels)**.** *Define the interaction-picture operators*

$$\mathcal{K}_j^{(\lambda)}(t) := \int d^d x\, K_{\mathrm{IR}}^{(\ell)}(x)\big(\partial_{\ln\lambda_{\mathrm{UV}}}\mathcal{H}_j^{(\alpha)}\big)(t,x;\lambda_{\mathrm{UV}}),$$
$$\mathcal{K}_j^{(\ell)}(t) := \int d^d x\, (\partial_{\ln\ell}K_{\mathrm{IR}}^{(\ell)})(x)\,\mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}}).$$

Then (7.131)–(7.132) *read*

$$\partial_\bullet U_j^{(\alpha)}(T) = -i\int_0^T dt\, U_j^{(\alpha)}(T,t)\,\mathcal{K}_j^{(\bullet)}(t)\,U_j^{(\alpha)}(t,0),\quad \bullet\in\{\ln\lambda_{\mathrm{UV}},\ln\ell\}.$$

Proposition 7.170 (Norm bounds and Lipschitz control)**.** *With $\|\cdot\|$ the operator norm and using unitarity of $U_j^{(\alpha)}(t_2,t_1)$,*

$$\big\|\partial_{\ln\lambda_{\mathrm{UV}}}U_j^{(\alpha)}(T)\big\| \le \int_0^T dt\,\big\|\mathcal{K}_j^{(\lambda)}(t)\big\| \le T\,\|K_{\mathrm{IR}}^{(\ell)}\|_{L^1}\sup_t\big\|\partial_{\ln\lambda_{\mathrm{UV}}}\mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})\big\|,$$

and

$$\big\|\partial_{\ln\ell}U_j^{(\alpha)}(T)\big\| \le \int_0^T dt\,\big\|\mathcal{K}_j^{(\ell)}(t)\big\| \le T\,\|\partial_{\ln\ell}K_{\mathrm{IR}}^{(\ell)}\|_{L^1}\sup_t\big\|\mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})\big\|.$$

Hence the maps $(\ln\lambda_{\mathrm{UV}},\ln\ell)\mapsto U_j^{(\alpha)}(T)$ are locally Lipschitz on certified bands.

Proof. Take norms inside (7.131)–(7.132); use $\|U_j^{(\alpha)}(t_2,t_1)\| = 1$ and Young's inequality $\big\|\int K * A\big\| \le \|K\|_{L^1}\|A\|$. □

Proposition 7.171 (Scale derivatives of the coherence amplitude)**.** *Let $\mathcal{C}_\alpha$ be given by* (7.115) *with $\rho_{\mathrm{phys}} := \rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$. Decompose $D_\bullet\mathcal{C}_\alpha$ into a* dynamical part *from the branches and a* kinematic part *from the preparation/projectors:*

$$\partial_\bullet\mathcal{C}_\alpha = \frac{\begin{array}{l}\mathrm{Tr}\Big(\mathsf{P}\,(\partial_\bullet U_1^{(\alpha)})\,\rho_{\mathrm{phys}}\,U_0^{(\alpha)\dagger}\,\mathsf{P}\Big)\\ +\,\mathrm{Tr}\Big(\mathsf{P}\,U_1^{(\alpha)}\,\rho_{\mathrm{phys}}\,(\partial_\bullet U_0^{(\alpha)\dagger})\,\mathsf{P}\Big)\end{array}}{\mathrm{Tr}(\mathsf{P}\rho_{\mathrm{phys}})} + \Delta_\bullet^{(\mathrm{kin})},$$
$$\text{for } \bullet\in\{\ln\lambda_{\mathrm{UV}},\ln\ell\},$$

where $\mathsf{P} := \mathsf{P}_{\mathrm{phys}}$ and

$$\Delta_\bullet^{(\mathrm{kin})} := \frac{\begin{array}{l}\mathrm{Tr}\Big((\partial_\bullet\mathsf{P})\,U_1^{(\alpha)}\rho_{\mathrm{phys}}U_0^{(\alpha)\dagger}\Big)\\ +\,\mathrm{Tr}\Big(\mathsf{P}\,U_1^{(\alpha)}(\partial_\bullet\rho_{\mathrm{phys}})U_0^{(\alpha)\dagger}\Big)\\ +\,\mathrm{Tr}\Big(\mathsf{P}\,U_1^{(\alpha)}\rho_{\mathrm{phys}}U_0^{(\alpha)\dagger}(\partial_\bullet\mathsf{P})\Big)\end{array}}{\mathrm{Tr}(\mathsf{P}\rho_{\mathrm{phys}})} - \mathcal{C}_\alpha\,\frac{\mathrm{Tr}\Big((\partial_\bullet\mathsf{P})\rho_{\mathrm{phys}}+\mathsf{P}(\partial_\bullet\rho_{\mathrm{phys}})\Big)}{\mathrm{Tr}(\mathsf{P}\rho_{\mathrm{phys}})}.$$

Inserting (7.131)–(7.132) *gives explicit band-safe expressions for the dynamical part.*

Proof. Differentiate the numerator/denominator of (7.115) and use the product rule together with $\partial_\bullet U^\dagger = -U^\dagger(\partial_\bullet U)\,U^\dagger$. The preparation and projector terms collect into $\Delta_\bullet^{(\mathrm{kin})}$. □

Corollary 7.172 (Bounds for $D_\lambda \mathcal{C}_\alpha$ and $D_\ell \mathcal{C}_\alpha$)**.** *On certified bands where* $\mathrm{Tr}(\mathsf{P}\rho_{\mathrm{phys}}) \geq c_0 > 0$,

$$\left|\partial_{\ln\lambda_{\mathrm{UV}}}\mathcal{C}_\alpha\right| \;\leq\; \frac{2T\,\|K_{\mathrm{IR}}^{(\ell)}\|_{L^1}}{c_0}\,\max_{j=0,1}\sup_t\left\|\partial_{\ln\lambda_{\mathrm{UV}}}\mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})\right\| \;+\; \left|\Delta_{\ln\lambda_{\mathrm{UV}}}^{(\mathrm{kin})}\right|,$$

and

$$\left|\partial_{\ln\ell}\mathcal{C}_\alpha\right| \;\leq\; \frac{2T\,\|\partial_{\ln\ell}K_{\mathrm{IR}}^{(\ell)}\|_{L^1}}{c_0}\,\max_{j=0,1}\sup_t\left\|\mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})\right\| \;+\; \left|\Delta_{\ln\ell}^{(\mathrm{kin})}\right|.$$

The same bounds propagate to the signed visibility $\Lambda_\alpha = \mathrm{Re}(e^{-i\phi_\alpha}\mathcal{C}_\alpha)$ *by the chain rule.*

Remark 7.173 (BRST/Nielsen naturality of scale derivatives)**.** Under eq. (7.30) and the BRST-compatibility of the branches, the dynamical kernels in (7.131)–(7.132) are BRST-natural (Lemma 7.160); ζ-exact pieces decouple on $\mathcal{H}_{\mathrm{phys}}$, and on-shell EOM insertions vanish. Thus $D_\lambda\Lambda_\alpha$ and $D_\ell\Lambda_\alpha$ inherit the gauge/BRST robustness used in the plateau metrics (Sections 7.3.2 and 7.3.4).

BRST/Nielsen protection after embedding. Because the knobs commute with $\hat{Q}_{\mathrm{BRST}}$ and carry ghost number 0, $\partial_{\alpha_{\mathrm{gf}}}$-variations of the embedded readouts reduce to ζ-exact and EOM insertions which vanish on shell, exactly as before embedding (Section 7.3.6). Hence the embedded visibilities $\Lambda_\alpha(\lambda_{\mathrm{UV}},\ell)$ are gauge-parameter independent on $\mathcal{H}_{\mathrm{phys}}$ [117, 91].

Proposition 7.174 (Embedded Nielsen/BRST protection)**.** *Let* $\mathcal{C}_\alpha$ *and* Λ_α *be the embedded readouts defined with* $U_j^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)$ *and* $\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$*. Assume* $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = [\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}] = 0$ *and the Nielsen identity eq.* (7.19)*. Then, on shell,*

$$\partial_{\alpha_{\mathrm{gf}}}\mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell) = 0, \qquad \partial_{\alpha_{\mathrm{gf}}}\Lambda_\alpha(\lambda_{\mathrm{UV}},\ell) = 0.$$

Proof. Apply eq. (7.19) to the embedded numerator/denominator (with explicit $\mathsf{P}_{\mathrm{phys}}$ and band knobs inside the trace). Knob BRST-closure and ghost number 0 imply BRST-naturality of the embedding; ζ-exact insertions decouple on $\mathcal{H}_{\mathrm{phys}}$ by quartet/positivity, and EOM insertions vanish on shell (as in Section 7.3.6). The same argument transfers from $\mathcal{C}_\alpha$ to Λ_α. □

Sector projectors and resolved visibilities. Let $\{\Pi_\beta\}$ denote the BRST-closed channel/sector projectors (scalar/vector/tensor sectors relative to $\bar{\Sigma}_{\mu\nu}^{(\ell)}$), commuting with $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$. Define the *sector-resolved* coherence amplitude by inserting Π_β at readout,

$$\begin{aligned}\mathcal{C}_{\alpha|\beta} &:= \frac{\mathrm{Tr}\Big(\Pi_\beta\,\mathsf{P}_{\mathrm{phys}}\,U_1^{(\alpha)}(T;\lambda_{\mathrm{UV}},\ell)\,\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}\,U_0^{(\alpha)\dagger}(T;\lambda_{\mathrm{UV}},\ell)\,\mathsf{P}_{\mathrm{phys}}\,\Pi_\beta\Big)}{\mathrm{Tr}(\Pi_\beta\,\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)})},\\ \Lambda_{\alpha|\beta} &:= \mathrm{Re}\Big(e^{-i\phi_\alpha}\mathcal{C}_{\alpha|\beta}\Big),\end{aligned} \tag{7.133}$$

which is manifestly gauge invariant and positive on $\mathcal{H}_{\text{phys}}$. If additionally $[\Pi_\beta, \mathcal{H}_j^{(\alpha)}] = 0$ (exact sector symmetry), the evolution is block-diagonal and $\Lambda_\alpha = \sum_\beta w_\beta \Lambda_{\alpha|\beta}$ with weights $w_\beta \geq 0$, $\sum_\beta w_\beta = 1$; otherwise (7.133) still defines a bona fide projector-resolved readout. Sectorwise plateaus are then certified by Section 7.3.11 using the compatibility criterion eq. (7.94).

Proposition 7.175 (Well-posedness, bounds, and gauge invariance)**.** *Let* $M_\alpha(T; \lambda_{\text{UV}}, \ell) := (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$ *be the embedded overlap. For any sector* β *with nonzero weight*

$$w_\beta := \frac{\mathrm{Tr}\Big(\Pi_\beta \, \mathsf{P}_{\text{phys}} \rho_{\text{phys}}^{(\lambda_{\text{UV}}, \ell)}\Big)}{\mathrm{Tr}\Big(\mathsf{P}_{\text{phys}} \rho_{\text{phys}}^{(\lambda_{\text{UV}}, \ell)}\Big)} > 0,$$

the quantity $\mathcal{C}_{\alpha|\beta}$ *in* (7.133) *is well-defined, satisfies* $|\mathcal{C}_{\alpha|\beta}| \leq 1$*, and is gauge-parameter independent on shell. Consequently,* $\Lambda_{\alpha|\beta} \in [-1, 1]$ *and inherits BRST/Nielsen protection and regulator stability.*

Proof. Denominator positivity follows from $w_\beta > 0$. Write $\mathcal{C}_{\alpha|\beta} = \mathrm{Tr}\Big(\rho^{(\beta)} M_\alpha\Big) / \mathrm{Tr}\Big(\rho^{(\beta)}\Big)$ with $\rho^{(\beta)} := \Pi_\beta \mathsf{P}_{\text{phys}} \rho_{\text{phys}} \mathsf{P}_{\text{phys}} \Pi_\beta \succeq 0$. Unitarity of M_α implies the bound by the same Cauchy–Schwarz/Hölder argument used earlier for un-resolved amplitudes. Gauge-parameter independence follows from Proposition 7.174 because Π_β is BRST-closed and commutes with the knobs, so the Nielsen reduction (exact+EOM) still vanishes on $\mathcal{H}_{\text{phys}}$. □

Proposition 7.176 (Additivity under exact sector symmetry)**.** *If* $[\Pi_\beta, \mathcal{H}_j^{(\alpha)}(t, \cdot; \lambda_{\text{UV}})] = 0$ *for all* t *and* j*, then the embedded propagators are block-diagonal and*

$$\mathcal{C}_\alpha = \sum_\beta w_\beta \, \mathcal{C}_{\alpha|\beta}, \qquad \Lambda_\alpha = \sum_\beta w_\beta \, \Lambda_{\alpha|\beta},$$

with weights w_β *as above (and a sector-independent phase* ϕ_α*).*

Proof. Block-diagonality gives $M_\alpha = \bigoplus_\beta M_{\alpha|\beta}$ and $\rho_{\text{phys}} = \sum_\beta \rho^{(\beta)}$ with $\mathrm{Tr}\, \rho^{(\beta)} = w_\beta \, \mathrm{Tr}(\mathsf{P}_{\text{phys}} \rho_{\text{phys}})$. Linearity of the trace yields the amplitude decomposition; applying $\mathrm{Re}(e^{-i\phi_\alpha} \cdot)$ gives the visibility statement. □

Remark 7.177 (Non-commuting sectors and certification)**.** If $[\Pi_\beta, \mathcal{H}_j^{(\alpha)}] \neq 0$, (7.133) still defines a valid sector-resolved readout (a "sandwiched" estimator). It remains gauge/BRST robust by Proposition 7.174 and admits the same Lipschitz/plateau analysis sectorwise. Certification then proceeds via Section 7.3.11 and the compatibility criterion eq. (7.94).

Regularisation stability and commuting limits. Replacing $(P_x, K_{\text{IR}}^{(\ell)})$ by $(\tilde{P}_x, \tilde{K}_{\text{IR}}^{(\ell)})$ with the same low-energy fixed point changes (7.130) by amounts controlled by Section 7.3.7; consequently the sector-resolved and aggregate visibilities obey the regulator bound (7.67), and the UV/IR swapped limits commute up to ε_{reg} (eq. (7.45)).

Proposition 7.178 (Regulator stability for embedded propagators and readouts)**.** *Let* $P := P_x(\lambda_{\text{UV}}) K_{\text{IR}}^{(\ell)}$ *and* $\tilde{P} := \tilde{P}_x(\lambda_{\text{UV}}) \tilde{K}_{\text{IR}}^{(\ell)}$ *be admissible band projectors with the* same *low-energy fixed point in the sense of Section 7.3.7. Then the embedded propagators in* (7.130) *satisfy*

$$\Big\| U_j^{(\alpha)}(T; \lambda_{\text{UV}}, \ell) - \tilde{U}_j^{(\alpha)}(T; \lambda_{\text{UV}}, \ell) \Big\| \;\leq\; \varepsilon_{\text{reg}}^{(U)},$$

and the overlap operators $M_\alpha := (U_0^{(\alpha)})^\dagger U_1^{(\alpha)}$ *obey*

$$\left\| M_\alpha(T;\lambda_{\mathrm{UV}},\ell) - \tilde{M}_\alpha(T;\lambda_{\mathrm{UV}},\ell) \right\| \;\le\; \varepsilon_{\mathrm{reg}}^{(M)}.$$

Consequently, the aggregate coherence amplitude and visibility satisfy the regulator bound (7.67)*:*

$$\left| \mathcal{C}_\alpha - \tilde{\mathcal{C}}_\alpha \right| \;\le\; \varepsilon_{\mathrm{reg}}, \qquad \left| \Lambda_\alpha - \tilde{\Lambda}_\alpha \right| \;\le\; \varepsilon_{\mathrm{reg}}.$$

Proof. Combine the Lipschitz/Duhamel control (7.131)–(7.132) with the admissibility norms and the robustness estimates in Section 7.3.7 to bound the generator differences inside the time-ordered exponentials; apply Grönwall-type bounds to obtain the stated operator-norm estimates. The trace functionals defining $\mathcal{C}_\alpha$ and Λ_α are Lipschitz on the admissible class, giving (7.67). □

Corollary 7.179 (Sector-resolved stability)**.** *Let* $\mathcal{C}_{\alpha|\beta}$ *and* $\Lambda_{\alpha|\beta}$ *be defined by* (7.133) *for any BRST-closed sector projector* Π_β *with nonzero weight. Then*

$$\left| \mathcal{C}_{\alpha|\beta} - \tilde{\mathcal{C}}_{\alpha|\beta} \right| \;\le\; \varepsilon_{\mathrm{reg}}, \qquad \left| \Lambda_{\alpha|\beta} - \tilde{\Lambda}_{\alpha|\beta} \right| \;\le\; \varepsilon_{\mathrm{reg}}.$$

Proof. Insert Π_β on both sides of the trace; $\|\Pi_\beta\| \le 1$ and the same Lipschitz/robustness arguments as above apply verbatim to the "sandwiched" functionals. □

Proposition 7.180 (Commuting UV/IR limits up to $\varepsilon_{\mathrm{reg}}$)**.** *Assume the UV/IR families* $(P_x, K_{\mathrm{IR}}^{(\ell)})$ *admit a common low-energy fixed point and the limits in eq.* (7.45) *exist along admissible paths. Then, for any certified time window and band,*

$$\left| \lim_{\ell\to\ell_\infty} \lim_{\lambda_{\mathrm{UV}}\to\lambda_\infty} \mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell) \;-\; \lim_{\lambda_{\mathrm{UV}}\to\lambda_\infty} \lim_{\ell\to\ell_\infty} \mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell) \right| \;\le\; \varepsilon_{\mathrm{reg}},$$

and likewise for Λ_α*, i.e. eq.* (7.45) *holds.*

Proof. Insert and subtract the fixed-point projector $P_\star := P_x(\lambda_\infty) K_{\mathrm{IR}}^{(\ell_\infty)}$ and use the triangle inequality together with (7.67). Each leg of the iterated limit is within $\varepsilon_{\mathrm{reg}}/2$ of the fixed-point readout, so their difference is $\le \varepsilon_{\mathrm{reg}}$. □

Summary. The embedding (7.130) implements the holosymmetric probe entirely within the band/IR window while preserving BRST, Nielsen, and sector structure. It yields explicit, band-safe scale-derivative formulas (7.131)–(7.132) used in the plateau metrics, and it supports sector-resolved diagnostics (7.133) without altering quadrant membership. Moreover, the construction is regulator-stable in the sense of (7.67) and its UV/IR limits commute up to $\varepsilon_{\mathrm{reg}}$ as certified by eq. (7.45) [114, 117, 91, 115, 82, 241].

7.4.4 Gauge/BRST Robustness and Anomaly Filters

Gauge-parameter variations modify the coherence amplitude only by EOM-proportional (and ζ-exact) insertions, so that

$$\partial_{\alpha_{\mathrm{gf}}} \mathcal{C}_\alpha = 0 \quad \text{on shell},$$

by the Nielsen master identity and quartet decoupling (Section 7.2.9 and eqs. (7.12), (7.19) and (7.66); see also [117, 91]). In the *law* channel, BRST-exact deformations of the branch generator must cancel on $\mathcal{H}_{\text{phys}}$ provided the Slavnov identity and anomaly filters hold (Section 7.2.8 and eq. (7.16)). We make this precise and then spell out the diagnostic triage.

Proposition 7.181 (Gauge-parameter independence on shell)**.** *Let $\mathcal{C}_\alpha$ be defined by (7.115) (or equivalently by (7.98) on $\mathcal{H}_{\text{phys}}$). Under the assumptions of the Nielsen identity eq. (7.19), BRST-closure of the band knobs eq. (7.30), and quartet/positivity eq. (7.12), one has*

$$\partial_{\alpha_{\text{gf}}}\mathcal{C}_\alpha = 0, \qquad \partial_{\alpha_{\text{gf}}}\Lambda_\alpha = 0 \quad \textit{on shell.}$$

Proof. Differentiate the (embedded) numerator/denominator w.r.t. α_{gf}. By eq. (7.19), each derivative is a sum of a BRST-exact commutator and EOM terms. The commutator vanishes between physical projectors by quartet/positivity; the EOM insertions vanish on shell (eqs. (6.333) and (6.334)). The statement for Λ_α follows by the chain rule. □

Cohomological invariance of the law channel. Consider the homotopy

$$\hat{H}_s(t) := H_0(t) + s\,\zeta\Delta G(t), \qquad s \in [0,1],$$

with H_0 the symmetric-law Hamiltonian of Quadrant I and ΔG a local, band-limited operator. Let $U_s(T)$ be the corresponding band/IR-smoothed propagator eq. (7.130), and define

$$\mathcal{C}_{\text{law}}(s) := \frac{\operatorname{Tr}\Big(\mathsf{P}_{\text{phys}}\,U_{s=1}(T)\,\rho_{\text{phys}}\,U_{s=0}^{\dagger}(T)\,\mathsf{P}_{\text{phys}}\Big)}{\operatorname{Tr}(\mathsf{P}_{\text{phys}}\rho_{\text{phys}})}.$$

Duhamel's formula gives

$$\frac{d}{ds}\,\mathcal{C}_{\text{law}}(s) = -i\int_0^T dt\;\frac{\operatorname{Tr}\Big(\mathsf{P}_{\text{phys}}\,U_1(T,t)\,\Big(\zeta\Delta G(t)\Big)\,U_s(t,0)\,\rho_{\text{phys}}\,U_0^{\dagger}(T)\,\mathsf{P}_{\text{phys}}\Big)}{\operatorname{Tr}(\mathsf{P}_{\text{phys}}\rho_{\text{phys}})}. \tag{7.134}$$

Using $\zeta\Delta G = [\hat{Q}_{\text{BRST}}, \Delta G]$ and cyclicity, the integrand is a BRST commutator plus EOM terms. On $\mathcal{H}_{\text{phys}}$ the commutator vanishes by quartet positivity and the Slavnov identity, while EOM terms vanish on shell (Section 7.2.6 and eqs. (6.333), (6.334) and (7.12)). Hence $d\mathcal{C}_{\text{law}}/ds = 0$ and

$$\mathcal{C}_{\text{law}}(1) = \mathcal{C}_{\text{law}}(0) = 1, \qquad \Lambda_{\text{law}} = 1 \quad \text{(ideal Quadrant I, anomaly-free).} \tag{7.135}$$

This is the operational form of cohomological BRST invariance [442, 117, 91].

Definition 7.182 (Anomaly functional and filter)**.** Let $\mathcal{S}$ denote the Slavnov operator (BRST Ward functional) and suppose the renormalised theory admits a local breaking Δ_{an} so that $\mathcal{S}(\Gamma) = \Delta_{\text{an}}$. Define the *projected anomaly functional* on $\mathcal{H}_{\text{phys}}$ by

$$\mathcal{A}_T \;:=\; \int_0^T dt\,\Big\|\;\mathsf{P}_{\text{phys}}\,\Big(\Delta_{\text{an}}(t)\Big)\,\mathsf{P}_{\text{phys}}\;\Big\|_{\text{op}}.$$

The *anomaly filter* Section 7.2.8 is said to *pass* on $[0,T]$ if $\mathcal{A}_T \le \varepsilon_{\text{an}}$ for a certified tolerance $\varepsilon_{\text{an}} \ge 0$.

Proposition 7.183 (Quantitative law-channel robustness)**.** *Let* $M_{\mathrm{law}} := (U_0^{(\mathrm{law})})^\dagger U_1^{(\mathrm{law})}$ *with* $U_1^{(\mathrm{law})}$ *defined by a BRST-exact deformation of* H_0 *as above. Then, for any physical preparation* ρ_{phys} *with* $\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}) \geq c_0 > 0$*,*

$$\left|\mathcal{C}_{\mathrm{law}} - 1\right| \;\leq\; \frac{\mathcal{A}_T}{c_0} \;+\; \varepsilon_{\mathrm{EOM}} \;+\; \varepsilon_{\mathrm{reg}},$$

where $\mathcal{A}_T$ *is the anomaly functional of Definition 7.182,* $\varepsilon_{\mathrm{EOM}}$ *controls off-shell EOM residuals, and* $\varepsilon_{\mathrm{reg}}$ *is the regulator tolerance from Section 7.3.7. In particular, if the anomaly filter passes and one is on shell with admissible regularisation, then* $\mathcal{C}_{\mathrm{law}} = 1 + \mathcal{O}(\varepsilon_{\mathrm{reg}})$*.*

Proof. Integrate (7.134) over $s \in [0,1]$, replace $[\hat{Q}_{\mathrm{BRST}}, \Delta G]$ by the Slavnov variation and decompose into (projected) anomaly plus EOM terms. Take operator norms inside the time-ordered insertions using unitarity of partial propagators; use $\mathrm{Tr}(\mathsf{P}\rho\mathsf{P}) \geq c_0$ and add the regulator tolerance from Section 7.3.7. □

Corollary 7.184 (Sector-resolved law-channel bounds)**.** *For any BRST-closed sector projector* Π_β *with weight* $w_\beta > 0$*,*

$$\left|\mathcal{C}_{\mathrm{law}|\beta} - 1\right| \;\leq\; \frac{1}{w_\beta}\,\mathcal{A}_T^{(\beta)} \;+\; \varepsilon_{\mathrm{EOM}} \;+\; \varepsilon_{\mathrm{reg}}, \qquad \mathcal{A}_T^{(\beta)} := \int_0^T dt\, \left\|\Pi_\beta \mathsf{P}_{\mathrm{phys}} \Delta_{\mathrm{an}}(t) \mathsf{P}_{\mathrm{phys}} \Pi_\beta\right\|_{\mathrm{op}}.$$

Proof. Insert Π_β on both sides of the trace in (7.134) and repeat the norm estimate sectorwise. □

Proposition 7.185 (Diagnostic triage for law-channel suppression)**.** *Suppose a certified plateau exhibits* $\left|1 - \mathcal{C}_{\mathrm{law}}\right| > \delta$ *beyond the joint tolerance* $\delta_\star := \varepsilon_{\mathrm{an}} + \varepsilon_{\mathrm{EOM}} + \varepsilon_{\mathrm{reg}}$*. Then at least one of:*

(a) Anomaly: $\mathcal{A}_T > \varepsilon_{\mathrm{an}}$ *(Slavnov identity broken); check Section 7.2.8 and eq. (7.16) and sectorwise diagnostics (Cor. 7.184).*

(b) Off-shell preparation: *EOM residuals exceed tolerance (verify eqs. (6.333) and (6.334) on the band).*

(c) Regulator pathology: *admissibility fails or numeric tolerance too loose; perform the regulator swap test of Section 7.3.7 and use the commuting-limits check eq. (7.45).*

If all three checks pass, re-calibrate the phase and re-run the plateau certification (Section 7.3.9); persistent suppression then constitutes evidence for genuine law-level incoherence.

Proposition 7.186 (Quantitative stability bound)**.** *Let the norm of the BRST-exact perturbation restricted to* $\mathcal{H}_{\mathrm{phys}}$ *be measured by* ϵ_{BRST}*, defined as*

$$\epsilon_{\mathrm{BRST}} := \sup_{t\in[0,T]} \left\|\mathsf{P}_{\mathrm{phys}}\, \zeta \Delta G(t)\, \mathsf{P}_{\mathrm{phys}}\right\|_{\mathrm{op}}.$$

Assume the denominator in (7.115) is normalised to 1, i.e. $\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}) = 1$ *(otherwise replace RHS below by* $1/c_0$ *with* $c_0 := \mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}) > 0$*). Then, from (7.134) and unitarity,*

$$\left|1 - \mathcal{C}_{\mathrm{law}}\right| \;\leq\; T\,\epsilon_{\mathrm{BRST}} \;+\; \mathcal{O}(T^2\,\epsilon_{\mathrm{BRST}}^2) \;+\; \varepsilon_{\mathrm{reg}}, \tag{7.136}$$

where $\varepsilon_{\mathrm{reg}}$ *accounts for admissible regulator differences (Section 7.3.7). In the anomaly-free case one has* $\epsilon_{\mathrm{BRST}} = 0$ *(cohomological triviality on* $\mathcal{H}_{\mathrm{phys}}$*), recovering (7.135).*

Proof. Integrate (7.134) over $s \in [0,1]$. Using unitarity of the partial propagators $U_s(t_2,t_1)$ and $\|\cdot\|_{\mathrm{op}}$ submultiplicativity,

$$\left|\mathcal{C}_{\mathrm{law}}(1) - \mathcal{C}_{\mathrm{law}}(0)\right| \le \int_0^T dt\, \left\|\mathsf{P}_{\mathrm{phys}}\, \zeta \Delta G(t)\, \mathsf{P}_{\mathrm{phys}}\right\|_{\mathrm{op}} + \mathcal{O}\Big(\int_0^T \int_0^t \epsilon_{\mathrm{BRST}}^2\, ds\, dt\Big) + \varepsilon_{\mathrm{reg}},$$

which gives $T\,\epsilon_{\mathrm{BRST}} + \mathcal{O}(T^2\epsilon_{\mathrm{BRST}}^2) + \varepsilon_{\mathrm{reg}}$. The $\mathcal{O}(T^2\epsilon_{\mathrm{BRST}}^2)$ term comes from the second and higher Duhamel/Picard iterates with two or more insertions of $\zeta\Delta G$ inside the time-ordered exponential. The regulator term follows from Section 7.3.7. □

Remark 7.187 (Normalisation)**.** If $\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}}) = c_0 \neq 1$, the bound becomes $\left|1 - \mathcal{C}_{\mathrm{law}}\right| \le (T/c_0)\,\epsilon_{\mathrm{BRST}} + \mathcal{O}(T^2\epsilon_{\mathrm{BRST}}^2) + \varepsilon_{\mathrm{reg}}$.

Failure modes and diagnostic triage. Observed suppressions of $|\mathcal{C}_\alpha|$ are interpreted through controlled tests:

1. **If $|\mathcal{C}_{\mathrm{law}}| < 1$:**
   (a) **(L1) Anomaly test:** Check eq. (7.18); compute the descent of the anomaly polynomial and re-verify $\mathcal{S}(\Gamma) = 0$ [443, 442].
   (b) **(L2) Gauge scan:** Vary α_{gf}; any residual dependence contradicts Nielsen protection Section 7.2.9.
   (c) **(L3) Regulator swap:** Replace $(P_x, K_{\mathrm{IR}}^{(\ell)}) \to (\tilde{P}_x, \tilde{K}_{\mathrm{IR}}^{(\ell)})$; violations beyond $\varepsilon_{\mathrm{reg}}$ indicate a UV/IR mismatch Section 7.3.7.
   (d) **(L4) Positivity/hyperbolicity:** Re-check eqs. (7.12) and (7.15); pathologies can feed into $|\mathcal{C}_{\mathrm{law}}| < 1$ via unphysical leakage.
2. **If $|\mathcal{C}_{\mathrm{state}}| < 1$:**
   (a) **(S1) Symmetry probe:** Verify $[Q, \rho_{\mathrm{phys}}] = 0$ (up to IR smearing); failure indicates state-level symmetry tension (7.128).
   (b) **(S2) IR uniformity:** Tighten/widen $K_{\mathrm{IR}}^{(\ell)}$; robust decay across plateau scales points to genuine state decoherence rather than IR artefacts.
   (c) **(S3) Sector check:** Inspect $\Lambda_{\alpha|\beta}$ and coherence coefficients (Section 7.3.11); exclude cancellations across sectors.
   (d) **(S4) Gauge/regulator sanity:** Repeat (L2)–(L3) to rule out overlay artefacts.

Proposition 7.188 (Soundness of the triage)**.** *Let $\delta_\star := \varepsilon_{\mathrm{an}} + \varepsilon_{\mathrm{EOM}} + \varepsilon_{\mathrm{reg}}$ be the joint certified tolerance from anomaly/EOM/regulator budgets. If (L2)–(L4) pass and (L1) fails, law-level suppression is attributed to anomaly ($\mathcal{A}_T > \varepsilon_{\mathrm{an}}$); if (L1), (L3), (L4) pass and (L2) fails, gauge fixing is defective; if all (L1)–(L4) pass yet $|1 - \mathcal{C}_{\mathrm{law}}| > \delta_\star$, declare law-level incoherence beyond certified budgets. Analogous statements hold for the state channel with (S1)–(S4), attributing residual suppression to genuine state decoherence when all sanity checks pass.*

Anomaly filters and cohomology. The algebraic conditions $\mathfrak{A}_{\text{gauge}} = \mathfrak{A}_{\text{mixed}} = \mathfrak{A}_{\text{grav}} = \mathbf{0}$ (Section 7.2.8) ensure that the would-be anomaly cocycle $\mathcal{A} \in H^{1,d}(\zeta \mid d)$ is trivial and removable by counterterms (Wess–Zumino consistency; cf. Definition 7.25) [442, 443, 91, 243]. When these filters hold, BRST nilpotency is preserved at the quantum level, guaranteeing that ζ-exact deformations (such as the law-branch difference) do not affect physical matrix elements—hence $\mathcal{C}_{\text{law}} = 1$ on certified plateaus.

Proposition 7.189 (Anomaly filters ⇒ cohomological triviality)**.** *Let $\mathcal{S}(\Gamma) = \Delta_{\text{an}}$ be the Slavnov functional with local breaking Δ_{an}. Assume the anomaly filters of Section 7.2.8 hold, i.e. $\mathfrak{A}_{\text{gauge}} = \mathfrak{A}_{\text{mixed}} = \mathfrak{A}_{\text{grav}} = \mathbf{0}$. Then the Wess–Zumino consistency condition $\zeta\Delta_{\text{an}} = 0 \pmod d$ implies*

$$[\Delta_{\text{an}}] = 0 \quad \textit{in} \quad H^{1,d}(\zeta \mid d),$$

hence there exist local counterterms Z (ghost number 0) and a $(d-1)$-form Ω such that

$$\Delta_{\text{an}} = \zeta\,\mathsf{Z} + d\Omega,$$

with Z as in Definition 7.25. The renormalised action $\Gamma' := \Gamma - \mathsf{Z}$ obeys the exact Slavnov identity $\mathcal{S}(\Gamma') = 0$ (cf. eq. (7.16)), and the renormalised BRST differential ζ is nilpotent on $\mathcal{H}_{\text{phys}}$.

Proof. The vanishing of the gauge, mixed, and gravitational anomaly polynomials implies that all potential descent representatives in the ζ-mod-d bicomplex are trivial in $H^{1,d}(\zeta \mid d)$ [442, 443]. By Wess–Zumino consistency, there exist local functionals Z of ghost number 0 and $(d-1)$-forms Ω such that $\Delta_{\text{an}} = \zeta\,\mathsf{Z} + d\Omega$; see Definition 7.25 for the precise descent relation and loopwise version. Adding the counterterm $-\mathsf{Z}$ yields the renormalised action $\Gamma' = \Gamma - \mathsf{Z}$ with $\mathcal{S}(\Gamma') = 0$ (cf. eq. (7.16)), which restores quantum BRST nilpotency on $\mathcal{H}_{\text{phys}}$. □

Proposition 7.190 (Operational consequence for the law channel)**.** *Suppose the anomaly filters hold and let the law-channel branch deformation be BRST-exact, $\zeta\Delta G(t)$, as in Section 7.4.2. Then for band/IR-smoothed propagators $U_{0,1}^{(\text{law})}(T)$ one has, on $\mathcal{H}_{\text{phys}}$,*

$$\mathsf{P}_{\text{phys}}(U_0^{(\text{law})})^\dagger U_1^{(\text{law})}\mathsf{P}_{\text{phys}} = \mathsf{I}_{\mathcal{H}_{\text{phys}}}, \qquad \Rightarrow \quad \mathcal{C}_{\text{law}} = 1, \quad \Lambda_{\text{law}} = 1 \quad \textit{on certified plateaus.}$$

Proof. By Prop. 7.189, ζ acts nilpotently on the renormalised theory and ζ-exact insertions decouple between physical projectors (quartet/positivity). In the Dyson expansion of $(U_0^{(\text{law})})^\dagger U_1^{(\text{law})}$ every occurrence of $\zeta\Delta G$ gives a BRST commutator whose contribution vanishes on $\mathcal{H}_{\text{phys}}$. Hence the overlap reduces to the identity on $\mathcal{H}_{\text{phys}}$, yielding $\mathcal{C}_{\text{law}} = 1$. □

Corollary 7.191 (Quantitative corollary with regulator tolerance)**.** *Under the assumptions above and admissible regularisation, the certified readout satisfies $\mathcal{C}_{\text{law}} = 1 + \mathcal{O}(\varepsilon_{\text{reg}})$ and $\Lambda_{\text{law}} = 1 + \mathcal{O}(\varepsilon_{\text{reg}})$, with ε_{reg} from Section 7.3.7.*

Summary. *Gauge robustness* (Nielsen) and *BRST robustness* (anomaly-free Slavnov identity) together imply that the holosymmetric probe's law channel is unity on shell, while the state channel cleanly diagnoses state-level symmetry tension or decoherence. Any departure is actionable via the triage above and must be reconciled before using the visibilities for mode identification [117, 91, 443, 442, 82, 241].

7.4.5 Plateau Coupling and Certification

Within any certified joint plateau $\mathfrak{P}_{\{\text{law,state}\}}$ (cf. Section 7.3), the channel visibilities obey the uniform bounds

$$\left\|\nabla_{(\lambda_{\mathrm{UV}},\ell)}\,\Lambda_\alpha\right\| \le \varepsilon_{\text{grad}}, \qquad \|\mathbf{H}\Lambda_\alpha\|_{\text{op}} \le \varepsilon_{\text{curv}}, \qquad \operatorname{osc}_{B_r}\Lambda_\alpha \le \varepsilon_{\text{osc}}, \tag{7.137}$$

and are regulator-stable in the sense of eq. (7.67). Let $\mathbf{\Lambda} := (\Lambda_{\text{law}}, \Lambda_{\text{state}})^\top$ and work in the log chart $(u, v) = (\ln \lambda_{\mathrm{UV}}, \ln \ell)$ (so $D_\lambda = \partial_u$, $D_\ell = \partial_v$).

Definition 7.192 (Joint plateau and geodesic balls)**.** Let $(u_\star, v_\star) \in \mathfrak{P}_{\{\text{law,state}\}}$. For $\rho > 0$, set $B_\rho(u_\star, v_\star) := \{(u, v) : \|(u, v) - (u_\star, v_\star)\| \le \rho\}$ with the Euclidean norm. The joint plateau is *certified* if (7.137) holds for both channels on every such ball with $\rho \le \rho_{\max}$ and the regulator bound of eq. (7.67) holds uniformly.

Local drift bounds and joint certification. For any (u, v) within a geodesic ball $B_\rho(u_\star, v_\star) \subset \mathfrak{P}_{\{\text{law,state}\}}$,

$$\|\mathbf{\Lambda}(u, v) - \mathbf{\Lambda}(u_\star, v_\star)\| \;\le\; \sqrt{2}\,\varepsilon_{\text{grad}}\,\rho \;+\; \tfrac{1}{2}\,\varepsilon_{\text{curv}}\,\rho^2 \;+\; \varepsilon_{\text{osc}} \;+\; \varepsilon_{\text{reg}}, \tag{7.138}$$

where $\|\cdot\|$ is the Euclidean norm in $\mathbb{R}^2$. The first two terms follow from mean-value/Taylor estimates using eq. (7.137); the last two account for local oscillation and regulator robustness. This bound couples the channels: a single radius ρ controls both simultaneously.

Proposition 7.193 (Vector drift via Jacobian/Hessian control)**.** *Let $F(u, v) := \mathbf{\Lambda}(u, v)$ and $\delta z := (u - u_\star, v - v_\star)$. Along any straight path $t \mapsto (u_\star, v_\star) + t\,\delta z$, $t \in [0, 1]$, one has*

$$\begin{aligned} F(u, v) - F(u_\star, v_\star) = &\int_0^1 J\Big((u_\star, v_\star) + t\,\delta z\Big)\,\delta z\,dt \\ &+ \frac{1}{2}\int_0^1 (1 - t)\,\mathbf{H}_F\Big((u_\star, v_\star) + t\,\delta z\Big)[\delta z, \delta z]\,dt \\ &+ \Delta_{\text{osc}} + \Delta_{\text{reg}}, \end{aligned}$$

where J is the Jacobian and $\mathbf{H}_F$ the block Hessian of F, and the remainders satisfy $\|\Delta_{\text{osc}}\| \le \varepsilon_{\text{osc}}$ and $\|\Delta_{\text{reg}}\| \le \varepsilon_{\text{reg}}$. Moreover, $\|J\|_{\text{op}} \le \sqrt{2}\,\varepsilon_{\text{grad}}$ and $\|\mathbf{H}_F\|_{\text{op}} \le \varepsilon_{\text{curv}}$, whence (7.138).

Proof. Use the integral mean-value/Taylor formula for vector-valued maps. The matrix J has rows $\nabla\Lambda_{\text{law}}^\top$ and $\nabla\Lambda_{\text{state}}^\top$, each bounded by $\varepsilon_{\text{grad}}$, so $\|J\|_{\text{op}} \le \|J\|_{\text{F}} \le \sqrt{2}\,\varepsilon_{\text{grad}}$. The block Hessian $\mathbf{H}_F$ is block-diagonal with blocks $\mathbf{H}\Lambda_\alpha$; its operator norm is the maximum of the block norms, bounded by $\varepsilon_{\text{curv}}$. The path length is $\|\delta z\| = \rho$. Bounds on the oscillation and regulator terms follow from Definition 7.192 and eq. (7.67). □

Coupling metrics. Define the Jacobian and the curvature couplings at $(u_\star, v_\star)$,

$$J_\star = \begin{pmatrix} D_\lambda\Lambda_{\text{law}} & D_\ell\Lambda_{\text{law}} \\ D_\lambda\Lambda_{\text{state}} & D_\ell\Lambda_{\text{state}} \end{pmatrix}_{(u_\star,v_\star)}, \qquad \mathcal{K}_\star := \max_{\alpha\in\{\text{law,state}\}} \|\mathbf{H}\Lambda_\alpha\|_{\text{op},(u_\star,v_\star)},$$

and the *gradient alignment* (coherence) coefficient

$$\chi_\star := \frac{\left|\langle \nabla\Lambda_{\text{law}}, \nabla\Lambda_{\text{state}}\rangle\right|}{\|\nabla\Lambda_{\text{law}}\|\,\|\nabla\Lambda_{\text{state}}\|} \in [0,1],$$

interpreted as the cosine of the angle between the channel gradients. Joint plateaus with small $\|J_\star\|$ are robust to knob perturbations; requiring $\chi_\star \le \chi_{\max}$ (e.g. $1/2$) prevents near-cancellations from masquerading as plateaus (sectorwise safeguards in Section 7.3.11).

Lemma 7.194 (Alignment safeguard)**.** *If* $\max_\alpha \|\nabla\Lambda_\alpha\| \le \varepsilon_{\text{grad}}$ *and* $\chi_\star \le \chi_{\max} < 1$*, then for any unit vector* $\hat n$ *in knob space,*

$$\left\|J_\star\,\hat n\right\| \;\le\; \sqrt{\varepsilon_{\text{grad}}^2 + \varepsilon_{\text{grad}}^2 + 2\,\chi_{\max}\,\varepsilon_{\text{grad}}^2} \;=\; \sqrt{2(1+\chi_{\max})}\,\varepsilon_{\text{grad}}.$$

Thus choosing $\chi_{\max} \le 1/2$ *improves the linear drift constant from* $\sqrt{2}$ *to* $\sqrt{3} < 1.732$*.*

Proof. Let $g_1 := \nabla\Lambda_{\text{law}}\cdot\hat n$, $g_2 := \nabla\Lambda_{\text{state}}\cdot\hat n$. Then $\|J_\star\hat n\|^2 = g_1^2 + g_2^2 \le \|\nabla\Lambda_{\text{law}}\|^2 + \|\nabla\Lambda_{\text{state}}\|^2 + 2|g_1 g_2| \le 2\varepsilon_{\text{grad}}^2 + 2\chi_{\max}\varepsilon_{\text{grad}}^2$. □

Certified operating point and reporting. Choose $(\lambda_\star, \ell_\star)$ (equivalently $(u_\star, v_\star)$) to maximise the inscribed radius $\rho_\star$ subject to $\|J_\star\|$ and $\mathcal{K}_\star$ minimisation.[4] The reported values are

$$\Lambda^\star_{\text{law}} := \Lambda_{\text{law}}(\lambda_\star, \ell_\star; T), \qquad \Lambda^\star_{\text{state}} := \Lambda_{\text{state}}(\lambda_\star, \ell_\star; T), \tag{7.139}$$

with a deterministic *plateau uncertainty* bounded by the right-hand side of (7.138) evaluated at $\rho = \rho_\star$, added in quadrature with the statistical error from Section 7.4.6. Gauge/BRST independence of these readouts on shell follows from Section 7.3.6, and regulator stability from Section 7.3.7 [117, 91, 114].

Proposition 7.195 (Existence of a certified operating point)**.** *If the certified joint plateau* $\mathfrak{P}_{\{\text{law,state}\}}$ *is nonempty, bounded, and closed in the log chart, then an operating point* $(u_\star, v_\star)$ *maximising* $\rho_\star$ *exists. Among maximisers, there exists one minimising* $\|J_\star\|$ *and* $\mathcal{K}_\star$*.*

Proof. Compactness ensures existence of a Chebyshev center (maximiser of the inscribed radius). Continuity of $J_\star$ and $\mathcal{K}_\star$ on the compact argmax set yields a minimiser by the extreme value theorem. □

Corollary 7.196 (Deterministic plateau uncertainty)**.** *Let* Δ_{det} *denote the deterministic plateau uncertainty at* $(u_\star, v_\star)$*. Then*

$$\Delta_{\text{det}} \;\le\; \sqrt{2}\,\varepsilon_{\text{grad}}\,\rho_\star \;+\; \tfrac{1}{2}\,\varepsilon_{\text{curv}}\,\rho_\star^2 \;+\; \varepsilon_{\text{osc}} \;+\; \varepsilon_{\text{reg}},$$

and the total reported uncertainty is $\sqrt{\Delta_{\text{det}}^2 + \Delta_{\text{stat}}^2}$ *with* Δ_{stat} *from Section 7.4.6.*

[4] Ties can be broken by minimising $\|\nabla\Lambda_{\text{law}}\|^2 + \|\nabla\Lambda_{\text{state}}\|^2$ or by maximising the regulator overlap (smallest observed drift under $(P,K)\to(\tilde P,\tilde K)$).

7.4.6 Error Budget and Robustness to Noise

Let N_x (N_y) be the number of ancilla shots used to estimate $\langle\sigma_x\rangle_\alpha$ ($\langle\sigma_y\rangle_\alpha$). Each outcome is ±1, so the standard errors are (binomial statistics)

$$\delta\langle\sigma_x\rangle_\alpha = \sqrt{\frac{1-\langle\sigma_x\rangle_\alpha^2}{N_x}}, \qquad \delta\langle\sigma_y\rangle_\alpha = \sqrt{\frac{1-\langle\sigma_y\rangle_\alpha^2}{N_y}}, \tag{7.140}$$

see, e.g., [287]. Propagating errors to the coherence magnitude $|\mathcal{C}_\alpha| = \sqrt{\langle\sigma_x\rangle_\alpha^2 + \langle\sigma_y\rangle_\alpha^2}$ gives (delta method, neglecting cross-covariance if x and y runs are disjoint)

$$\delta|\mathcal{C}_\alpha| \;\approx\; \frac{1}{|\mathcal{C}_\alpha|}\sqrt{\langle\sigma_x\rangle_\alpha^2\,\delta\langle\sigma_x\rangle_\alpha^2 + \langle\sigma_y\rangle_\alpha^2\,\delta\langle\sigma_y\rangle_\alpha^2}\,, \qquad \delta\Lambda_\alpha \le \delta|\mathcal{C}_\alpha|. \tag{7.141}$$

If $N_x = N_y = N$, (7.140)–(7.141) reduce to the compact form used in Section 7.4.1. For small samples, exact Clopper–Pearson intervals can replace (7.140) (optional).

Proposition 7.197 (Shot-noise formulas and non-asymptotic bounds)**.** *Let $X_k \in \{\pm1\}$ be i.i.d. with mean $\mu_x = \langle\sigma_x\rangle_\alpha$. Then $\widehat{\mu}_x = \frac{1}{N_x}\sum_k X_k$ satisfies $\mathrm{Var}(\widehat{\mu}_x) = \frac{1-\mu_x^2}{N_x}$, yielding (7.140). The same holds for Y_ℓ estimating $\langle\sigma_y\rangle_\alpha$. Moreover, for any $\delta \in (0,1)$, Hoeffding gives a distribution-free concentration:*

$$\Pr\Big(|\widehat{\mu}_x - \mu_x| \ge \epsilon\Big) \le 2\,e^{-2N_x\epsilon^2} \quad\Rightarrow\quad \epsilon = \sqrt{\frac{\ln(2/\delta)}{2N_x}},$$

which can replace Gaussian error bars when needed.

Lemma 7.198 (Delta-method with optional covariance)**.** *If the x and y estimates are obtained from independent shot sets, (7.141) holds. If a joint scheme induces $\mathrm{Cov}(\widehat{\mu}_x, \widehat{\mu}_y) \neq 0$, then*

$$\delta|\mathcal{C}_\alpha| \;\approx\; \frac{1}{|\mathcal{C}_\alpha|}\sqrt{\mu_x^2\,\delta\mu_x^2 + \mu_y^2\,\delta\mu_y^2 + 2\,\mu_x\mu_y\,\mathrm{Cov}(\widehat{\mu}_x,\widehat{\mu}_y)}\,,$$

with $\mu_{x,y} := \langle\sigma_{x,y}\rangle_\alpha$ and $\delta\mu_{x,y}$ from (7.140). The bound $\delta\Lambda_\alpha \le \delta|\mathcal{C}_\alpha|$ follows since Λ_α is a phase-rotated projection of $\mathcal{C}_\alpha$ onto $\mathbb{R}$.

Corollary 7.199 (Equal-shot simplification and worst-case bound)**.** *If $N_x = N_y = N$ and runs are independent, then*

$$\delta|\mathcal{C}_\alpha| \;\approx\; \frac{1}{\sqrt{N}}\sqrt{1 - \frac{|\mathcal{C}_\alpha|^2}{2}} \;\le\; \frac{1}{\sqrt{N}},$$

where the inequality is a worst-case bound over all (μ_x, μ_y) with $\mu_x^2 + \mu_y^2 = |\mathcal{C}_\alpha|^2$.

Proposition 7.200 (Shot allocation optimality)**.** *Given a fixed total budget $N_{\mathrm{tot}} = N_x + N_y$ and independent runs, the first-order allocation minimising $\delta|\mathcal{C}_\alpha|$ is*

$$\frac{N_x}{N_y} \;\approx\; \frac{|\mu_x|\sqrt{1-\mu_x^2}}{|\mu_y|\sqrt{1-\mu_y^2}}\,.$$

For $|\mu_x| \approx |\mu_y|$ this reduces to $N_x \approx N_y$.

Phase uncertainty. If $\Lambda_\alpha = \mathrm{Re}(e^{-i\phi_\alpha}\mathcal{C}_\alpha)$ is reported, a phase uncertainty $\delta\phi_\alpha$ (from calibration at $(\lambda_\star, \ell_\star)$) contributes

$$(\delta\Lambda_\alpha)_\phi \;\approx\; |\mathcal{C}_\alpha|\,\delta\phi_\alpha,$$

to be added in quadrature with (7.141). Echo-style phase choices (common-mode cancellation) minimise $\delta\phi_\alpha$ without affecting $|\mathcal{C}_\alpha|$.

Proposition 7.201 (Phase-error bound)**.** *Let $\Lambda_\alpha = \mathrm{Re}(e^{-i\phi_\alpha}\mathcal{C}_\alpha)$ with $\mathcal{C}_\alpha = |\mathcal{C}_\alpha|e^{i\theta_\alpha}$. Then $\partial_{\phi_\alpha}\Lambda_\alpha = -|\mathcal{C}_\alpha|\sin(\theta_\alpha - \phi_\alpha)$, so $|(\delta\Lambda_\alpha)_\phi| \le |\mathcal{C}_\alpha|\,\delta\phi_\alpha$, with equality at quadrature ($\theta_\alpha - \phi_\alpha = \pm\pi/2$).*

SPAM calibration (affine correction). Static state-preparation-and-measurement (SPAM) errors act as an affine map on the Bloch-plane readout,

$$\begin{pmatrix}\langle\sigma_x\rangle\\ \langle\sigma_y\rangle\end{pmatrix}_{\mathrm{meas}} = A\begin{pmatrix}\langle\sigma_x\rangle\\ \langle\sigma_y\rangle\end{pmatrix}_{\mathrm{true}} + \mathbf{b},$$

with an invertible 2×2 matrix A and offset $\mathbf{b}$. Two-phase calibration at $(\lambda_\star, \ell_\star)$ with known branch identities $U_{0,1}^{(\alpha)} = \nVdash$ (and a $\pi/2$ phase-shifted variant) identifies $(A, \mathbf{b})$; corrected estimates use $(A^{-1}, -A^{-1}\mathbf{b})$, and the associated calibration uncertainty is folded into the tolerance budget of Section 7.3.9.

Proposition 7.202 (Unbiased affine SPAM correction and amplification factor)**.** *If $(\widehat{A}, \widehat{\mathbf{b}}) = (A, \mathbf{b})$ exactly, the corrected estimator is unbiased: $\widehat{\mathbf{s}}_{\mathrm{true}} = A^{-1}(\mathbf{s}_{\mathrm{meas}} - \mathbf{b})$ with $\mathbb{E}[\widehat{\mathbf{s}}_{\mathrm{true}}] = \mathbf{s}_{\mathrm{true}}$. If $(\widehat{A}, \widehat{\mathbf{b}})$ have errors $(\Delta A, \Delta\mathbf{b})$ with $\|A^{-1}\Delta A\| \le \eta < 1$, then*

$$\frac{\|\delta\widehat{\mathbf{s}}_{\mathrm{true}}\|}{\|\delta\mathbf{s}_{\mathrm{meas}}\|} \;\le\; \kappa_2(A) \;+\; \mathcal{O}(\eta), \qquad \kappa_2(A) := \|A\|_2\,\|A^{-1}\|_2,$$

so calibration inflates statistical errors by at most the condition number $\kappa_2(A)$ (to first order), and introduces a bias of order $\|A^{-1}\Delta\mathbf{b}\| + \|A^{-1}\Delta A\|\,\|\mathbf{s}_{\mathrm{meas}} - \mathbf{b}\|$.

Total uncertainty and acceptance. For each channel at $(\lambda_\star, \ell_\star)$ report

$$\varepsilon_{\mathrm{tot},\alpha} := \sqrt{\Big(\sqrt{2}\,\varepsilon_{\mathrm{grad}}\,\rho_\star + \tfrac{1}{2}\varepsilon_{\mathrm{curv}}\,\rho_\star^2 + \varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}}\Big)^2 + \Big(\delta|\mathcal{C}_\alpha|\Big)^2 + \Big((\delta\Lambda_\alpha)_\phi\Big)^2},$$

and accept the certification only if $\varepsilon_{\mathrm{tot},\alpha}$ lies below the policy threshold set for downstream mode-identification. Gauge/BRST invariance and regulator robustness of the estimates are ensured by Sections 7.3.6 and 7.3.7 [117, 91, 114].

Proposition 7.203 (Decision rule soundness)**.** *Under the joint plateau assumptions and independent shot allocations, the acceptance rule $\varepsilon_{\mathrm{tot},\alpha} \le \varepsilon_{\mathrm{policy}}$ controls the total (deterministic+statistical+phase) deviation in the reported $\Lambda_\alpha^\star$ at level $\varepsilon_{\mathrm{policy}}$, with SPAM-inflation absorbed via $\kappa_2(A)$ in $\delta|\mathcal{C}_\alpha|$.*

Remark (provisional mode tags). Any mode tagging inferred from $\Lambda_{\mathrm{law}}^\star, \Lambda_{\mathrm{state}}^\star$ (e.g., "graviton-like," "Higgs-like," "apeiron," "chrono–kymon") is *provisional* until validated across quadrants per the stated policy; tags must not be treated as definitive until multi-quadrant plateau compatibility is demonstrated.

7.5 Exact Identities at the Symmetry Point (Baseline for Symmetry Breaking)

This section records the exact Ward, Slavnov–Taylor, and BRST/cohomological identities that hold in Quadrant I at the G-invariant vacuum fixed in Section 7.1. All statements are formulated *on the band* with the UV/IR knobs of Section 7.3 and are to be read on the physical sector $\mathcal{H}_{\rm phys}$ introduced in Section 7.2. They provide the baseline against which symmetry-breaking effects in other quadrants will be measured. Our conventions follow algebraic renormalization and BRST quantization [117, 442, 91].

7.5.1 Band-limited Source Formalism and BRST-exact Gauge Fixing

Introduce sources for the band-limited fields and their BRST variations:

$$\begin{aligned} \mathcal{J}\cdot\varphi &:= J_\Phi\cdot\hat{\mathbf{\Phi}}_{\lambda_{\rm UV}} + J_\Theta\cdot\hat{\mathbf{\Theta}}_{\lambda_{\rm UV}} + \bar\eta\cdot c + \eta\cdot\bar c + B\cdot b, \\ \mathcal{K}\cdot\zeta\varphi &:= K_\Phi\cdot\zeta\hat{\mathbf{\Phi}}_{\lambda_{\rm UV}} + K_\Theta\cdot\zeta\hat{\mathbf{\Theta}}_{\lambda_{\rm UV}} + K_c\cdot\zeta c + K_{\bar c}\cdot\zeta\bar c + K_b\cdot\zeta b\,, \end{aligned} \tag{7.142}$$

where "$\cdot$" includes spacetime integration with the IR window $K_{\rm IR}^{(\ell)}$ and implicit traces, and all fields are projected by $P_x(\lambda_{\rm UV})$ as in Section 7.3.1. The total action is

$$S_{\rm tot} = S_{\Phi,\Theta}^{(\lambda_{\rm UV},\ell)} \;+\; \zeta\Psi \;+\; \mathcal{J}\cdot\varphi \;+\; \mathcal{K}\cdot\zeta\varphi, \tag{7.143}$$

with $\zeta\Psi$ the BRST-exact gauge-fixing/ghost term (ghost number 0), cf. Section 7.1.3. Define

$$Z[\mathcal{J},\mathcal{K}] := \int\mathcal{D}\varphi\;\exp\Big\{i\,S_{\rm tot}\Big\}, \qquad W := -i\ln Z, \qquad \Gamma := \mathsf{Legendre}_{\mathcal{J}}(W) - \mathcal{K}\cdot\zeta\varphi, \tag{7.144}$$

where the Legendre transform is with respect to $\mathcal{J}$ at fixed $\mathcal{K}$. Band-limiting and IR smearing commute with the BRST charge (ghost number 0); in particular,

$$[\hat Q_{\rm BRST},\, P_x(\lambda_{\rm UV})] = 0, \qquad \zeta\Big(K_{\rm IR}^{(\ell)} * \,\cdot\,\Big) = 0, \tag{7.145}$$

so the source formalism descends consistently to $\mathcal{H}_{\rm phys}$.

Definition 7.204 (Band-limited Slavnov functional)**.** Write $\varphi = (\hat{\mathbf{\Phi}}_{\lambda_{\rm UV}}, \hat{\mathbf{\Theta}}_{\lambda_{\rm UV}}, c, \bar c, b)$ and $\mathcal{K} = (K_\Phi, K_\Theta, K_c, K_{\bar c}, K_b)$ with ghost-number assignments standard in BRST ($\mathrm{gh}(c) = 1$, $\mathrm{gh}(\bar c) = -1$, $\mathrm{gh}(b) = 0$, and $\mathrm{gh}(K_\phi) = -1 - \mathrm{gh}(\phi)$). For any functional $F[\varphi,\mathcal{K}]$ define the (band-limited) Zinn–Justin antibracket

$$(F,G) := \frac{\delta_r F}{\delta\varphi}\cdot\frac{\delta_l G}{\delta\mathcal{K}} - \frac{\delta_r F}{\delta\mathcal{K}}\cdot\frac{\delta_l G}{\delta\varphi},$$

and the Slavnov functional

$$\mathcal{S}(F) := \frac{1}{2}\,(F,F).$$

The dot-contractions include the IR kernel $K_{\rm IR}^{(\ell)}$ and UV projector $P_x(\lambda_{\rm UV})$ as in Section 7.3.1.

Proposition 7.205 (Band Slavnov–Taylor identities for W and Γ)**.** *Under BRST invariance of the measure and* (7.145)*, the connected generator W and the 1PI functional Γ satisfy*

$$\mathcal{S}(W) = 0, \qquad \mathcal{S}(\Gamma) = 0, \tag{7.146}$$

exactly on the band in Quadrant I.

Proof. Consider the BRST change of variables $\varphi \mapsto \varphi + \epsilon\,\zeta\varphi$ in the path integral defining Z; the Jacobian is unity by standard arguments, while $\zeta(S_{\mathrm{tot}}) = \zeta(\zeta\Psi) + \zeta(\mathcal{J}\cdot\varphi) + \zeta(\mathcal{K}\cdot\zeta\varphi) = 0$ since $\zeta^2 = 0$, $\zeta(\mathcal{J}\cdot\varphi) = \mathcal{J}\cdot\zeta\varphi$, and the $\mathcal{K}$-term cancels it by construction. Band-limited commutation (7.145) ensures no extra terms arise. Passing to W and performing the Legendre transform at fixed $\mathcal{K}$ yields (7.146). □

Lemma 7.206 (Linearised Slavnov operator)**.** *Define $\mathcal{B}_\Gamma X := (\Gamma, X)$. If $\mathcal{S}(\Gamma) = 0$, then $\mathcal{B}_\Gamma^2 = 0$. Moreover, $\mathcal{B}_\Gamma$ implements the quantum BRST differential on composite operators, restricted to the band.*

Proof. Jacobi identity for the antibracket implies $(\Gamma, (\Gamma, X)) = \frac{1}{2}((\Gamma,\Gamma), X) = 0$ when $\mathcal{S}(\Gamma) = 0$. □

Proposition 7.207 (Band-limited Ward identities for global G)**.** *Let $\delta^a_G\varphi = R^a[\varphi]$ be the (infinitesimal) global G-symmetry at the G-invariant vacuum of Quadrant I, with the band-limited action $S^{(\lambda_{\mathrm{UV}},\ell)}_{\Phi,\Theta}$ invariant and Ψ chosen G-invariant. Then*

$$\mathcal{W}_a(\Gamma) = 0, \qquad \mathcal{W}_a := \frac{\delta\Gamma}{\delta\varphi}\cdot R^a[\varphi], \tag{7.147}$$

and analogously for W. If the background-field split is used, (7.147) *becomes the background Ward identity with band knobs inserted.*

Proof. Repeat the change-of-variables argument using δ^a_G in the band-limited path integral; invariance of the measure and G-invariance of $S^{(\lambda_{\mathrm{UV}},\ell)}_{\Phi,\Theta} + \zeta\Psi$ give the identity. The band operations commute with δ^a_G by construction. □

Proposition 7.208 (Nielsen (gauge-parameter) identity on the band)**.** *Let α_{gf} enter only through the gauge fermion $\Psi(\alpha_{\mathrm{gf}})$. Then*

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\big(\Gamma, \partial_{\alpha_{\mathrm{gf}}}\Psi\big) = -\,\mathcal{B}_\Gamma\big(\partial_{\alpha_{\mathrm{gf}}}\Psi\big), \tag{7.148}$$

with all products band-limited as above. Consequently, $\partial_{\alpha_{\mathrm{gf}}}\Gamma$ is $\mathcal{B}_\Gamma$-exact, and physical, BRST-closed observables are gauge-parameter independent.

Proof. Differentiate Z with respect to α_{gf}; only $\zeta\Psi$ varies. Using the antibracket/linearised identity $\mathcal{B}_\Gamma X = (\Gamma, X)$ (Prop. 7.212) with $X = \partial_{\alpha_{\mathrm{gf}}}\Psi$, and the band commutation (7.145), yields (7.148). □

Proposition 7.209 (Ghost, antighost, and b equations)**.** *Assuming the usual linear dependence of Ψ on $\bar{c}$ and b, one obtains (band-limited) equations of motion*

$$\frac{\delta\Gamma}{\delta b} = \mathcal{G}_b, \qquad \frac{\delta\Gamma}{\delta\bar{c}} = \mathcal{G}_{\bar{c}}, \qquad \frac{\delta\Gamma}{\delta c} = \mathcal{G}_c, \tag{7.149}$$

where $\mathcal{G}_\bullet$ are local functionals fixed by the chosen gauge and knobs. These identities are compatible with (7.146) *and* (7.148)*.*

Proof. Direct variation of (7.143) with respect to the corresponding fields; the band operations commute with these algebraic variations. □

Proposition 7.210 (Cohomology baseline on the band)**.** *Let* $\mathsf{H}^0(\mathcal{B}_\Gamma)$ *denote the cohomology at ghost number* 0 *of the linearised operator* $\mathcal{B}_\Gamma$ *defined on the band. Then* $\mathsf{H}^0(\mathcal{B}_\Gamma)$ *is isomorphic to the space of gauge-invariant, G-invariant local functionals modulo band-limited EOMs. In particular, physical insertions and S-matrix elements restricted to* $\mathcal{H}_{\text{phys}}$ *are represented by* $\mathcal{B}_\Gamma$*-closed classes.*

Proof. Standard algebraic renormalisation/cohomology arguments apply verbatim since (7.145) ensures the band operations preserve ghost number and commute with ζ; locality is preserved by the L^1 IR window and projector locality. See [117, 442]. □

Remark 7.211 (Exactly at the symmetry point)**.** At the G-invariant vacuum of Quadrant I, (7.147), (7.146), and (7.148) together constitute the exact baseline: *any* departure observed in other quadrants must be attributed to (i) controlled, certified symmetry breaking (law or state), (ii) anomaly terms excluded by the filters of Section 7.2.8, or (iii) violations of admissibility/regularisation stability addressed in Section 7.3.7.

7.5.2 Slavnov–Taylor Identity and Linearized Operator

Introduce the Slavnov functional (Zinn–Justin identity) for the band-limited 1PI action:

$$\mathcal{S}(\Gamma) := \int d^dx \left[\frac{\delta\Gamma}{\delta\Phi}\frac{\delta\Gamma}{\delta K_\Phi} + \frac{\delta\Gamma}{\delta\Theta}\frac{\delta\Gamma}{\delta K_\Theta} + \frac{\delta\Gamma}{\delta c}\frac{\delta\Gamma}{\delta K_c} + \frac{\delta\Gamma}{\delta \bar{c}}\frac{\delta\Gamma}{\delta K_{\bar{c}}} + \frac{\delta\Gamma}{\delta b}\frac{\delta\Gamma}{\delta K_b} \right] = 0, \tag{7.150}$$

which is the band/IR version of eq. (7.16). Following [117, 442], define the *linearized* Slavnov operator acting on a functional X:

$$\begin{aligned} \mathcal{B}_\Gamma X := \int d^dx \Bigg[& \frac{\delta\Gamma}{\delta\Phi}\frac{\delta X}{\delta K_\Phi} + \frac{\delta X}{\delta\Phi}\frac{\delta\Gamma}{\delta K_\Phi} + \frac{\delta\Gamma}{\delta\Theta}\frac{\delta X}{\delta K_\Theta} + \frac{\delta X}{\delta\Theta}\frac{\delta\Gamma}{\delta K_\Theta} \\ & + \frac{\delta\Gamma}{\delta c}\frac{\delta X}{\delta K_c} + \frac{\delta X}{\delta c}\frac{\delta\Gamma}{\delta K_c} + \frac{\delta\Gamma}{\delta \bar{c}}\frac{\delta X}{\delta K_{\bar{c}}} + \frac{\delta\Gamma}{\delta b}\frac{\delta X}{\delta K_b} \Bigg]. \end{aligned} \tag{7.151}$$

If $\mathcal{S}(\Gamma) = 0$, then $\mathcal{B}_\Gamma^2 = 0$ (nilpotent) and cohomology classes $H^0(\mathcal{B}_\Gamma)$ characterize physical, gauge-invariant composite operators. These statements hold *on the band* by (7.145) and ensure that BRST-exact insertions do not contribute to physical matrix elements in $\mathcal{H}_{\text{phys}}$ [117, 91].

Proposition 7.212 (Antibracket form and equivalence)**.** *Let* (F, G) *denote the (band-limited) Zinn–Justin antibracket defined as in Definition 7.204. Then*

$$\mathcal{S}(\Gamma) = \tfrac{1}{2}(\Gamma, \Gamma), \qquad \mathcal{B}_\Gamma X = (\Gamma, X),$$

with all contractions understood with the UV projector $P_x(\lambda_{\text{UV}})$ *and IR window* $K_{\text{IR}}^{(\ell)}$*. Hence* (7.150) *is equivalent to* $(\Gamma, \Gamma) = 0$*.*

Proof. A direct comparison of the components in (7.150) and (7.151) with the antibracket definitions (including the source sector) yields the stated identities; band operations commute with functional differentiation by (7.145). □

Lemma 7.213 (Nilpotency of the linearized operator)**.** *If $\mathcal{S}(\Gamma) = 0$, then $\mathcal{B}_\Gamma^2 = 0$ on the space of local integrated functionals (band-limited).*

Proof. Using Proposition 7.212 and the graded Jacobi identity, $\mathcal{B}_\Gamma^2 X = (\Gamma, (\Gamma, X)) = \frac{1}{2}((\Gamma, \Gamma), X) = 0$ when $(\Gamma, \Gamma) = 0$. □

Proposition 7.214 (Ghost number and cohomological gradings)**.** *Assign* $\mathrm{gh}(\Phi) = \mathrm{gh}(\Theta) = \mathrm{gh}(b) = 0$, $\mathrm{gh}(c) = 1$, $\mathrm{gh}(\bar{c}) = -1$, *and* $\mathrm{gh}(K_\phi) = -1 - \mathrm{gh}(\phi)$. *Then* $\mathrm{gh}(\mathcal{B}_\Gamma) = +1$, *so* $\mathcal{B}_\Gamma : \mathsf{F}^g \to \mathsf{F}^{g+1}$. *The cohomology* $\mathsf{H}^g(\mathcal{B}_\Gamma)$ *is thus naturally* $\mathbb{Z}$*-graded; physical insertions correspond to* $\mathsf{H}^0(\mathcal{B}_\Gamma)$ *modulo band-limited EOMs.*

Lemma 7.215 (Doublet lemma (band-limited))**.** *If a pair (u, v) forms a $\mathcal{B}_\Gamma$-doublet, $\mathcal{B}_\Gamma u = v$, $\mathcal{B}_\Gamma v = 0$, then (u, v) does not contribute to the cohomology: any $\mathcal{B}_\Gamma$-closed functional depending on (u, v) is $\mathcal{B}_\Gamma$-exact up to functionals independent of (u, v). In particular, $(\bar{c}, b)$ and the source pairs form doublets, so they drop out of* $\mathsf{H}^0(\mathcal{B}_\Gamma)$.

Proof. Standard homotopy-contraction argument (see [117]) applies verbatim since the band kernels commute with $\mathcal{B}_\Gamma$. □

Proposition 7.216 (Quantum Action Principle and anomaly consistency)**.** *If radiative corrections generate a breaking $\mathcal{S}(\Gamma) = \Delta_{\mathrm{an}}$ (ghost number $+1$), then the Quantum Action Principle implies the* Wess–Zumino consistency condition

$$\mathcal{B}_\Gamma \, \Delta_{\mathrm{an}} = 0,$$

so $\Delta_{\mathrm{an}} \in \mathsf{H}^1(\mathcal{B}_\Gamma)$ (band-limited). If the anomaly filters of Section 7.2.8 hold, then Δ_{an} is $\mathcal{B}_\Gamma$-exact modulo total derivatives and EOMs, and can be removed by local counterterms (cf. Prop. 7.189).

Proof. Differentiate $\mathcal{S}(\Gamma) = \Delta_{\mathrm{an}}$ with $\mathcal{B}_\Gamma$ and use Lemma 7.213 to obtain $\mathcal{B}_\Gamma \Delta_{\mathrm{an}} = 0$. Cohomological triviality follows from the anomaly filters. □

Proposition 7.217 (Stability of the identity and counterterm characterization)**.** *Let $\Gamma \mapsto \Gamma + \hbar^n \Delta\Gamma$ be a finite renormalization at order n that preserves (7.150). Then*

$$\mathcal{B}_\Gamma(\Delta\Gamma) = 0.$$

Hence admissible counterterms are representatives of $\mathsf{H}^0(\mathcal{B}_\Gamma)$ (modulo band-limited EOMs and total derivatives). By Lemma 7.215, they can be chosen G-invariant and independent of $(\bar{c}, b)$ and sources, matching the physical invariant basis.

Proof. Insert $\Gamma + \hbar^n \Delta\Gamma$ into $\mathcal{S}(\Gamma) = 0$ and retain $\mathcal{O}(\hbar^n)$ terms; linearization gives $\mathcal{B}_\Gamma(\Delta\Gamma) = 0$. The cohomological statement follows from the previous lemmas. □

Proposition 7.218 (Nielsen identity in linearized form)**.** *If the gauge parameter α_{gf} enters only via the gauge fermion $\Psi(\alpha_{\mathrm{gf}})$, then*

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\big(\partial_{\alpha_{\mathrm{gf}}}\Psi\big)\,,$$

i.e. the gauge–parameter derivative is $\mathcal{B}_\Gamma$–exact. Thus any BRST–closed, ghost–number–zero physical functional is gauge–parameter independent on the band (cf. (7.340)).

Proof. Differentiate the band-limited path integral with respect to α_{gf}; only $\zeta\Psi$ varies. Using the Zinn–Justin antibracket equivalence $\mathcal{B}_\Gamma X = (\Gamma, X)$ (Prop. 7.212) with $X = \partial_{\alpha_{\mathrm{gf}}}\Psi$ yields the result. □

Remark 7.219 (Physical matrix elements on $\mathcal{H}_{\mathrm{phys}}$)**.** Because $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = 0$ and $\zeta(K_{\mathrm{IR}}^{(\ell)} * \cdot) = 0$ (eq. (7.145)), the band-limited BRST charge descends to $\mathcal{H}_{\mathrm{phys}}$ and $\mathcal{B}_\Gamma$-exact insertions decouple between physical projectors (quartet/positivity). Hence physical matrix elements and ancilla readouts computed in Section 7.4 are insensitive to $\mathcal{B}_\Gamma$-exact deformations, providing the exact symmetry-point baseline for the probe.

7.5.3 Gauge-fixing, Antighost, and b-equations

For a general gauge fermion Ψ the ghost/antighost sector obeys exact equations of motion (Quantum Action Principle) [117]:

$$\frac{\delta\Gamma}{\delta b} = \frac{\delta}{\delta b}\big(\zeta\Psi\big) = \mathcal{F}_{\mathrm{gf}}(\Phi, \Theta; \alpha_{\mathrm{gf}}), \qquad \frac{\delta\Gamma}{\delta \bar{c}} = \frac{\delta}{\delta \bar{c}}\big(\zeta\Psi\big) - \partial_\mu \frac{\delta\Gamma}{\delta K_\mu^{(A)}} \ \text{(if gauge vectors are present)}, \tag{7.152}$$

and the *ghost equation* (global ghost-number Ward identity) constrains the dependence on c and its source K_c.[5] These identities are exact at the G-invariant vacuum and commute with the band/IR knobs by (7.145). Together with Section 7.5.2, they imply the decoupling of ζ-exact terms from $\mathcal{H}_{\mathrm{phys}}$ matrix elements.

Definition 7.220 (Quantum Action Principle (band version))**.** Let Z, W, and Γ be the band-limited generating functionals defined in (7.144), with UV/IR tagging that commutes with BRST and with functional differentiation (cf. (7.145)). For any local deformation $\delta_\xi S$ of the action (including changes of couplings, field redefinitions, or a gauge-fermion variation $\delta_\xi\Psi$ entering as $s\Psi$), the variation of the 1PI functional is the insertion of a *local* composite operator:

$$\partial_\xi\Gamma \;=\; \int d^d x\; \mathcal{N}_\xi(x),$$

where $\mathcal{N}_\xi(x)$ is a local polynomial (power-counting bounded) in fields/sources and their derivatives. If the deformation is BRST-exact, $\delta_\xi S = s\,\Xi$, then

$$\partial_\xi\Gamma \;=\; -\,\mathcal{B}_\Gamma(\Xi)\,,$$

[5] We keep the gauge representation abstract; when explicit gauge vectors A_μ are present, $K_\mu^{(A)}$ is the source for $\zeta A_\mu = D_\mu c$ and (7.152) reduces to the standard pair (Landau gauge: $\partial_\mu A^\mu = 0$ implies a linear b-equation).

i.e. the breaking is $\mathcal{B}_\Gamma$-exact. These statements hold on the band because the tagging is linear, local/pseudolocal, and BRST-closed (no anomaly on the band). Standard QAP references include [82, 91].

Proposition 7.221 (QAP form of the b- and antighost equations on the band)**.** *Let Γ be the band-limited 1PI functional of (7.144) with BRST-exact gauge fixing $s\Psi$ (we write $\zeta\Psi$ in components). Then the functional derivatives with respect to the Nakanishi–Lautrup field b^a and the antighost $\bar{c}^a$ satisfy the (band) equations*

$$\frac{\delta\Gamma}{\delta b^a(x)} \;=\; \mathcal{F}^a_{\mathrm{gf}}\big(x;\lambda_{\mathrm{UV}},\ell\big), \qquad \frac{\delta\Gamma}{\delta \bar{c}^a(x)} \;+\; \mathcal{R}^{\,a}\big(x;\lambda_{\mathrm{UV}},\ell\big) \;=\; 0, \tag{7.153}$$

where $\mathcal{F}^a_{\mathrm{gf}}$ and $\mathcal{R}^{\,a}$ are local *functionals fixed by the gauge fermion Ψ (hence by the chosen gauge condition) and by the band knobs $(\lambda_{\mathrm{UV}},\ell)$. In linear covariant gauges, $\mathcal{F}^a_{\mathrm{gf}}$ reduces to the gauge condition (e.g. $\partial_\mu A^{a\mu} - \alpha_{\mathrm{gf}}\, b^a$ up to conventions), while $\mathcal{R}^{\,a}$ is the standard source term built from the 1PI source that couples to sA^a_μ (the Zinn–Justin source $K^{\mu(A)a}$).*

Proof idea. Differentiate $\zeta\Psi$ algebraically with respect to b and $\bar{c}$ and use that band operations commute with functional differentiation by (7.145). If A_μ is present, the $\bar{c}$-equation acquires the standard source term proportional to the derivative of Γ w.r.t. $K^{(A)}_\mu$ (the source for ζA_μ), reproducing (7.152).

Proof. (1) Starting point and band commutativity. Work with the band-limited path integral $Z[J,\text{sources}]$ whose action is $S_{\mathrm{band}} = S_0^{\mathrm{band}} + s\Psi^{\mathrm{band}}$; UV/IR tagging acts as in (7.145) and commutes with BRST and with functional derivatives. Introduce sources $J_b, J_{\bar{c}}$ for $b, \bar{c}$ and the Zinn–Justin sources K that couple to BRST variations $s\varphi$. Legendre-transform to Γ as in (7.144).

(2) b-equation (algebraic EOM). The gauge fermion Ψ depends on b at most algebraically (no derivatives, no kinetic term for b). Hence the functional integral over b is Gaussian/algebraic, and a shift of the b-integration variable yields the exact identity in the connected functional W:

$$\frac{\delta W}{\delta J^a_b(x)} \;=\; \Big\langle\, \mathcal{F}^a_{\mathrm{gf}}(x) \,\Big\rangle,$$

where $\mathcal{F}^a_{\mathrm{gf}}$ is the gauge-fixing function fixed by Ψ (e.g. the gauge condition). Legendre transforming gives $\delta\Gamma/\delta b^a(x) = \mathcal{F}^a_{\mathrm{gf}}(x)$, now with all entries *band-limited*. No quantum breaking can appear here: by QAP Definition 7.220 any breaking would be a local polynomial with the ghost number and dimensions of b; power counting and ghost number force the classical form, so $(7.153)_1$ holds exactly [82, 91].

(3) Antighost equation. Consider the variation of the integrand under the *inhomogeneous* shift $\bar{c}^a \mapsto \bar{c}^a + \varepsilon^a$ (at fixed sources). In $s\Psi$ the $\bar{c}$ only appears linearly through the gauge-fixing term $\bar{c}\,\mathcal{G}(A,c,\ldots)$ determined by Ψ and through the Zinn–Justin sector coupling the source $K^{\mu(A)}$ to sA_μ. By a standard change of variables in the path integral and integration by parts one obtains, in the connected generating functional,

$$\frac{\delta W}{\delta J^a_{\bar{c}}(x)} \;+\; \Big\langle\, \mathcal{R}^{\,a}(x) \,\Big\rangle \;=\; 0,$$

where $\mathcal{R}^a$ is the local composite induced by the sA sector (in linear covariant gauges, $\mathcal{R}^a = \partial_\mu K^{\mu(A)a}$ up to conventions). Legendre transforming gives the 1PI relation

$$\frac{\delta\Gamma}{\delta\bar{c}^a(x)} \;+\; \mathcal{R}^a(x) \;=\; 0.$$

Again, by the QAP Definition 7.220 any radiative breaking would be a *local* insertion with ghost number -1 and canonical dimension bounded by the gauge-fixing sector; the only such insertion is the classical $\mathcal{R}^a$ which is already present, so the identity is stable under renormalisation on the band [82, 91].

(4) Band locality and stability. Throughout, UV/IR tagging is linear and BRST-closed, hence it commutes with the changes of variables used above and preserves locality (the kernels are pseudodifferential of order ≤ 0 on the band). Therefore the QAP applies verbatim to the band-limited Γ, and (7.153) holds exactly with *local* $\mathcal{F}^a_{\mathrm{gf}}$ and $\mathcal{R}^a$ determined by Ψ and $(\lambda_{\mathrm{UV}}, \ell)$.

This proves the proposition. □

Proposition 7.222 (Ghost equation with linear breaking (band-limited))**.** *There exists a local Ward operator $\mathcal{G}^a(x)$ of ghost number -1 (the* ghost Ward operator*) such that:*

$$\mathcal{G}^a(x)\,\Gamma = \Delta^a_c(x). \tag{7.154}$$

Here the breaking Δ^a_c *is linear in the external Zinn–Justin sources (e.g. $K^{\mu(A)a}, K^{(\Phi)}_A, K^{(\Theta)}_A, \ldots$) and therefore receives no loop corrections beyond tree level (stability of the breaking by the QAP). In Landau gauge the breaking reduces to a term purely linear in $K^{\mu(A)a}$ and is independent of dynamical fields. All contractions and kernels are understood "on the band," i.e. with $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ inserted as in (7.144), and tagging commutes with BRST by (7.145).*

Proof idea. Perform the change of variables $c \mapsto c + \epsilon$ in the band-limited path integral (constant shift in ghost number $+1$). The Jacobian is unity and the only variation originates from source terms coupled to ζc; passing to Γ yields a linear functional in the sources, i.e. Δ_c. Band operations commute with the shift.

Proof. **1) Setup on the band and sources.** Let Z, W, and Γ be the band-limited generating functionals defined in (7.144). The gauge-fixed action is $S_{\mathrm{band}} = S_{0,\mathrm{band}} + s\Psi_{\mathrm{band}}$, with BRST variations $s\bar{c}^a = b^a$, $sb^a = 0$, and $s\varphi^A = R^A{}_a(\varphi)\,c^a$ for generic matter/gauge multiplets φ^A. Introduce Zinn–Justin sources K that couple linearly to the BRST variations $s\varphi$, so the source part reads schematically $\int d^dx\, K_A\, s\varphi^A$ (and analogously for gauge fields). By (7.145), $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ commute with s and with functional differentiation, so the usual algebra is unaffected on the band.

2) Constant ghost shift in the path integral. Consider the change of variables (translation) in the band-limited path integral

$$c^a(x) \;\mapsto\; c^a(x) + \epsilon^a(x), \qquad \epsilon^a(x) \text{ arbitrary test function (ghost number } +1).$$

The functional measure is translation invariant, hence its Jacobian is 1. The only variation of the integrand comes from the explicit c-dependence in $s\Psi_{\text{band}}$ *via* $s\varphi^A$ and from the Zinn–Justin source term $\int K_A\, s\varphi^A$. At the level of the connected generator W, this yields the identity

$$\int d^dx\, \epsilon^a(x) \left[\frac{\delta W}{\delta J_c^a(x)} + \Big\langle \frac{\delta(s\Psi_{\text{band}})}{\delta c^a(x)} \Big\rangle + \int d^dy\, K_A(y) \, \Big\langle \tfrac{\delta(s\varphi^A(y))}{\delta c^a(x)} \Big\rangle \right] = 0.$$

Legendre-transforming to the 1PI functional Γ and using the standard relations between $\delta W/\delta J$ and classical fields gives a local operator identity acting on Γ:

$$\frac{\delta\Gamma}{\delta c^a(x)} \;+\; \mathcal{U}^a(x;\Phi,\Theta,\ldots) \;+\; \int d^dy\, K_A(y)\, \frac{\delta(s\varphi^A(y))}{\delta c^a(x)} \;=\; 0, \tag{7.155}$$

where $\mathcal{U}^a$ collects the contribution from $s\Psi_{\text{band}}$ expressed in 1PI variables (see Step 4). Equation (7.155) holds *on the band* since tagging commutes with all steps.

3) Definition of the ghost Ward operator and the breaking. Define the (band) ghost Ward operator $\mathcal{G}^a(x)$ acting on functionals F by

$$\mathcal{G}^a(x)\, F \;:=\; \frac{\delta F}{\delta c^a(x)} \;+\; \int d^dy\, \frac{\delta F}{\delta K_A(y)}\, \frac{\delta\big(s\varphi^A(y)\big)}{\delta c^a(x)} \;+\; \bar{c}^b(x)\, \Xi^{ab}\Big[x; \frac{\delta F}{\delta b}\Big], \tag{7.156}$$

where the last term is the algebraic piece enforced by $s\bar{c} = b$ (its concrete form is fixed by the gauge fermion and is linear in the functional derivative w.r.t. b; see Step 4). By construction, $\mathcal{G}^a$ has ghost number -1 and is local. Evaluating (7.156) on $F = \Gamma$ and comparing with (7.155) we obtain

$$\mathcal{G}^a(x)\,\Gamma \;=\; \Delta_c^a(x), \qquad \Delta_c^a(x) \text{ local and linear in the Zinn–Justin sources.}$$

Explicitly,

$$\Delta_c^a(x) \;=\; -\mathcal{U}^a(x;\Phi,\Theta,\ldots)\Big|_{\text{linear in sources}} \;=\; \sum_{\mathsf{A}} \mathcal{C}^a{}_{\mathsf{A}}(\partial, \text{rep.})\, K^{\mathsf{A}}(x), \tag{7.157}$$

with $\mathcal{C}$ a differential operator fixed by the BRST variations $s\varphi$ (representation matrices, covariant derivatives, etc.). Thus Δ_c is *linear* in the external sources and contains no dynamical-field dependence in Landau gauge (Step 4).

4) Landau gauge and explicit form of the linear breaking. In linear covariant gauges one may choose a gauge fermion of the form $\Psi = \int d^dx\, \bar{c}^a\, \mathcal{G}^a(A,\Phi,\Theta,\ldots) - \frac{\alpha_{\text{gf}}}{2}\, \bar{c}^a b^a$, so that $s\Psi$ is linear in b and $\bar{c}$. Using $s\bar{c}^a = b^a$ and $sA_\mu^a = D_\mu c^a$, the $\bar{c}$-shift–induced piece in (7.155) precisely yields the algebraic $\bar{c}\,\delta/\delta b$ contribution indicated in (7.156), and the remaining terms can be arranged so that the breaking depends only on the Zinn–Justin sources. In particular, for the Landau gauge $\alpha_{\text{gf}} = 0$ one finds

$$\Delta_c^a(x) \;=\; \partial_\mu K^{\mu(A)a}(x) \quad \text{(up to representation/gauge-coupling conventions)},$$

independent of dynamical fields. This is the standard linear breaking of the ghost equation (no field-dependent terms) adapted to the band setting [52, 91].

5) Locality and stability of the breaking (QAP). By the band version of the Quantum Action Principle (QAP; Definition 7.220), the variation induced by the local ghost translation is represented in Γ by insertion of a *local* composite. Ghost number and power counting restrict the possible local insertions on the r.h.s. to be linear in the external sources (they carry the appropriate ghost number). Hence Δ_c is *purely linear* and receives no loop-generated non-linear corrections: its form is tree-level exact and stable under renormalisation [82, 91]. Because $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with BRST and functional differentiation (and are of order ≤ 0), the argument lifts verbatim to the band-limited functionals.

Conclusion. With $\mathcal{G}^a(x)$ defined by (7.156), the identity $\mathcal{G}^a(x)\Gamma = \Delta_c^a(x)$ holds on the band, the breaking Δ_c is local and linear in the Zinn–Justin sources, and in Landau gauge it is independent of dynamical fields. Stability follows from the QAP, completing the proof. □

Definition 7.223 (Jet bundles, total derivatives, and local functionals (Chapter 7 conventions))**.** Let the basic fields be collectively $\varphi^A \in \{\Phi^A, \Theta^A, c^a, \bar{c}^a, b^a, \dots\}$ over spacetime M. For a multi–index $\alpha = (\mu_1 \cdots \mu_k)$, write $\partial_\alpha := \partial_{\mu_1} \cdots \partial_{\mu_k}$ and denote jet coordinates by $\varphi^A_{(\alpha)} := \partial_\alpha \varphi^A$ at a common point $x \in M$. The r–jet bundle J^r has local coordinates $(x^\mu, \varphi^A_{(\alpha)})_{|\alpha|\leq r}$; the infinite jet J^∞ collects all orders. The algebra of local functions $\mathcal{F}_{\mathrm{loc}}$ consists of polynomials/smooth functions of finitely many jet coordinates.
(i) Total derivative. The horizontal (total) derivative acts on jet coordinates by

$$D_\mu \;:=\; \partial_\mu \;+\; \sum_{A,\alpha} \varphi^A_{(\alpha\mu)}\, \frac{\partial}{\partial \varphi^A_{(\alpha)}}\,, \qquad D_\alpha := D_{\mu_1} \cdots D_{\mu_k} \;\text{ for }\; \alpha = (\mu_1 \cdots \mu_k). \tag{7.158}$$

(ii) Euler–Lagrange operator. For a local density $f \in \mathcal{F}_{\mathrm{loc}}$,

$$\mathbf{E}_A(f) \;:=\; \sum_{|\alpha|\geq 0} (-D)_\alpha \left(\frac{\partial f}{\partial \varphi^A_{(\alpha)}} \right), \qquad \delta \int f\, d^dx = \int \delta\varphi^A\, \mathbf{E}_A(f)\, d^dx \;+\; \text{boundary}. \tag{7.159}$$

(iii) Band/IR compatibility. Replace fields by jointly tagged ones from Definition 7.28: $\varphi^A \mapsto \varphi^A_{\lambda_{\mathrm{UV}},\ell}$. Under the standing assumption that $[\,\nabla_\mu, P_x(\lambda_{\mathrm{UV}})\,] = 0$ and $K_{\mathrm{IR}}^{(\ell)}$ is a scalar kernel, tagging commutes with differentiation (cf. item (iv) of Definition 7.28):

$$D_\mu\Big(\varphi^A_{\lambda_{\mathrm{UV}},\ell}\Big) = \Big(D_\mu \varphi^A\Big)_{\lambda_{\mathrm{UV}},\ell}, \qquad D_\alpha\Big(\varphi^A_{\lambda_{\mathrm{UV}},\ell}\Big) = \Big(D_\alpha \varphi^A\Big)_{\lambda_{\mathrm{UV}},\ell}. \tag{7.160}$$

Local band–limited functionals are integrals of densities built from finitely many tagged jets.
(iv) BRST/Slavnov prolongation on jets. Writing the BRST variation as $s\,\varphi^A = R^A(\varphi, \partial\varphi, \dots)$, its prolongation acts by

$$s\,\varphi^A_{(\alpha)} = D_\alpha\Big(R^A(\varphi, \partial\varphi, \dots)\Big). \tag{7.161}$$

Here $\mathcal{B}_\Gamma$ acts derivationally on $\mathcal{F}_{\mathrm{loc}}$ and commutes with D_μ on the band.
(v) Doublet counting and contracting homotopy (for $(\bar{c}, b)$). Let N_{dbl} count jets of the BRST doublet $(\bar{c}^a, b^a)$:

$$N_{\mathrm{dbl}} := \sum_{a,\alpha} \left(\bar{c}^a_{(\alpha)} \frac{\partial}{\partial \bar{c}^a_{(\alpha)}} + b^a_{(\alpha)} \frac{\partial}{\partial b^a_{(\alpha)}} \right).$$

Define the contracting homotopy κ on jet generators by

$$\kappa\big(b^a_{(\alpha)}\big) = \bar{c}^a_{(\alpha)}, \qquad \kappa\big(\bar{c}^a_{(\alpha)}\big) = 0, \qquad [\kappa, D_\mu] = 0, \tag{7.162}$$

and extend κ to $\mathcal{F}_{\mathrm{loc}}$ by graded Leibniz. With $s\,\bar{c}^a = b^a$, $s\,b^a = 0$, one has the homotopy identity

$$\{\, s, \kappa \,\} = N_{\mathrm{dbl}}\,. \tag{7.163}$$

Hence, if a local functional X is s–closed (or $\mathcal{B}_\Gamma$–closed on the band) and $N_{\mathrm{dbl}}X = n > 0$, then $X = \frac{1}{n}\, s(\kappa X)$ up to total derivatives and equations of motion; this is the doublet decoupling used in Lemma 7.224.

Lemma 7.224 (Doublet decoupling)**.** *With the ghost-number assignments of Section 7.5.2, $(\bar{c}, b)$ form a BRST doublet. Consequently, any $\mathcal{B}_\Gamma$-closed local functional that depends on $(\bar{c}, b)$ is $\mathcal{B}_\Gamma$-exact up to equations of motion and total derivatives. Hence $(\bar{c}, b)$ do not contribute to $\mathsf{H}^0(\mathcal{B}_\Gamma)$ and drop out of physical matrix elements on $\mathcal{H}_{\mathrm{phys}}$.*

Full proof. **(1) Linearised Slavnov operator and the doublet.** Let $\mathcal{B}_\Gamma$ be the linearised Slavnov operator around the band-limited 1PI functional Γ (see (7.144)). By Stage I anomaly filters, $\mathcal{B}_\Gamma^2 = 0$ on the band. Off shell (with Nakanishi–Lautrup fields present) one has

$$\mathcal{B}_\Gamma\,\bar{c}^a = b^a, \qquad \mathcal{B}_\Gamma\,b^a = 0, \qquad \mathrm{gh}(\bar{c}^a) = -1,\ \mathrm{gh}(b^a) = 0$$

(Section 7.5.2). Band/IR maps commute with BRST and carry ghost number 0 (eq. (7.145)), so these relations hold "on the band".

(2) Jet framework and operators N_{dbl}, κ. Work in the algebra of local functionals built from finitely many jets of the fields (Chapter 7 jets; Definition 7.223). Let D_μ be the total derivatives (7.158), and let the BRST action be prolonged to jets as in (7.161). Define the doublet-counting operator and the contracting homotopy on jets by

$$N_{\mathrm{dbl}} := \sum_{a,\alpha} \left(\bar{c}^a_{(\alpha)} \frac{\partial}{\partial \bar{c}^a_{(\alpha)}} + b^a_{(\alpha)} \frac{\partial}{\partial b^a_{(\alpha)}} \right), \qquad \kappa\big(b^a_{(\alpha)}\big) = \bar{c}^a_{(\alpha)}, \quad \kappa\big(\bar{c}^a_{(\alpha)}\big) = 0, \quad [\kappa, D_\mu] = 0,$$

and extend κ by the graded Leibniz rule; cf. (7.162). By construction,

$$\{\, \mathcal{B}_\Gamma, \kappa \,\} = N_{\mathrm{dbl}} \quad \text{on jet generators, prolonged via (7.161).} \tag{7.164}$$

(3) Cohomological form of (7.164). When applied to any local functional F, the identity (7.164) produces boundary terms (from integrations by parts with D_μ) and, if needed, Euler–Lagrange pieces generated by the jet-to-configuration reduction ((7.159)). Therefore

$$\{\mathcal{B}_\Gamma, \kappa\}\, F = \ N_{\mathrm{dbl}}\, F \ + \ (\text{total derivatives}) \ + \ (\text{terms} \propto \text{EOM}). \tag{7.165}$$

Since our cohomology is taken modulo total derivatives and equations of motion, these extras are immaterial. Band/IR tagging commutes with derivatives (Definition 7.28, item (iv), eq. (7.160)), hence (7.165) is unaffected "on the band".

(4) Decomposition by N_{dbl}-degree. Let F be a $\mathcal{B}_\Gamma$-closed local functional of ghost number 0: $\mathcal{B}_\Gamma F = 0$. Decompose $F = \sum_{n\geq 0} F^{(n)}$ with $N_{\mathrm{dbl}} F^{(n)} = n\, F^{(n)}$. Projecting (7.165) onto the n-eigenspace ($n > 0$) and using $\mathcal{B}_\Gamma F^{(n)} = 0$ gives

$$n\, F^{(n)} = \{\mathcal{B}_\Gamma, \kappa\} F^{(n)} = \mathcal{B}_\Gamma(\kappa F^{(n)}) \;+\; (\mathrm{mod\ EOM},\, d).$$

Hence, for every $n \geq 1$,

$$F^{(n)} = \mathcal{B}_\Gamma\!\left(\tfrac{1}{n}\,\kappa F^{(n)}\right) \quad \mathrm{mod\ (EOM},\, d).$$

Iterating over n eliminates all dependence on $(\bar{c}, b)$ up to $\mathcal{B}_\Gamma$-exact terms.

(5) Consequences. Only $F^{(0)}$ (independent of $(\bar{c}, b)$) can represent a nontrivial class, so $(\bar{c}, b)$ do not contribute to $\mathsf{H}^0(\mathcal{B}_\Gamma)$. Since insertions that are $\mathcal{B}_\Gamma$-exact vanish in physical matrix elements on $\mathcal{H}_{\mathrm{phys}}$ (Nielsen/BRST cohomological invariance), the doublet drops out of observables.

Band/IR remark. All steps are preserved under joint IR/UV tagging (Definition 7.28): $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ commute with the G-action and with D_μ, and are BRST-closed (item (ii) of Definition 7.28), so the homological construction carries over verbatim on the band. □

Definition 7.225 (Linear covariant gauges and Landau limit)**.** With joint IR/UV tagging as in Definition 7.28, fix BRST-exact gauge fixing by the gauge fermion

$$\Psi \;=\; \int d^d x\, K^{(\ell)}_{\mathrm{IR}}(x)\, \bar{c}^a(x) \Big(F^a(\Phi, \Theta)(x) - \tfrac{\alpha_{\mathrm{gf}}}{2}\, b^a(x) \Big),$$

where F^a is linear in the gauge potential (e.g. $F^a = \partial_\mu A^{\mu a}$, implicitly projected by $P_x(\lambda_{\mathrm{UV}})$). The one-parameter family $\alpha_{\mathrm{gf}} \geq 0$ defines the linear covariant gauges; eliminating b by its algebraic equation gives $b^a = \alpha_{\mathrm{gf}}^{-1} F^a$ for $\alpha_{\mathrm{gf}} > 0$. The *Landau limit* is $\alpha_{\mathrm{gf}} \to 0$, in which the b-equation imposes the linear constraint $F^a = 0$ on the band. This convention is stable under the QAP in the algebraic renormalisation framework and preserves the BRST cohomology (see [117, 82, 91]).

Proposition 7.226 (Linear covariant gauge as an illustrative instance)**.** *Suppose* $\Psi = \int d^d x\, K^{(\ell)}_{\mathrm{IR}}(x)\, \bar{c}^a \Big(F^a(\Phi, \Theta) - \tfrac{\alpha_{\mathrm{gf}}}{2}\, b^a \Big)$ *with F linear in the gauge field (e.g. $F^a = \partial_\mu A^{\mu a}$, understood band-limited by $P_x(\lambda_{\mathrm{UV}})$). Then*

$$\frac{\delta \Gamma}{\delta b^a} = F^a - \alpha_{\mathrm{gf}}\, b^a, \qquad \frac{\delta \Gamma}{\delta \bar{c}^a} = \frac{\delta F^a}{\delta A^b_\mu} \frac{\delta \Gamma}{\delta K^{(A)\mu b}} - \partial_\mu \frac{\delta \Gamma}{\delta K^{(A)\mu a}},$$

and the ghost equation reads $\mathcal{G}^a(x)\,\Gamma = \partial_\mu K^{(A)\mu a}(x)$ (all identities understood on the band). In the Landau limit $\alpha_{\mathrm{gf}} \to 0$, the b-equation imposes $F^a = 0$ linearly, and $\Delta_c = \partial_\mu K^{(A)\mu a}$ is a linear, tree-level exact breaking.

Proof idea. Insert the gauge fermion of Definition 7.225 into Proposition 7.221 to get $\delta\Gamma/\delta b^a = F^a - \alpha_{\mathrm{gf}} b^a$ and $\delta\Gamma/\delta \bar{c}^a = \frac{\delta F^a}{\delta A^b_\mu}\, \delta\Gamma/\delta K^{(A)\mu b} - \partial_\mu\, \delta\Gamma/\delta K^{(A)\mu a}$. The ghost equation then follows directly from Proposition 7.222: $\mathcal{G}^a(x)\Gamma = \partial_\mu K^{(A)\mu a}(x)$. Taking the Landau limit $\alpha_{\mathrm{gf}} \to 0$ gives $F^a = 0$ and a purely linear, tree-level exact breaking.

Full proof. **1) Gauge fixing and BRST variations.** With the gauge fermion Ψ as stated and BRST rules $s\,\bar{c}^a = b^a$, $s\,b^a = 0$, $s\,A^a_\mu = (D_\mu c)^a$ (and s acting as a derivation on other fields), the gauge-fixing+ghost density is

$$\mathcal{L}_{\mathrm{gf+gh}} = s\left[K^{(\ell)}_{\mathrm{IR}}\,\bar{c}^a\Big(F^a - \tfrac{\alpha_{\mathrm{gf}}}{2}b^a\Big)\right] = K^{(\ell)}_{\mathrm{IR}}\left[b^a\Big(F^a - \tfrac{\alpha_{\mathrm{gf}}}{2}b^a\Big) - \bar{c}^a\,sF^a\right].$$

Because F is linear in A, $sF^a = \frac{\delta F^a}{\delta A^b_\mu}\,(D_\mu c)^b$. Joint IR/UV tagging commutes with the BRST action and with derivatives (cf. Definition 7.28, items (ii)–(iv)), so these equalities hold on the band.

2) b-equation (algebraic). In the path integral, the field b^a appears only algebraically. The classical identity

$$\frac{\delta S}{\delta b^a} = K^{(\ell)}_{\mathrm{IR}}\Big(F^a - \alpha_{\mathrm{gf}}\,b^a\Big)$$

is therefore stable under renormalisation by the Quantum Action Principle (QAP): linear, non-derivative algebraic equations are not deformed by loops (they can at most receive local redefinitions that are ruled out by ghost number and power counting). Passing to the 1PI functional and dropping the common $K^{(\ell)}_{\mathrm{IR}}$ factor that commutes with functional differentiation (on the band) yields

$$\frac{\delta\Gamma}{\delta b^a} = F^a - \alpha_{\mathrm{gf}}\,b^a,$$

exactly. See the algebraic-renormalisation treatment of auxiliary b-fields [117]; compare also the standard linear covariant gauges [82, 91].

3) Antighost equation. Varying the action w.r.t. $\bar{c}^a$ gives

$$\frac{\delta S}{\delta \bar{c}^a} = -\,K^{(\ell)}_{\mathrm{IR}}\,\frac{\delta F^a}{\delta A^b_\mu}\,(D_\mu c)^b.$$

Introduce Zinn–Justin sources $K^{(A)\mu b}$ coupled to sA^b_μ in the usual way (band-limited as in (7.144)); then, by definition of the Legendre transform,

$$\frac{\delta\Gamma}{\delta K^{(A)\mu b}} = \big\langle (D_\mu c)^b \big\rangle.$$

Using this and integrating by parts in the covariant derivative (keeping the band kernels, which commute with ∂_μ), one finds

$$\frac{\delta\Gamma}{\delta\bar{c}^a} = \frac{\delta F^a}{\delta A^b_\mu}\,\frac{\delta\Gamma}{\delta K^{(A)\mu b}} - \partial_\mu \frac{\delta\Gamma}{\delta K^{(A)\mu a}},$$

which is the claimed antighost equation on the band (QAP ensures stability; cf. [117]).

4) Ghost equation and its linear breaking. Perform the rigid shift $c^a \mapsto c^a + \epsilon^a$ in the (band-limited) path integral. The Jacobian is 1, and only terms that depend explicitly on c contribute. In linear covariant gauges, the dependence appears via the BRST variations

coupled to Zinn–Justin sources. Standard manipulations (or QAP) yield a local "ghost Ward operator" $\mathcal{G}^a(x)$ acting on Γ with a breaking that is *linear* in sources:

$$\mathcal{G}^a(x)\,\Gamma = \partial_\mu K^{(A)\mu a}(x).$$

Linearity implies the breaking receives no loop corrections beyond tree level (stability of the breaking) [117]; see also the textbook discussion of the ghost equation in covariant gauges [82, 91]. Band kernels commute with derivatives and carry ghost number 0 (cf. Definition 7.28), so the same identity holds on the band.

5) Landau limit. For $\alpha_{\rm gf} \to 0$ the b-equation becomes the linear constraint $F^a = 0$, implementing the (band-limited) gauge condition. The ghost equation's breaking remains $\Delta_c = \partial_\mu K^{(A)\mu a}$, which—being linear and source-only—is tree-level exact by the QAP [117].

Conclusion. The three identities follow from BRST-exact gauge fixing, the QAP, and the commutation properties of the joint IR/UV tagging. Their form is preserved on the band, and Landau gauge reduces the b-equation to the linear gauge constraint. □

Corollary 7.227 (Compatibility with Slavnov–Taylor and Nielsen)**.** *Equations* (7.152) *and Proposition 7.222 are compatible with the band Slavnov identity* (7.150) *and the band Nielsen identity* (7.148)*: applying* $\mathcal{B}_\Gamma$ *to* (7.152) *reproduces identities among sources that follow from* (7.150)*, while* $\partial_{\alpha_{\rm gf}}$*–variations are* $\mathcal{B}_\Gamma$*–exact and thus decouple from BRST–closed physical functionals.*

Full proof. **(A) Compatibility with the band Slavnov–Taylor identity.** Recall the band ST identity

$$\mathcal{S}(\Gamma) = \int d^dx \left(\frac{\delta\Gamma}{\delta K_A}\frac{\delta\Gamma}{\delta\varphi^A} + b^a \frac{\delta\Gamma}{\delta\bar{c}^a} \right) = 0,$$

and the linearised Slavnov operator

$$\mathcal{B}_\Gamma F = \int d^dx \left(\frac{\delta\Gamma}{\delta K_A}\frac{\delta F}{\delta\varphi^A} + \frac{\delta F}{\delta K_A}\frac{\delta\Gamma}{\delta\varphi^A} + b^a \frac{\delta F}{\delta\bar{c}^a} \right), \qquad \mathcal{B}_\Gamma\Gamma = 0,$$

which is nilpotent on the band modulo EOM and total derivatives (anomaly filters; band commutation properties from Definition 7.28, items (ii)–(iv); cf. [117]).

Differentiate $\mathcal{S}(\Gamma) = 0$ w.r.t. $b^a(x)$:

$$\mathcal{B}_\Gamma\left(\frac{\delta\Gamma}{\delta b^a(x)} \right) + \frac{\delta\Gamma}{\delta\bar{c}^a(x)} = 0. \tag{$\star$}$$

Insert the b–equation from (7.152), $\delta\Gamma/\delta b^a = F^a - \alpha_{\rm gf}\, b^a$. Since $\mathcal{B}_\Gamma b^a = 0$, we obtain

$$\frac{\delta\Gamma}{\delta\bar{c}^a(x)} = -\,\mathcal{B}_\Gamma F^a(x).$$

Because F^a depends only on the gauge field, $\mathcal{B}_\Gamma$ acts on it via the $K^{(A)}$–channel; integrating by parts (band kernels commute with ∂_μ), this yields exactly the antighost equation in (7.152),

$$\frac{\delta\Gamma}{\delta\bar{c}^a} = \frac{\delta F^a}{\delta A^b_\mu}\frac{\delta\Gamma}{\delta K^{(A)\mu b}} - \partial_\mu \frac{\delta\Gamma}{\delta K^{(A)\mu a}},$$

thus showing that applying $\mathcal{B}_\Gamma$ to the b–equation reproduces the antighost identity dictated by ST.

Likewise, differentiating $\mathcal{S}(\Gamma) = 0$ w.r.t. $\bar{c}^a(x)$ gives

$$\mathcal{B}_\Gamma\left(\frac{\delta\Gamma}{\delta\bar{c}^a(x)}\right) = 0, \tag{$\star\star$}$$

which is the $\mathcal{B}_\Gamma$–closure of the antighost equation. Eqs. ($\star$)–($\star\star$) are the standard algebraic–renormalisation compatibility relations (now "on the band"); see [117] and textbook expositions [82, 91].

(B) Compatibility with the band Nielsen identity. The band Nielsen identity (eq. (7.148); cf. Proposition 7.236) reads

$$\partial_{\alpha_{\rm gf}}\Gamma = -\,\mathcal{B}_\Gamma\big(\partial_{\alpha_{\rm gf}}\Psi\big) = \int d^dx\,\frac{\delta\Gamma}{\delta\varphi^A(x)}\,\mathcal{N}^A(x;\alpha_{\rm gf}),$$

so $\partial_{\alpha_{\rm gf}}\Gamma$ is $\mathcal{B}_\Gamma$–exact (and EOM–proportional). Apply $\partial_{\alpha_{\rm gf}}$ to (7.152) and use the commutation of band operations with functional differentiation (Definition 7.28, items (ii)–(iv)):

$$\partial_{\alpha_{\rm gf}}\left(\frac{\delta\Gamma}{\delta b^a} - F^a + \alpha_{\rm gf} b^a\right) = \frac{\delta}{\delta b^a}\big(\partial_{\alpha_{\rm gf}}\Gamma\big) - b^a = -\,\frac{\delta}{\delta b^a}\,\mathcal{B}_\Gamma(\partial_{\alpha_{\rm gf}}\Psi) - b^a.$$

Because functional differentiation commutes with $\mathcal{B}_\Gamma$ on the band and $\frac{\delta}{\delta b^a}(\partial_{\alpha_{\rm gf}}\Psi) = -(1/2)\,\bar{c}^a$ for the linear covariant family, the r.h.s. becomes $-\mathcal{B}_\Gamma\big(-(1/2)\bar{c}^a\big) - b^a = 0$ using $\mathcal{B}_\Gamma\bar{c}^a = b^a$. Thus the b–equation is stable under $\alpha_{\rm gf}$–variations in $\mathcal{B}_\Gamma$–exact form. The same reasoning applied to the antighost equation shows its $\partial_{\alpha_{\rm gf}}$–variation is $\mathcal{B}_\Gamma$–exact as well. Consequently, for any BRST–closed ghost–number–zero functional $\mathcal{O}$ (physical observable),

$$\partial_{\alpha_{\rm gf}}\,\mathcal{O} = \big\langle \mathcal{B}_\Gamma(\cdots)\big\rangle \equiv 0 \quad \text{in } \mathcal{H}_{\rm phys},$$

establishing decoupling in the physical sector (Nielsen–type independence; cf. [117]).

Conclusion. Part (A) shows that acting with $\mathcal{B}_\Gamma$ on (7.152) reproduces identities among sources fixed by (7.150); part (B) shows $\partial_{\alpha_{\rm gf}}$–variations are $\mathcal{B}_\Gamma$–exact and hence inert on BRST–closed physical functionals. This proves the corollary. □

Remark 7.228 (Operational consequence)**.** Lem. 7.224 implies that SPAM-like systematics associated with $(\bar{c}, b)$ cannot pollute the certified visibilities on $\mathcal{H}_{\rm phys}$; remaining gauge-parameter dependences are controlled by the Nielsen identity and the anomaly filters, as used throughout Section 7.4.

7.5.4 Global G Ward Identities at the Dymmetric Vacuum

Let G act linearly on the matter multiplets (Φ, Θ)—with *gaiamiti* mean field Φ and *tantrakyma* mean field Θ—via generators T^a:

$$\delta^a\Phi = i\,T^a\Phi, \qquad \delta^a\Theta = i\,T^a\Theta,$$

and take ghosts $(c, \bar{c}, b)$ to be G-singlets unless stated otherwise. At the G-invariant vacuum (Quadrant I), the band-limited generating functionals obey the exact Ward identities

$$\mathcal{W}^a W = 0, \qquad \mathcal{W}^a \Gamma = 0, \tag{7.166}$$

with Ward operators

$$\mathcal{W}^a := \int d^d x \, (J_\Phi \, \delta^a \Phi \; + \; J_\Theta \, \delta^a \Theta \; + \; K_\Phi \, \delta^a(\zeta \Phi) \; + \; K_\Theta \, \delta^a(\zeta \Theta)) \, ,$$

and similarly in the 1PI variables. Here Φ, Θ are the 1PI mean fields conjugate to the sources J_Φ, J_Θ for the band-limited operator fields $\hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}}$ and $\hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}}$ (cf. the source formalism). Band/IR operations commute with G and BRST by (7.145), hence $\delta^a(\zeta\phi) = \zeta(\delta^a \phi)$ for $\phi \in \{\Phi, \Theta\}$.

Proposition 7.229 (Band-limited global Ward identities for W and Γ)**.** *Assume (i) $S_{\Phi,\Theta}^{(\lambda_{\mathrm{UV}},\ell)}$ is G-invariant at the symmetry point, (ii) the gauge fermion Ψ is G-invariant, and (iii) (7.145). Then the connected functional W and the 1PI functional Γ satisfy (7.166) exactly on the band.*

Proof. Let $\varphi = (\hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}}, \hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}}, c, \bar{c}, b)$ denote the band-limited operator fields and

$$Z[\mathcal{J}, \mathcal{K}] = \int \mathcal{D}\varphi \; \exp\!\Big\{ i \Big(S_{\Phi,\Theta}^{(\lambda_{\mathrm{UV}},\ell)} + \zeta\Psi + \mathcal{J}\cdot\varphi + \mathcal{K}\cdot\zeta\varphi \Big) \Big\},$$

with $\mathcal{J}\cdot\varphi = \int (J_\Phi \cdot \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}} + J_\Theta \cdot \hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}})$ and $\mathcal{K}\cdot\zeta\varphi = \int (K_\Phi \cdot \zeta\hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}} + K_\Theta \cdot \zeta\hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}})$, where the dots include contraction with the IR window $K_{\mathrm{IR}}^{(\ell)}$ (cf. the source formalism). By (7.145), the band/IR operations commute with BRST and carry ghost number 0; we also assume they are G-scalars so they commute with the G-action.

Step 1 (Change of variables and measure). Consider the global G variation $\delta^a \varphi = R^a[\varphi]$ with $\delta^a \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}} = i\, T^a \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}}$, $\delta^a \hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}} = i\, T^a \hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}}$, and ghosts $(c, \bar{c}, b)$ taken G-singlets (the generalisation is immediate if they transform trivially in another representation). Perform in the path integral the change of variables $\varphi \mapsto \varphi + \epsilon\, \delta^a \varphi$ with constant Grassmann-even ϵ. Since the transformation is linear and global, the functional measure is invariant (Jacobian $= 1$) and

$$0 = \delta^a Z = \int \mathcal{D}\varphi \; i\, \delta^a \Big(S_{\Phi,\Theta}^{(\lambda_{\mathrm{UV}},\ell)} + \zeta\Psi + \mathcal{J}\cdot\varphi + \mathcal{K}\cdot\zeta\varphi \Big) \, e^{i(\cdots)}.$$

Step 2 (Variation of the action pieces). At the symmetry point, assumption (i) gives $\delta^a S_{\Phi,\Theta}^{(\lambda_{\mathrm{UV}},\ell)} = 0$. Assumption (ii) implies $\delta^a(\zeta\Psi) = \zeta(\delta^a\Psi) = 0$ because Ψ is G-invariant and δ^a commutes with ζ (both band-limited by (7.145)). Thus only the source sector varies:

$$\delta^a(\mathcal{J}\cdot\varphi + \mathcal{K}\cdot\zeta\varphi) = \int d^d x \Big(J_\Phi \, \delta^a \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}} + J_\Theta \, \delta^a \hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}} + K_\Phi \, \delta^a(\zeta \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}}) + K_\Theta \, \delta^a(\zeta \hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}}}) \Big).$$

Because band/IR operations commute with G and BRST (assumption (iii) and (7.145)), we have $\delta^a(\zeta \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}}) = \zeta(\delta^a \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}}) = i\,\zeta(T^a \hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}}})$ and analogously for Θ.

Step 3 (Ward identity for W). Divide $\delta^a Z = 0$ by Z and use $W = -i \ln Z$ to obtain

$$0 = \int d^d x \, (J_\Phi \, \delta^a \Phi + J_\Theta \, \delta^a \Theta + K_\Phi \, \delta^a(\zeta\Phi) + K_\Theta \, \delta^a(\zeta\Theta)) \equiv \mathcal{W}^a W,$$

where we identified the mean fields $\Phi = \delta W/\delta J_\Phi$, $\Theta = \delta W/\delta J_\Theta$ and the BRST insertions $\zeta\Phi = \delta W/\delta K_\Phi$, $\zeta\Theta = \delta W/\delta K_\Theta$ in the standard way. This is precisely the first identity in (7.166).

Step 4 (Legendre transform to Γ). Define the 1PI functional at fixed $\mathcal{K}$ by the usual Legendre transform $\Gamma[\Phi,\Theta;\mathcal{K}] = W[\mathcal{J},\mathcal{K}] - \int(J_\Phi\,\Phi + J_\Theta\,\Theta)$, with $\Phi = \delta W/\delta J_\Phi$, $\Theta = \delta W/\delta J_\Theta$ and inverse relations $J_\Phi = -\delta\Gamma/\delta\Phi$, $J_\Theta = -\delta\Gamma/\delta\Theta$. Act with $\mathcal{W}^a$ on Γ:

$$\mathcal{W}^a\Gamma = \int d^dx\Big(\frac{\delta\Gamma}{\delta\Phi}\,\delta^a\Phi + \frac{\delta\Gamma}{\delta\Theta}\,\delta^a\Theta + \frac{\delta\Gamma}{\delta K_\Phi}\,\delta^a(\zeta\Phi) + \frac{\delta\Gamma}{\delta K_\Theta}\,\delta^a(\zeta\Theta)\Big).$$

Using the Legendre relations $\delta\Gamma/\delta\Phi = -J_\Phi$, $\delta\Gamma/\delta\Theta = -J_\Theta$ and the identities $\delta\Gamma/\delta K_\Phi = -\,\delta W/\delta K_\Phi = -(\zeta\Phi)$, $\delta\Gamma/\delta K_\Theta = -(\zeta\Theta)$ (Legendre transform taken at fixed $\mathcal{K}$), we get

$$\mathcal{W}^a\Gamma = -\int d^dx\,(J_\Phi\,\delta^a\Phi + J_\Theta\,\delta^a\Theta + K_\Phi\,\delta^a(\zeta\Phi) + K_\Theta\,\delta^a(\zeta\Theta)) = -\,\mathcal{W}^aW.$$

Since $\mathcal{W}^aW = 0$ from Step 3, it follows that $\mathcal{W}^a\Gamma = 0$, i.e. the second identity in (7.166).

Step 5 (Band/IR remarks and contact terms). Potential total-derivative (contact) terms from the G-variation of $S^{(\lambda_{\mathrm{UV}},\ell)}_{\Phi,\Theta}$ vanish at the symmetric vacuum and under the L^1 IR window $K^{(\ell)}_{\mathrm{IR}}$; moreover, the G-invariance of Ψ eliminates gauge-fixing contact terms. The commutation relations in (7.145) ensure that the foregoing manipulations hold *on the band*. Therefore the Ward identities are exact in the band-limited theory.

Combining Steps 3–4 proves that both the connected generator W and the 1PI functional Γ obey (7.166) exactly on the band, as claimed. □

Proposition 7.230 (Compatibility with Slavnov and linearised BRST)**.** *Let $\mathcal{S}(\Gamma) = 0$ (band Slavnov identity, Section 7.5.2). Then*

$$\mathcal{W}^a\big(\mathcal{S}(\Gamma)\big) = 0, \qquad [\mathcal{W}^a, \mathcal{B}_\Gamma] = 0,$$

so the linearised Slavnov cohomology $\mathsf{H}^\bullet(\mathcal{B}_\Gamma)$ is G-equivariant. In particular, $\mathsf{H}^0(\mathcal{B}_\Gamma)$ decomposes into G-irreps; physical representatives are G-invariant classes at the symmetry point.

Proof. All statements are understood on the band; by (7.145), band/IR operations commute with G and with BRST, and carry ghost number 0.

1) Ward operator in 1PI variables and its properties. Recall that for any functional $F[\Phi,\Theta;K_\Phi,K_\Theta]$ we have

$$\mathcal{W}^aF = \int d^dx\Big(\frac{\delta F}{\delta\Phi}\,\delta^a\Phi + \frac{\delta F}{\delta\Theta}\,\delta^a\Theta + \frac{\delta F}{\delta K_\Phi}\,\delta^a(\zeta\Phi) + \frac{\delta F}{\delta K_\Theta}\,\delta^a(\zeta\Theta)\Big),$$

with $\delta^a\Phi = iT^a\Phi$, $\delta^a\Theta = iT^a\Theta$ and $\delta^a(\zeta\phi) = \zeta(\delta^a\phi)$. Since the G-action is linear and band-limited, $\mathcal{W}^a$ is a graded derivation (ghost number 0) of the functional algebra:

$$\mathcal{W}^a(FG) = (\mathcal{W}^aF)G + F(\mathcal{W}^aG).$$

2) $\mathcal{W}^a$ is a derivation of the antibracket. Let $(\cdot,\cdot)$ denote the Zinn–Justin antibracket, and use the standard form $(F,G)=\int\Big(\frac{\delta_r F}{\delta\Phi}\frac{\delta_l G}{\delta K_\Phi}-\frac{\delta_r F}{\delta K_\Phi}\frac{\delta_l G}{\delta\Phi}+(\Phi\to\Theta)\Big)$ with band-limited contractions. A direct application of the product rule for $\mathcal{W}^a$ and the linearity of δ^a gives

$$\mathcal{W}^a(F,G)=(\mathcal{W}^a F,G)+(F,\mathcal{W}^a G). \tag{7.167}$$

No extra contact terms arise because (i) the Ward variations are linear in the fields/sources, and (ii) the band/IR kernels commute with G.

3) $\mathcal{W}^a(\mathcal{S}(\Gamma))=0$. With $\mathcal{S}(\Gamma)=\frac{1}{2}(\Gamma,\Gamma)$,

$$\mathcal{W}^a\Big(\mathcal{S}(\Gamma)\Big)=\tfrac{1}{2}\,\mathcal{W}^a(\Gamma,\Gamma)=\tfrac{1}{2}\Big((\mathcal{W}^a\Gamma,\Gamma)+(\Gamma,\mathcal{W}^a\Gamma)\Big)\overset{\mathcal{W}^a\Gamma=0}{=}0,$$

where $\mathcal{W}^a\Gamma=0$ is precisely the Ward identity for Γ (see (7.166) and Prop. 7.229), and we used (7.167).

4) $[\mathcal{W}^a,\mathcal{B}_\Gamma]=0$. Using $\mathcal{B}_\Gamma X=(\Gamma,X)$ and (7.167),

$$[\mathcal{W}^a,\mathcal{B}_\Gamma]X=\mathcal{W}^a(\Gamma,X)-(\Gamma,\mathcal{W}^a X)=(\mathcal{W}^a\Gamma,X)+(\Gamma,\mathcal{W}^a X)-(\Gamma,\mathcal{W}^a X)=(\mathcal{W}^a\Gamma,X)=0.$$

Thus the Ward operator commutes with the linearised Slavnov operator.

5) G-equivariance of cohomology. Because $[\mathcal{W}^a,\mathcal{B}_\Gamma]=0$ and $\mathrm{gh}(\mathcal{W}^a)=0$,

$$\mathcal{B}_\Gamma X=0\ \Rightarrow\ \mathcal{B}_\Gamma(\mathcal{W}^a X)=0,\qquad X=\mathcal{B}_\Gamma Y\ \Rightarrow\ \mathcal{W}^a X=\mathcal{B}_\Gamma(\mathcal{W}^a Y).$$

Hence $\mathcal{W}^a$ maps $\mathcal{B}_\Gamma$-cocycles to cocycles and coboundaries to coboundaries, inducing a well-defined G-action on $\mathsf{H}^\bullet(\mathcal{B}_\Gamma)$. In particular, $\mathsf{H}^0(\mathcal{B}_\Gamma)$ decomposes into G-irreducible representations; the physical representatives at the symmetry point are precisely the G-invariant classes.

This establishes the proposition. □

Proposition 7.231 (Momentum-space constraints and tensor structures)**.** *Write the 1PI two-point functions in momentum space as kernels $\Gamma^{(2)}_{\Phi\Phi}(p)$, $\Gamma^{(2)}_{\Theta\Theta}(p)$, etc. Then:*

(i) G-covariance: $[T^a,\Gamma^{(2)}_{\Phi\Phi}(p)]=0$ *and analogously for other sectors. Hence $\Gamma^{(2)}(p)$ is block-diagonal in G-irreps, with each block proportional to the identity on the irrep space (Schur).*

(ii) No spurionic masses: *symmetry-breaking mass terms are forbidden; mass matrices must commute with all T^a and thus be irrep-wise proportional to the identity. Mixing between distinct irreps is prohibited.*

(iii) Current transversality: *for conserved G-currents J^a_μ, the band-limited polarisation tensor satisfies*

$$p_\mu\,\Pi^{\mu\nu}_{ab}(p)=0,\qquad \Pi^{\mu\nu}_{ab}(p)=\Pi_{ab}(p^2)\,\Pi^{\mu\nu}_{\mathrm{T}}(p),$$

with the standard transverse projector $\Pi^{\mu\nu}_{\mathrm{T}}(p)=\eta^{\mu\nu}-p^\mu p^\nu/p^2$ and no longitudinal piece at the symmetry point.

Proof. Work at the symmetric vacuum, with vanishing mean fields and sources, and assume translation invariance on the band so that 1PI kernels are diagonal in total momentum (the band operations commute with G and translations, cf. eq. (7.145)).

(i) G-covariance of two-point kernels. The global Ward identity (7.166) for Γ reads

$$\int d^dx \left(\frac{\delta\Gamma}{\delta\Phi(x)}\,\delta^a\Phi(x) + \frac{\delta\Gamma}{\delta\Theta(x)}\,\delta^a\Theta(x) \right) = 0, \qquad \delta^a\Phi = i\,T^a\Phi, \quad \delta^a\Theta = i\,T^a\Theta. \tag{7.168}$$

Differentiate (7.168) functionally with respect to $\Phi(y)$ and $\Phi(z)$, then set all mean fields to zero. Using

$$\Gamma^{(2)}_{\Phi\Phi}(y,z) := \left.\frac{\delta^2\Gamma}{\delta\Phi(y)\,\delta\Phi(z)}\right|_{\Phi=\Theta=0},$$

and the linearity of $\delta^a\Phi = iT^a\Phi$, one finds

$$i\int d^dx\; \Gamma^{(2)}_{\Phi\Phi}(x,y)\,T^a\,\delta(x-z) - i\int d^dx\; T^a\,\delta(x-y)\,\Gamma^{(2)}_{\Phi\Phi}(x,z) = 0.$$

Fourier transforming and using momentum conservation (the band kernels preserve translation invariance) gives

$$\Gamma^{(2)}_{\Phi\Phi}(p)\,T^a - T^a\,\Gamma^{(2)}_{\Phi\Phi}(p) = 0, \qquad \text{i.e.} \quad [\Gamma^{(2)}_{\Phi\Phi}(p), T^a] = 0, \tag{7.169}$$

and analogously for $\Theta\Theta$ and cross sectors (when allowed). Thus each two-point kernel commutes with the G-action; decomposing the field space into G-irreps, Schur's lemma implies that $\Gamma^{(2)}(p)$ is block-diagonal in irreps and proportional to the identity on each irrep block.

(ii) No spurionic masses / irrep-wise identity. By definition, a (quadratic) mass term is the momentum-independent part of the 1PI two-point kernel at $p = 0$:

$$M_\Phi := \Gamma^{(2)}_{\Phi\Phi}(p=0).$$

From (7.169) with $p = 0$ we have $[M_\Phi, T^a] = 0$ for all a. Hence M_Φ must be proportional to the identity on each irrep block and cannot mix inequivalent irreps. Any would-be "spurionic" mass mixing different irreps would transform nontrivially and violate the commutation with T^a, contradicting (7.169). The same reasoning applies to Θ and to allowed Φ–Θ mixing: the mass matrix must be G-invariant and therefore block-diagonal in G-irreps, with each block a scalar multiple of the identity.

(iii) Current transversality and tensor structure. Introduce a source A^a_μ coupled to the conserved Noether current J^μ_a of G, and denote by $\Pi^{\mu\nu}_{ab}(x-y)$ the (band-limited) 1PI current–current kernel (polarisation tensor). The global Ward identity yields, upon varying with respect to A^a_μ and A^b_ν and Fourier transforming,

$$p_\mu\,\Pi^{\mu\nu}_{ab}(p) = \mathcal{A}^\nu_{ab}(p), \tag{7.170}$$

where $\mathcal{A}^\nu_{ab}(p)$ collects possible contact (local) terms and anomaly contributions. At the symmetric vacuum in Quadrant I, the anomaly filters enforce the absence of gauge/global G anomalies (cohomological triviality), so $\mathcal{A}^\nu_{ab}(p) = 0$ (see Section 7.2.8 and the cohomology baseline). Therefore

$$p_\mu\,\Pi^{\mu\nu}_{ab}(p) = 0. \tag{7.171}$$

Lorentz covariance on the band implies the general decomposition

$$\Pi^{\mu\nu}_{ab}(p) = \Pi^{\mathrm{T}}_{ab}(p^2)\,\Pi^{\mu\nu}_{\mathrm{T}}(p) + \Pi^{\mathrm{L}}_{ab}(p^2)\,\Pi^{\mu\nu}_{\mathrm{L}}(p), \quad \Pi^{\mu\nu}_{\mathrm{T}} = \eta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}, \quad \Pi^{\mu\nu}_{\mathrm{L}} = \frac{p^\mu p^\nu}{p^2}.$$

Contracting with p_μ and using (7.171) forces $\Pi^{\mathrm{L}}_{ab}(p^2) \equiv 0$, whence

$$\Pi^{\mu\nu}_{ab}(p) = \Pi_{ab}(p^2)\,\Pi^{\mu\nu}_{\mathrm{T}}(p),$$

as claimed. Since the band/IR operations commute with G and BRST (eq. (7.145)), no extra longitudinal pieces are generated by the embedding; anomaly freedom ensures there is no residual local breaking on the right-hand side of (7.170).

Combining the three parts establishes items (i)–(iii). □

Proposition 7.232 (Three-point Ward–Takahashi identity (schematic))**.** *Let $\Gamma^{\mu;AB}_a(p,q)$ be the 1PI vertex for J^μ_a with fields carrying indices A, B in a G-representation. Then*

$$p_\mu\,\Gamma^{\mu;AB}_a(p,q) = i\Big[(T_a)^A{}_C\,\Gamma^{CB}(q+p) - \Gamma^{AC}(q)\,(T_a)^B{}_C\Big],$$

with all quantities band-limited. This enforces G-covariant tensor bases for three-point structures and implies selection rules for vanishing couplings between inequivalent irreps.

Proof. All statements are understood *on the band*; by (7.145), the UV projector and IR window commute with G and with BRST and carry ghost number 0.

Setup with a local spurion and the local Ward identity. Couple the conserved G-current J^μ_a to a classical source (spurion) $A^a_\mu(x)$ and regard Γ as a functional $\Gamma[\Phi, \Theta; A, K]$ (sources K omitted below for brevity). Promote the constant G parameter to a local function $\epsilon^a(x)$ and consider the spurionic variations

$$\delta_\epsilon \Phi = i\,\epsilon^a T_a \Phi, \qquad \delta_\epsilon \Theta = i\,\epsilon^a T_a \Theta, \qquad \delta_\epsilon A^a_\mu = -\partial_\mu \epsilon^a,$$

with ghosts $(c, \bar{c}, b)$ taken G-singlets. G-invariance of the action and of the gauge fermion at the symmetry point, together with the commutation of band/IR operations with G, imply the *local* Ward identity for the 1PI functional (no anomaly in Quadrant I):

$$\partial^x_\mu \frac{\delta\Gamma}{\delta A^a_\mu(x)} = i\,\frac{\delta\Gamma}{\delta\Phi^A(x)}(T_a)^A{}_B\,\Phi^B(x) + i\,\frac{\delta\Gamma}{\delta\Theta^A(x)}(T_a)^A{}_B\,\Theta^B(x). \tag{7.172}$$

(The band/IR kernels commute with ∂_μ and with the G-action, so (7.172) holds "on the band" without extra contact terms.)

Differentiate to obtain the three-point identity. Differentiate (7.172) w.r.t. $\Phi^A(y)$ and $\Phi^B(z)$ and set $(\Phi, \Theta, A) = (0, 0, 0)$:

$$\partial^x_\mu\,\Gamma^{\mu;AB}_a(x; y, z) = i\,(T_a)^A{}_C\,\Gamma^{CB}(y, z)\,\delta(x - y) - i\,\Gamma^{AC}(y, z)\,(T_a)^B{}_C\,\delta(x - z),$$

where

$$\Gamma^{\mu;AB}_a(x; y, z) := \left.\frac{\delta^3\Gamma}{\delta A^a_\mu(x)\,\delta\Phi^A(y)\,\delta\Phi^B(z)}\right|_0, \qquad \Gamma^{CB}(y, z) := \left.\frac{\delta^2\Gamma}{\delta\Phi^C(y)\,\delta\Phi^B(z)}\right|_0.$$

(The same steps apply for Θ or mixed Φ/Θ legs.)

Fourier transform and momentum routing. Define Fourier transforms with the total momentum conserved by translation invariance (preserved by the band/IR embedding):

$$\Gamma_a^{\mu;AB}(p,q) := \int d^dx\, d^dy\, d^dz\; e^{\,ip\cdot x+iq\cdot y-i(q+p)\cdot z}\,\Gamma_a^{\mu;AB}(x;y,z),$$
$$\Gamma^{CB}(k) := \int d^dy\, d^dz\; e^{\,ik\cdot(y-z)}\,\Gamma^{CB}(y,z).$$

Multiplying the x-space identity by $e^{\,ip\cdot x+iq\cdot y-i(q+p)\cdot z}$ and integrating, the derivatives ∂_μ^x become ip_μ, and the delta functions set $x=y$ or $x=z$, yielding

$$p_\mu\,\Gamma_a^{\mu;AB}(p,q) = i\Big[(T_a)^A{}_C\,\Gamma^{CB}(q+p) - \Gamma^{AC}(q)\,(T_a)^B{}_C\Big].$$

This is the Ward–Takahashi identity in momentum space (with band-limited kernels); see, e.g., [82, 409, 91].

Remarks. (i) The same derivation goes through for Θ-legs and for mixed Φ/Θ legs, with the corresponding representation matrices. (ii) The anomaly filters ensure there is no local breaking on the r.h.s. of (7.172); hence no extra contact terms survive in momentum space. (iii) Because $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ are G-scalars and commute with ∂_μ, the band embedding does not spoil the identity.

This completes the proof. □

Corollary 7.233 (Projector decomposition and $\Pi_{\mathrm{T}}/\Pi_{\mathrm{L}}$ split)**.** *In Lorentz-invariant sectors, any two-point tensor kernel admits the decomposition* $\Gamma^{\mu\nu}(p) = \Gamma_{\mathrm{T}}(p^2)\,\Pi_{\mathrm{T}}^{\mu\nu}(p) + \Gamma_{\mathrm{L}}(p^2)\,\Pi_{\mathrm{L}}^{\mu\nu}(p)$*, with* $\Pi_{\mathrm{L}}^{\mu\nu}(p) = p^\mu p^\nu/p^2$*. At the symmetry point and for conserved currents,* $\Gamma_{\mathrm{L}} \equiv 0$*. G-invariance implies* Γ_{T} *is irrep-wise scalar, i.e. identical across components within the same irrep.*

Proof of Corollary 7.233. Work in a Lorentz-invariant sector so any rank-2 tensor built from p^μ and $\eta^{\mu\nu}$ decomposes as

$$\Gamma^{\mu\nu}(p) = A(p^2)\,\Pi_{\mathrm{T}}^{\mu\nu}(p) + B(p^2)\,\Pi_{\mathrm{L}}^{\mu\nu}(p), \qquad \Pi_{\mathrm{T}}^{\mu\nu} := \eta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}, \quad \Pi_{\mathrm{L}}^{\mu\nu} := \frac{p^\mu p^\nu}{p^2}.$$

This is the unique Lorentz-covariant decomposition. For a conserved current, the three-point Ward–Takahashi identity

$$p_\mu\,\Gamma_a^{\mu;AB}(p,q) = i\Big[(T_a)^A{}_C\,\Gamma^{CB}(q+p) - \Gamma^{AC}(q)\,(T_a)^B{}_C\Big]$$

(Proposition 7.232) implies transversality of the corresponding two-point kernel at the symmetry point, $p_\mu\,\Gamma^{\mu\nu}(p) = 0$, hence $B \equiv 0$ and only the transverse projector survives. Finally, G-invariance means $\Gamma^{\mu\nu}$ intertwines equivalent G-representations; by Schur's lemma it is proportional to the identity within each irrep, so Γ_{T} is irrep-wise scalar. (See also [82, 91].) □

Proposition 7.234 (Stability under renormalisation and anomaly filters)**.** *If the anomaly filters of Section 7.2.8 hold, the breaking of (7.166) is at most linear in external sources (QAP) and can be removed by local counterterms; thus the Ward identities are stable under renormalisation on the band.*

Proof of Proposition 7.234. Assume the anomaly filters of Section 7.2.8 hold so the local Ward identity for the 1PI functional Γ is valid on the band (no anomaly term):

$$\partial_\mu^x \frac{\delta\Gamma}{\delta A_\mu^a(x)} = i\,\frac{\delta\Gamma}{\delta\Phi^A(x)}(T_a)^A{}_B\Phi^B(x) + i\,\frac{\delta\Gamma}{\delta\Theta^A(x)}(T_a)^A{}_B\Theta^B(x),$$

with the UV projector $P_x(\lambda_{\mathrm{UV}})$ and IR window $K_{\mathrm{IR}}^{(\ell)}$ commuting with ∂_μ and the G-action. By the Quantum Action Principle (QAP), any breaking that appears at intermediate renormalisation steps is a *local* polynomial in fields and sources, at most linear in external sources, and constrained by the same quantum numbers. Such local breakings can be cancelled order by order by adding local counterterms chosen within the symmetry-allowed basis, thereby restoring the Ward identity after renormalisation. Because band/IR operations are linear, *-preserving, and commute with G (cf. Definition 7.28 and Proposition 7.30), the same argument applies on the band. Therefore the Ward identities are stable under renormalisation on the band. (Background: [82, 91].) □

Remark 7.235 (Operational baseline)**.** Propositions 7.229–7.234 provide the *exact* symmetric baseline used in Section 7.4: transversality, irrep block-diagonality, and the absence of spurionic mass/mixing at the symmetry point are the invariants against which law/state-channel visibilities are compared in other quadrants.

7.5.5 Nielsen Identity at the Symmetry Point

Gauge-parameter variations of Γ are controlled by the Nielsen (gauge-parameter) identity:

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = \int d^dx\,\frac{\delta\Gamma}{\delta\varphi^A(x)}\,\mathcal{N}^A(x;\alpha_{\mathrm{gf}}) \quad\Rightarrow\quad \partial_{\alpha_{\mathrm{gf}}}\Big(\text{on-shell observables}\Big) = 0, \tag{7.173}$$

where $A \in \{\Phi, \Theta, c, \bar{c}, b\}$ and

$$\mathcal{N}^A(x;\alpha_{\mathrm{gf}}) := -\,\frac{\delta}{\delta K_A(x)}\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi\Big) \;\equiv\; \Big\langle\, \zeta\,\partial_{\alpha_{\mathrm{gf}}}\Psi \,\Big\rangle_\Gamma.$$

The first equality is the antibracket/linearised form $\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi\Big)$ (cf. Propositions 7.212 and 7.218), expanded at vanishing sources so that the variation is proportional to the equations of motion $\delta\Gamma/\delta\varphi^A$. The second (expectation) form is the standard insertion map induced by Γ. Since $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with $\hat{Q}_{\mathrm{BRST}}$ eq. (7.145), (7.173) holds *on the band*; on-shell physical poles, visibilities, and certified plateaus are gauge-parameter independent in Quadrant I [117, 91].

Proposition 7.236 (Band Nielsen identity in EOM form)**.** *Let α_{gf} enter only through the gauge fermion $\Psi(\alpha_{\mathrm{gf}})$, and assume the anomaly filters hold so that BRST is nilpotent on the band. Then*

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi\Big) = \int d^dx\,\frac{\delta\Gamma}{\delta\varphi^A(x)}\,\mathcal{N}^A(x;\alpha_{\mathrm{gf}}),$$

with $\mathcal{N}^A$ defined above. In particular, $\partial_{\alpha_{\mathrm{gf}}}\Gamma$ is proportional to the equations of motion and thus $\mathcal{B}_\Gamma$-exact.

Proof idea. Differentiate the band-limited path integral Z with respect to $\alpha_{\rm gf}$; only $\zeta\Psi$ varies. Passing to Γ and using the antibracket representation of the linearised Slavnov operator (Prop. 7.212) gives $\partial_{\alpha_{\rm gf}}\Gamma = -(\Gamma, \partial_{\alpha_{\rm gf}}\Psi) = -\mathcal{B}_\Gamma(\partial_{\alpha_{\rm gf}}\Psi)$. Expanding the antibracket at vanishing sources yields the EOM form with the antifield (source) derivative: $\mathcal{N}^A(x;\alpha_{\rm gf}) := -\delta(\partial_{\alpha_{\rm gf}}\Psi)/\delta K_A(x)$. Band/IR operations commute with BRST and carry ghost number 0 eq. (7.145), so no additional terms arise.

Proof. **Setup and extended Slavnov–Taylor identity.** Gauge fixing enters the band-limited generating functional only through the BRST-exact term $s\,\Psi(\alpha_{\rm gf})$, with $s^2 = 0$ on the band by the anomaly filters (Definition 7.28 and Proposition 7.30 and eq. (7.145)). Introduce the standard BRST doublet $(\alpha_{\rm gf}, \chi)$ with $s\,\alpha_{\rm gf} = \chi$, $s\,\chi = 0$, and define the gauge-fixed classical action $\Sigma(\Phi, K; \alpha_{\rm gf}, \chi) := \Sigma_0(\Phi, K) + s\,\Psi(\alpha_{\rm gf}) - \chi\,\partial_{\alpha_{\rm gf}}\Psi$. The 1PI vertex functional Γ satisfies the (band) Slavnov functional identity

$$\mathcal{S}(\Gamma) = 0, \qquad \mathcal{S}(F) := \int d^dx \left(\frac{\delta F}{\delta K_A}\frac{\delta F}{\delta \varphi^A} + b^a \frac{\delta F}{\delta \bar{c}^a} \right),$$

with the usual Zinn–Justin sources K_A and (algebraic) Nakanishi–Lautrup fields b^a [91, 82]. Differentiating the *extended* identity $\mathcal{S}(\Gamma) + \chi\,\partial_{\alpha_{\rm gf}}\Gamma = 0$ with respect to χ and then setting $\chi = 0$ gives the Nielsen identity in linearised (BV) form:

$$\partial_{\alpha_{\rm gf}}\Gamma = -\,\mathcal{B}_\Gamma\big(\partial_{\alpha_{\rm gf}}\Psi\big), \qquad \mathcal{B}_\Gamma X := \int d^dx \left(\frac{\delta\Gamma}{\delta K_A}\frac{\delta X}{\delta \varphi^A} + \frac{\delta\Gamma}{\delta \varphi^A}\frac{\delta X}{\delta K_A} + b^a \frac{\delta X}{\delta \bar{c}^a} \right), \tag{7.174}$$

where we used the antibracket/linearised-Slavnov equivalence (Proposition 7.212). All steps are valid "on the band" since $P_x(\lambda_{\rm UV})$ and $K_{\rm IR}^{(\ell)}$ commute with s, carry ghost number 0, and commute with derivatives (Definition 7.28 and Proposition 7.30).

EOM representation. Expand $\mathcal{B}_\Gamma$ on $X = \partial_{\alpha_{\rm gf}}\Psi$:

$$\mathcal{B}_\Gamma\big(\partial_{\alpha_{\rm gf}}\Psi\big) = \int d^dx \left(\frac{\delta\Gamma}{\delta K_A}\frac{\delta}{\delta\varphi^A}\partial_{\alpha_{\rm gf}}\Psi + \frac{\delta\Gamma}{\delta\varphi^A}\frac{\delta}{\delta K_A}\partial_{\alpha_{\rm gf}}\Psi + b^a\frac{\delta}{\delta\bar{c}^a}\partial_{\alpha_{\rm gf}}\Psi \right).$$

Define the (band) Nielsen kernel by the canonical rule already fixed above,

$$\mathcal{N}^A(x;\alpha_{\rm gf}) \;:=\; -\frac{\delta}{\delta K_A(x)}\partial_{\alpha_{\rm gf}}\Psi,$$

so the second term becomes $-\int(\delta\Gamma/\delta\varphi^A)\,\mathcal{N}^A$. For the remaining two pieces we use: (i) the algebraic b–equation of motion eliminates the b–term (or, equivalently, expresses it as a $\mathcal{B}_\Gamma$–exact variation that vanishes in the cohomology of ghost number 0); (ii) in the gauge-fixed coordinates obtained by the canonical map generated by Ψ (BV gauge fixing), the $\alpha_{\rm gf}$–dependence of Ψ is entirely along the antifield/source direction,[6] hence $(\partial_{\alpha_{\rm gf}}\Psi)_{,\varphi^A} = 0$ at fixed K, and the first term vanishes. We thus obtain

$$\mathcal{B}_\Gamma\big(\partial_{\alpha_{\rm gf}}\Psi\big) = -\int d^dx\,\frac{\delta\Gamma}{\delta\varphi^A(x)}\,\mathcal{N}^A(x;\alpha_{\rm gf}),$$

[6] Concretely, after the canonical transformation $\varphi^*_A \mapsto K_A + \delta\Psi/\delta\varphi^A$, the functional $\partial_{\alpha_{\rm gf}}\Psi$ acquires only K–dependence at fixed (φ, K), so $(\partial_{\alpha_{\rm gf}}\Psi)_{,\varphi^A} = 0$ at fixed K. If one keeps a residual φ–dependence, the associated term is itself $\mathcal{B}_\Gamma$–exact and can be absorbed by a local field redefinition; see the homological decomposition discussed with Proposition 7.212.

and, by (7.174),

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = \int d^d x\, \frac{\delta\Gamma}{\delta\varphi^A(x)}\, \mathcal{N}^A(x;\alpha_{\mathrm{gf}}).$$

Conclusion and exactness. Therefore $\partial_{\alpha_{\mathrm{gf}}}\Gamma$ is proportional to the Euler–Lagrange equations and is $\mathcal{B}_\Gamma$–exact. In particular, all (band) BRST-closed observables—such as the visibilities used in this chapter—are independent of α_{gf} when evaluated in $\mathcal{H}_{\mathrm{phys}}$ (cf. the Nielsen independence remarks in Remark 6.254). □

Lemma 7.237 (On-shell gauge-parameter independence)**.** *Let $\mathcal{O}[\Phi,\Theta]$ be a BRST-closed, ghost-number 0 functional representing a physical observable (e.g. an S-matrix element, a pole residue, a certified visibility readout restricted to $\mathcal{H}_{\mathrm{phys}}$). Then*

$$\partial_{\alpha_{\mathrm{gf}}}\, \mathcal{O}\Big|_{\text{on shell}} = 0.$$

Proof idea. Differentiate $\mathcal{O}$: $\partial_{\alpha_{\mathrm{gf}}}\mathcal{O} = \int d^d x\, \frac{\delta\mathcal{O}}{\delta\varphi^A(x)}\, \mathcal{N}^A(x)$, using Prop. 7.236. On shell (stationary point of Γ) we have $\delta\Gamma/\delta\varphi^A = 0$. Since $\mathcal{N}^A$ is generated from $\partial_{\alpha_{\mathrm{gf}}}\Psi$ by one antifield derivative, it carries the same EOM proportionality; hence its insertion vanishes on the solution space of the field equations. Moreover, $\mathcal{O}$ being BRST-closed eliminates possible $\mathcal{B}_\Gamma$-exact contributions. Therefore $\partial_{\alpha_{\mathrm{gf}}}\mathcal{O} = 0$ on shell.

Proof. **Preliminaries.** Work on the band where the UV projector and IR window are BRST-closed and commute with derivatives and internal symmetries (cf. eq. (7.145)); the Slavnov functional identity holds, $\mathcal{S}(\Gamma) = 0$, with linearised operator $\mathcal{B}_\Gamma$ (ghost number +1). Gauge-parameter dependence enters only via the gauge fermion $\Psi(\alpha_{\mathrm{gf}})$.

Step 1: Band Nielsen identity for Γ. By Proposition 7.236 one has the (EOM) Nielsen form

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\big(\partial_{\alpha_{\mathrm{gf}}}\Psi\big) = \int d^d x\, \frac{\delta\Gamma}{\delta\varphi^A(x)}\, \mathcal{N}^A(x;\alpha_{\mathrm{gf}}), \qquad \mathcal{N}^A(x;\alpha_{\mathrm{gf}}) := -\frac{\delta}{\delta K_A(x)}\big(\partial_{\alpha_{\mathrm{gf}}}\Psi\big). \tag{7.175}$$

Step 2: How on-shell solutions move with α_{gf}. Let $\varphi_\star(\alpha_{\mathrm{gf}})$ solve the field equations, $\delta\Gamma/\delta\varphi^A\big|_{\varphi_\star} = 0$. Differentiate this stationarity condition w.r.t. α_{gf}:

$$0 = \frac{d}{d\alpha_{\mathrm{gf}}}\Big(\frac{\delta\Gamma}{\delta\varphi^A}\Big)_{\varphi_\star} = \Gamma_{AB}(\varphi_\star)\,\partial_{\alpha_{\mathrm{gf}}}\varphi^B_\star \;+\; \Big(\frac{\delta}{\delta\varphi^A}\,\partial_{\alpha_{\mathrm{gf}}}\Gamma\Big)_{\varphi_\star},$$

where $\Gamma_{AB} := \delta^2\Gamma/\delta\varphi^A\delta\varphi^B$. Using (7.175) and differentiating under the integral,

$$\frac{\delta}{\delta\varphi^A}\,\partial_{\alpha_{\mathrm{gf}}}\Gamma = \Gamma_{AC}\,\mathcal{N}^C + \frac{\delta\Gamma}{\delta\varphi^C}\,\frac{\delta\mathcal{N}^C}{\delta\varphi^A}.$$

At $\varphi_\star$ the second term vanishes; thus $\Gamma_{AB}(\varphi_\star)\,\big(\partial_{\alpha_{\mathrm{gf}}}\varphi^B_\star - \mathcal{N}^B(\varphi_\star)\big) = 0$. Assuming the usual regularity (invertibility of Γ_{AB} on the physical subspace; gauge zero-modes are projected out by the BRST quartet/physical projector), we conclude

$$\partial_{\alpha_{\mathrm{gf}}}\varphi^A_\star = \mathcal{N}^A\big(\varphi_\star\big). \tag{7.176}$$

Step 3: $\alpha_{\rm gf}$-derivative of on-shell $\mathcal{O}$. Since $\mathcal{O}$ has no explicit antifield dependence and gauge-parameter enters only through the fields,

$$\partial_{\alpha_{\rm gf}} \mathcal{O}\big(\varphi_\star(\alpha_{\rm gf})\big) = \int d^d x \, \frac{\delta \mathcal{O}}{\delta \varphi^A(x)} \, \partial_{\alpha_{\rm gf}} \varphi^A_\star(x).$$

Using (7.176) gives the *characteristic* (Nielsen) contraction

$$\partial_{\alpha_{\rm gf}} \mathcal{O}\Big|_{\text{on shell}} = \int d^d x \, \frac{\delta \mathcal{O}}{\delta \varphi^A(x)} \, \mathcal{N}^A(x;\alpha_{\rm gf}). \tag{7.177}$$

Step 4: BRST-closedness ⇒ vanishing of the characteristic contraction. By definition of $\mathcal{N}^A$ and the BV antibracket $(\cdot,\cdot)$,

$$\int d^d x \, \frac{\delta \mathcal{O}}{\delta \varphi^A(x)} \, \mathcal{N}^A(x) = - \int d^d x \, \frac{\delta \mathcal{O}}{\delta \varphi^A(x)} \, \frac{\delta}{\delta K_A(x)} \big(\partial_{\alpha_{\rm gf}} \Psi\big) = - \, (\mathcal{O}, \partial_{\alpha_{\rm gf}} \Psi)\Big|_{K=0}.$$

The Jacobi identity together with $\mathcal{S}(\Gamma) = 0$ implies the standard linearisation property $\mathcal{B}_\Gamma X = (\Gamma, X) + \cdots$ (the extra $b\delta/\delta\bar{c}$ term does not contribute here: $\mathcal{O}$ has ghost number 0 and no $\bar{c}$-dependence). Since $\mathcal{O}$ is BRST-closed, $\mathcal{B}_\Gamma \mathcal{O} = 0$, hence $(\Gamma, \mathcal{O}) \approx 0$ on the stationary surface.[7] Therefore $(\mathcal{O}, \partial_{\alpha_{\rm gf}} \Psi)$ is $\mathcal{B}_\Gamma$-exact on shell, and BRST-exact deformations do not change physical (cohomology) classes on $\mathcal{H}_{\rm phys}$. Accordingly, the right-hand side of (7.177) vanishes, giving $\partial_{\alpha_{\rm gf}} \mathcal{O}\big|_{\text{on shell}} = 0$.

Conclusion. On-shell solutions move along the Nielsen vector field (7.176); BRST-closed observables are constant along this flow in the physical sector, hence are gauge-parameter independent on shell. □

Proposition 7.238 (Extended Slavnov trick ⇒ band Nielsen identity)**.** *Promote the gauge parameter to a BRST doublet $(\alpha_{\rm gf}, \chi)$ with $s\,\alpha_{\rm gf} = \chi$ and $s\,\chi = 0$, and extend the classical action by the s-exact term $s\int d^d x\, \alpha_{\rm gf}\Psi = \int d^d x \, \big(\chi\,\Psi - \alpha_{\rm gf}\, s\Psi\big)$. Assuming the anomaly filters (nilpotent BRST on the band) and using that the UV/IR tagging commutes with s (cf. eq. (7.145)), the* extended *Slavnov functional identity*

$$\widetilde{\mathcal{S}}(\Gamma) \equiv \mathcal{S}(\Gamma) \; + \; \chi\, \partial_{\alpha_{\rm gf}} \Gamma \; = \; 0$$

holds for the 1PI functional Γ on the band. Differentiating w.r.t. χ and setting $\chi = 0$ gives

$$\partial_{\alpha_{\rm gf}} \Gamma = - \, \mathcal{B}_\Gamma\big(\partial_{\alpha_{\rm gf}} \Psi\big),$$

i.e. the band Nielsen identity of EOM form (identical to Proposition 7.236).

Proof. By construction, the χ-coupling enters Γ only through the s-exact insertion $\int \chi\,\Psi$, and the extended BRST invariance yields $\widetilde{\mathcal{S}}(\Gamma) = 0$. Taking $\partial/\partial\chi$ and then $\chi{=}0$,

$$0 = \frac{\partial}{\partial \chi} \widetilde{\mathcal{S}}(\Gamma)\Big|_{\chi=0} = \frac{\partial}{\partial \chi} \mathcal{S}(\Gamma)\Big|_{\chi=0} \; + \; \partial_{\alpha_{\rm gf}} \Gamma.$$

[7] More precisely, $(\Gamma, \mathcal{O})$ is proportional to the equations of motion when $\mathcal{O}$ is antifield independent; this vanishes on shell.

The chain rule together with the linearisation of $\mathcal{S}$ at Γ gives $\frac{\partial}{\partial\chi}\mathcal{S}(\Gamma)\big|_{\chi=0} = \mathcal{B}_\Gamma\Big(\frac{\partial\Gamma}{\partial\chi}\big|_{\chi=0}\Big)$. Since the only χ-dependence is the linear insertion $\int\chi\,\Psi$, the Quantum Action Principle and s-closure on the band imply $\frac{\partial\Gamma}{\partial\chi}\big|_{\chi=0} = \partial_{\alpha_{\rm gf}}\Psi$. Hence $0 = \mathcal{B}_\Gamma(\partial_{\alpha_{\rm gf}}\Psi) + \partial_{\alpha_{\rm gf}}\Gamma$, which is the stated identity. Band/IR operations commute with s and carry ghost number 0 so no extra terms arise. □

Corollary 7.239 (On-shell independence via the doublet)**.** *For any BRST-closed, ghost-number* 0 *observable* $\mathcal{O}$ *evaluated on stationary points of* Γ, $\partial_{\alpha_{\rm gf}}\mathcal{O}|_{\text{on shell}} = 0$.

Proof. Combine Proposition 7.238 with the characteristic flow $\partial_{\alpha_{\rm gf}}\varphi^A_\star = \mathcal{N}^A(\varphi_\star)$ derived in the proof of Lemma 7.237; BRST-closedness of $\mathcal{O}$ implies constancy along this flow in $\mathcal{H}_{\rm phys}$. □

Corollary 7.240 (Pole-mass Nielsen identity (band-limited))**.** *Let* $\Delta^{-1}(p)$ *denote a renormalised* 1*PI two-point kernel for a physical mode, and suppose* $\Delta^{-1}(p^2 = m_\star^2) = 0$ *with finite residue. Then near the pole*

$$\partial_{\alpha_{\rm gf}}\Delta^{-1}(p) = \mathcal{C}(p)\,\Delta^{-1}(p) \quad \Rightarrow \quad \partial_{\alpha_{\rm gf}} m_\star^2 = 0,$$

with $\mathcal{C}$ *regular at* $p^2 = m_\star^2$*. Hence the pole position is gauge-parameter independent on the band.*

Proof. Apply Prop. 7.236 to the quadratic sector: the variation of the two-point kernel is EOM-proportional, i.e. right-multiplication by a regular form factor (and its transpose in mixed sectors). Evaluating at the zero of Δ^{-1} kills the r.h.s., implying the pole condition is stationary in $\alpha_{\rm gf}$. Regularity follows from the anomaly filters and standard QAP arguments [117, 91]. □

Corollary 7.241 (Gauge-parameter independence of certified visibilities)**.** *For the holosymmetric probe on* $\mathcal{H}_{\rm phys}$*, the complex coherence amplitude* $\mathcal{C}_\alpha$ *and any phase-fixed visibility* Λ_α *(defined on a certified plateau) obey*

$$\partial_{\alpha_{\rm gf}}\mathcal{C}_\alpha = 0, \qquad \partial_{\alpha_{\rm gf}}\Lambda_\alpha = 0,$$

up to admissible regulator tolerances.

Proof. Insert the Nielsen identity into the readout expressions (either (7.115) or (7.98)). All $\partial_{\alpha_{\rm gf}}$-variations reduce to $\mathcal{B}_\Gamma$-exact (EOM) insertions, which vanish on $\mathcal{H}_{\rm phys}$ by BRST closure and on-shell conditions; band/IR commutation guarantees these manipulations hold on the band. □

Remark 7.242 (Ghost number and sector structure)**.** Ghost-number counting gives $\mathrm{gh}(\partial_{\alpha_{\rm gf}}\Psi) = 0$ and $\mathrm{gh}(\mathcal{N}^A) = -1 + \mathrm{gh}(K_A)$, so the insertion in (7.173) preserves total ghost number 0. If sector projectors Π_β commute with $P_x(\lambda_{\rm UV})$ and $K_{\rm IR}^{(\ell)}$, the identity holds sectorwise, yielding projector-resolved Nielsen statements consistent with Section 7.4.3.

7.5.6 Cohomological Content and Physical Operators

Let $\mathcal{B}_\Gamma$ be the linearised ST operator (7.151). Physical, gauge-invariant composite operators $\mathcal{O}$ at the symmetric point are the cohomology classes

$$\mathcal{O} \in H^0(\mathcal{B}_\Gamma) \qquad \text{with} \qquad \mathcal{B}_\Gamma \mathcal{O} = 0, \quad \mathcal{O} \sim \mathcal{O} + \mathcal{B}_\Gamma X. \tag{7.178}$$

All statements below are understood *on the band*; the UV/IR knobs commute with BRST and carry ghost number 0, cf. (7.145).

Proposition 7.243 (Well-definedness on the physical sector)**.** *Let $\mathcal{O}$ be a local composite with $\mathrm{gh}(\mathcal{O}) = 0$. If $\mathcal{B}_\Gamma \mathcal{O} = 0$, then for any physical in/out states $|\Psi_{\mathrm{in}}\rangle, |\Psi_{\mathrm{out}}\rangle \in \mathcal{H}_{\mathrm{phys}}$ (BRST-closed modulo null states) and any set of additional BRST-closed insertions,*

$$\langle \Psi_{\mathrm{out}}| \, \mathcal{O} \, |\Psi_{\mathrm{in}}\rangle \quad \textit{is independent of the representative} \quad \mathcal{O} \mapsto \mathcal{O} + \mathcal{B}_\Gamma X.$$

Proof. On $\mathcal{H}_{\mathrm{phys}}$ (BRST cohomology at ghost number 0), the insertion of a $\mathcal{B}_\Gamma$-exact operator is a BRST commutator and vanishes by the quartet mechanism/positivity and cyclicity; see algebraic BRST treatments [442, 117]. Band/IR commutation (7.145) prevents extra contact terms. □

Proposition 7.244 (Källén–Lehmann positivity on $\mathcal{H}_{\mathrm{phys}}$)**.** *Let $\mathcal{O} \in H^0(\mathcal{B}_\Gamma)$ be local and Hermitian. Then its two-point function on $\mathcal{H}_{\mathrm{phys}}$ admits the Källén–Lehmann representation*

$$\langle \mathcal{O}(x)\, \mathcal{O}(0) \rangle_{\mathrm{phys}} = \int_0^\infty d\mu^2 \; \rho_{\mathcal{O}}(\mu^2)\, \Delta_+(x;\mu^2), \qquad \rho_{\mathcal{O}}(\mu^2) \geq 0,$$

with Δ_+ the free Wightman function and $\rho_{\mathcal{O}}$ a non-negative spectral density [241, 82]. The spectral measure and support are invariant under $\mathcal{O} \mapsto \mathcal{O} + \mathcal{B}_\Gamma X$.

Proof. Restrict correlators to $\mathcal{H}_{\mathrm{phys}}$ via $\mathsf{P}_{\mathrm{phys}}$ (quartet decoupling) [442, 117]. The induced inner product is positive and the Wightman axioms hold for band-smeared locals [241]; spectral decomposition then yields the stated form [82]. $\mathcal{B}_\Gamma$-exact shifts drop out by the previous proposition. □

Proposition 7.245 (Renormalisation stability of $H^0(\mathcal{B}_\Gamma)$)**.** *Assume the anomaly filters so that $\mathcal{S}(\Gamma) = 0$ to all orders. Then the space of physical operators is stable under renormalisation: counterterms can be chosen so that the renormalised operator $\mathcal{O}_R$ and $\mathcal{B}_{\Gamma_R}$ satisfy*

$$\mathcal{B}_{\Gamma_R} \mathcal{O}_R = 0, \qquad \mathcal{O}_R \sim \mathcal{O}_R + \mathcal{B}_{\Gamma_R} X_R,$$

and the mixing matrix is block-upper-triangular between cohomology classes and $\mathcal{B}_{\Gamma_R}$-exact operators. Anomalous dimensions on H^0 are gauge-parameter independent [117, 91].

Proof. Algebraic renormalisation (Quantum Action Principle) with preserved Slavnov identity controls composite-operator mixings and ensures stability of BRST cohomology classes [117]. Nielsen identities render gauge-parameter variations $\mathcal{B}_\Gamma$-exact, so eigenvalues on H^0 do not depend on α_{gf} [91]. □

Lemma 7.246 (Sectorwise decomposition)**.** *Let $\{\Pi_\beta\}$ be BRST-closed sector projectors commuting with the UV/IR knobs. If $\mathcal{O} \in H^0(\mathcal{B}_\Gamma)$, then $\mathcal{O}_\beta := \Pi_\beta \mathcal{O} \Pi_\beta$ defines a class in $H^0(\mathcal{B}_\Gamma)$ (possibly trivial), and*

$$\langle \mathcal{O}(x)\, \mathcal{O}(0)\rangle_{\text{phys}} = \sum_\beta \langle \mathcal{O}_\beta(x)\, \mathcal{O}_\beta(0)\rangle_{\text{phys}},$$

with no cross terms.

Proof. $[\Pi_\beta, \mathcal{B}_\Gamma] = 0$ (BRST-closure), so $\mathcal{B}_\Gamma \mathcal{O} = 0 \Rightarrow \mathcal{B}_\Gamma \mathcal{O}_\beta = 0$. Orthogonality removes cross terms. Positivity sectorwise follows from Prop. 7.244. □

Corollary 7.247 (Gauge-parameter independence on shell)**.** *Let $\mathcal{O} \in H^0(\mathcal{B}_\Gamma)$ and consider any on-shell observable built from $\mathcal{O}$ (pole mass/residue, certified visibility from BRST-closed inputs). Then*

$$\partial_{\alpha_{\text{gf}}}(\textit{observable}) = 0 \quad \textit{on shell},$$

up to admissible regulator tolerances [117, 91].

Remark 7.248 (Connection to holosymmetric visibilities)**.** The channel overlap operators used by the holosymmetric probe are assembled from BRST-closed, band-limited ingredients; their matrix elements depend only on cohomology classes, so visibilities/echoes inherit the positivity and Nielsen/BRST robustness discussed above [117, 442, 91].

7.5.7 Background-field Option

Background split and band-limited gauge fixing. Adopt the background-field method (BFM) [114, 91] by splitting the mean/1PI fields into

$$\Phi \to \bar{\Phi} + \phi, \qquad \Theta \to \bar{\Theta} + \vartheta,$$

where $(\bar{\Phi}, \bar{\Theta})$ are classical background fields and (ϕ, ϑ) are the quantum fields integrated over in the path integral. Choose a *background-covariant* gauge fermion Ψ_{bkg} so that background gauge invariance is manifest. All band/IR operations commute with BRST and with the global/background G-action, cf. (7.145); in particular the band-limited sources and kernels are G-scalars.

Background Ward identity and Slavnov identity. Let $\Gamma[\bar{\Phi}, \bar{\Theta}; \phi, \vartheta, K]$ denote the band-limited 1PI action with sources K only for the *quantum* BRST variations. Denote by δ^a_{bkg} the background G-variation:

$$\delta^a_{\text{bkg}} \bar{\Phi} = i\, T^a \bar{\Phi},$$
$$\delta^a_{\text{bkg}} \bar{\Theta} = i\, T^a \bar{\Theta},$$
$$\delta^a_{\text{bkg}}(\phi, \vartheta) \text{ linear s.t. } \bar{\Phi} + \phi,\ \bar{\Theta} + \vartheta \text{ transform covariantly.}$$

Define the *background Ward operator* acting on 1PI functionals by

$$\mathcal{W}^a_{\text{bkg}} := \int d^d x \left(\frac{\delta}{\delta \bar{\Phi}}\, \delta^a_{\text{bkg}} \bar{\Phi} + \frac{\delta}{\delta \bar{\Theta}}\, \delta^a_{\text{bkg}} \bar{\Theta} + \frac{\delta}{\delta K_\Phi}\, \delta^a_{\text{bkg}}(\zeta\phi) + \frac{\delta}{\delta K_\Theta}\, \delta^a_{\text{bkg}}(\zeta\vartheta) \right),$$

where $\delta^a_{\mathrm{bkg}}(\zeta\phi) = \zeta(\delta^a_{\mathrm{bkg}}\phi)$ etc. by background covariance of Ψ_{bkg}. Then, at the symmetry point and *on the band*,

$$\mathcal{W}^a_{\mathrm{bkg}}\,\Gamma = 0, \qquad \mathcal{S}(\Gamma) = 0, \tag{7.179}$$

i.e. the background Ward identity holds *in addition* to the band Slavnov identity (7.150) [114, 91]. The proof is the standard change-of-variables derivation with background-local transformations, and goes through verbatim because band/IR knobs commute with BRST and with G (7.145).

Proposition 7.249 (Compatibility with Slavnov and linearised BRST in BFM)**.** *Assume* (7.179)*. Then*

$$\mathcal{W}^a_{\mathrm{bkg}}\Big(\mathcal{S}(\Gamma)\Big) = 0, \qquad [\mathcal{W}^a_{\mathrm{bkg}},\, \mathcal{B}_\Gamma] = 0.$$

Consequently, the linearised cohomology $\mathsf{H}^\bullet(\mathcal{B}_\Gamma)$ *is* G*-equivariant under the background symmetry.*

Proof. Use the antibracket form $\mathcal{S}(\Gamma) = \frac{1}{2}(\Gamma,\Gamma)$ and that $\mathcal{W}^a_{\mathrm{bkg}}$ is a derivation of the antibracket (background variations are linear). Then $\mathcal{W}^a_{\mathrm{bkg}}\mathcal{S}(\Gamma) = \frac{1}{2}[(\mathcal{W}^a_{\mathrm{bkg}}\Gamma,\Gamma) + (\Gamma, \mathcal{W}^a_{\mathrm{bkg}}\Gamma)] = 0$. For the commutator, $[\mathcal{W}^a_{\mathrm{bkg}}, \mathcal{B}_\Gamma]X = \mathcal{W}^a_{\mathrm{bkg}}(\Gamma, X) - (\Gamma, \mathcal{W}^a_{\mathrm{bkg}}X) = (\mathcal{W}^a_{\mathrm{bkg}}\Gamma, X) = 0$. □

Background Nielsen identity and on-shell independence. If the gauge-fixing parameter α_{gf} enters only via $\Psi_{\mathrm{bkg}}(\alpha_{\mathrm{gf}})$, the band Nielsen identity holds in the BFM:

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi_{\mathrm{bkg}}\Big),$$

which is background-covariant because $\partial_{\alpha_{\mathrm{gf}}}\Psi_{\mathrm{bkg}}$ is a background scalar. Therefore on-shell, BRST-closed observables that are background-gauge invariant are *gauge-parameter independent* on the band [117, 91].

Proposition 7.250 (Transversality and renormalisation simplifications (BFM))**.** *Let* $\Pi^{\mu\nu}_{ab}$ *denote the background current (or background gauge field)* 1*PI two-point kernel. Then*

$$p_\mu\,\Pi^{\mu\nu}_{ab}(p) = 0, \qquad \Pi^{\mu\nu}_{ab}(p) = \Pi_{ab}(p^2)\,\Pi^{\mu\nu}_{\mathrm{T}}(p),$$

with $\Pi^{\mu\nu}_{\mathrm{T}} = \eta^{\mu\nu} - p^\mu p^\nu/p^2$*, exactly on the band. Moreover, renormalisation constants are constrained by background Ward identities; in particular, the gauge coupling renormalisation can be extracted from the background two-point function with manifest gauge invariance [114, 91].*

Sketch. The local background Ward identity (spurion method) implies transversality as in the non-BFM case, now with background sources; commuting of band/IR knobs with derivatives ensures no extra longitudinal terms. Renormalisation constraints follow from requiring (7.179) after counterterms: only background-covariant structures appear, yielding the standard BFM relations [114, 91]. □

Summary. If the background-field method is used, the 1PI action obeys *both* the background Ward identities and the Slavnov identity,

$$\mathcal{W}^a_{\rm bkg}\,\Gamma = 0, \qquad \mathcal{S}(\Gamma) = 0,$$

with all products and sources band-limited. This guarantees: (i) manifest gauge/BRST robustness of physical matrix elements and visibilities; (ii) exact transversality/selection rules enforced by G at the background level; and (iii) gauge-parameter independence of on-shell quantities, with renormalisation simplified by background covariance [114, 91, 117, 442, 82, 241]. Band/IR knobs preserve these identities by (7.145).

7.5.8 Global Ward Identities at the Symmetric Point

Let $\{T_a\}$ be generators of the unbroken global symmetry G in Quadrant I, and let J^μ_a be the associated conserved Noether currents. We assume the UV generator $\mathcal{D}_x$ is G-invariant so that

$$[Q_a, \mathcal{D}_x] = 0 \quad \Rightarrow \quad [Q_a, P_x(\lambda_{\rm UV})] = 0, \qquad Q_a := \int_{\Sigma_t} d\Sigma_\mu\, J^\mu_a, \tag{7.180}$$

and IR smearing is G-blind. Hence all band/IR operations commute with G ("bandwise symmetry"). For any gauge-invariant composite $\mathcal{O}$ (built from BRST-cohomology classes, cf. Section 7.5.6), invariance of $S^{(\lambda_{\rm UV},\ell)}_{\Phi,\Theta}$ under $\delta_a\varphi := i\,T_a\varphi$ yields the *position-space Ward identity* (with all insertions IR-smoothed as in eq. (7.33))

$$\partial^{(x)}_\mu\, \langle J^\mu_a(x)\, \mathcal{O}(x_1,\dots,x_n)\rangle = -i \sum_{j=1}^{n} \delta^{(d)}(x - x_j)\, \langle \delta_a \mathcal{O}(x_1,\dots,x_n)\rangle, \tag{7.181}$$

which descends to $\mathcal{H}_{\rm phys}$ because BRST-exact pieces decouple and $P_x(\lambda_{\rm UV})$ carries ghost number 0 (Section 7.2.6 and eq. (7.30)). In momentum space this becomes the standard *Ward–Takahashi identity* for 1PI functions (computed from Γ in eq. (7.144)) [91, 82]:

$$k_\mu\, \Gamma^\mu_{J_a\,\mathcal{O}_1\dots\mathcal{O}_n}(k; p_1,\dots,p_n) = \sum_{j=1}^{n} \Gamma_{\mathcal{O}_1\dots(\delta_a\mathcal{O}_j)\dots\mathcal{O}_n}(p_1,\dots,p_n). \tag{7.182}$$

At the G-invariant vacuum fixed in Section 7.1, $\delta_a\bar\Phi = \delta_a\bar\Theta = 0$, so the one-point identity reduces to current conservation,

$$\partial_\mu \langle J^\mu_a\rangle_{\bar\Phi,\bar\Theta} = 0. \tag{7.183}$$

Proposition 7.251 (Band-limited local Ward identity)**.** *Under the assumptions above and anomaly filters (so that BRST is nilpotent and global G is non-anomalous), the identity* (7.181) *holds* on the band *for any set of BRST-closed, gauge-invariant composites $\{\mathcal{O}_j\}$.*

Proof. Promote the constant G parameter to a test function $\epsilon_a(x)$ and perform the change of variables $\varphi \mapsto \varphi + i\,\epsilon_a T_a\varphi$ in the band-limited path integral defining correlators. The functional measure is invariant (global linear change), the variation of $S^{(\lambda_{\rm UV},\ell)}_{\Phi,\Theta}$ yields the conserved current via Noether's theorem, and the source insertions vary by $\delta_a\mathcal{O}_j$. Because $P_x(\lambda_{\rm UV})$ and $K^{(\ell)}_{\rm IR}$ commute with G and BRST (ghost number 0), no extra contact terms appear from the band/IR embedding. Integrating by parts transfers $\partial_\mu\epsilon_a$ onto J^μ_a, giving (7.181). BRST-exact contributions vanish on $\mathcal{H}_{\rm phys}$ by quartet decoupling [442, 117]. □

Proposition 7.252 (Momentum-space Ward–Takahashi identity on the band)**.** *Fourier transforming* (7.181) *and passing to* 1*PI kernels via the Legendre transform (at fixed band/IR knobs) yields* (7.182)*. In particular, for a single* $\mathcal{O}$ *in a representation of* G*, the three-point* 1*PI vertex satisfies* $k_\mu \Gamma^\mu_{J_a \mathcal{O}\mathcal{O}} = i[(T_a)\Gamma - \Gamma(T_a)]$ *[91, 82].*

Proof. Standard manipulations [82, 91]: (i) Fourier transform the local identity; (ii) use connected amputated functions and then the Legendre transform to 1PI kernels. The band/IR knobs commute with derivatives and do not alter momentum routing, so the textbook derivation carries over unchanged. □

Corollary 7.253 (Transversality and irrep constraints)**.** *Let* $\Pi^{\mu\nu}_{ab}(k)$ *be the* 1*PI current–current kernel. Then* $k_\mu \Pi^{\mu\nu}_{ab}(k) = 0$ *and* $\Pi^{\mu\nu}_{ab}(k) = \Pi_{ab}(k^2)\,(\eta^{\mu\nu} - k^\mu k^\nu/k^2)$ *at the symmetry point. Moreover, two-point* 1*PI kernels of matter operators commute with the* G*-action and are block-diagonal in* G*-irreps (Schur), with irrep-wise scalar structures; mixing between inequivalent irreps is forbidden [91].*

Proof. Apply (7.182) with $\mathcal{O} = J^\nu_b$ to obtain transversality; apply it with matter operators to deduce commutation with T_a and invoke Schur's lemma. The band embedding preserves these tensorial statements because it is G-blind and derivative-compatible. □

Remark 7.254 (Compatibility with BRST and Nielsen identities)**.** The global Ward identities commute with the Slavnov identity and with the linearised BRST operator on the band (cf. Section 7.5.2), so they descend to the physical cohomology classes that define observables [117, 442]. Gauge-parameter variations are $\mathcal{B}_\Gamma$-exact (Nielsen identity), hence on-shell Ward consequences (transversality, pole positions, certified visibilities) are gauge-parameter independent [91].

Two-point structures and transversality.

Proposition 7.255 (Current two-point tensor structure and KL-positivity on the band)**.** *Let* J^μ_a *denote the conserved Noether currents of the unbroken global symmetry* G *at the symmetric vacuum (Quadrant I), with band/IR operations commuting with* G *and BRST. Then the* 1*PI current–current kernel is transverse and admits the unique transverse decomposition*

$$k_\mu \Gamma^{\mu\nu}_{J_a J_b}(k) = 0 \quad \Rightarrow \quad \Gamma^{\mu\nu}_{J_a J_b}(k) = \Pi^{ab}_{\mathrm{T}}(k^2)\; P^{\mu\nu}_{\mathrm{T}}(k; \bar{\Sigma}^{(\ell)}), \tag{7.184}$$

where the transverse projector with respect to the IR metric $\bar{\Sigma}^{(\ell)}_{\mu\nu}$ *is*

$$P^{\mu\nu}_{\mathrm{T}}(k; \bar{\Sigma}^{(\ell)}) := \bar{\Sigma}^{(\ell)\mu\nu} - \frac{k^\mu k^\nu}{\bar{\Sigma}^{(\ell)\rho\sigma} k_\rho k_\sigma}\,, \qquad k_\mu P^{\mu\nu}_{\mathrm{T}} = 0, \tag{7.185}$$

and $\Pi^{ab}_{\mathrm{T}}(k^2)$ *is a symmetric matrix of scalar form factors in the adjoint indices* (a, b)*. Moreover, on the physical Hilbert space* $\mathcal{H}_{\mathrm{phys}}$ *the (band-smeared) current correlator has a Källén–Lehmann representation with a positive semidefinite spectral matrix:*

$$\langle\!\langle J^\mu_a(k)\, J^\nu_b(-k) \rangle\!\rangle_{\mathcal{H}_{\mathrm{phys}}} = P^{\mu\nu}_{\mathrm{T}}(k; \bar{\Sigma}^{(\ell)}) \int_0^\infty d\mu^2\; \frac{\rho^{ab}_J(\mu^2)}{k^2 + \mu^2 - i0}, \qquad \rho^{ab}_J(\mu^2) \succeq 0. \tag{7.186}$$

Proof. Transversality. Apply the global Ward identity in momentum space to the three-point 1PI vertex with one current insertion and two current legs (or equivalently differentiate the local Ward identity with respect to sources for J_b^ν and amputate). Using (7.182) (derived on the band) one finds $k_\mu\,\Gamma^{\mu\nu}_{J_a J_b}(k) = 0$; by symmetry of the two-point kernel the analogous contraction with k_ν also vanishes. The band/IR embedding commutes with derivatives and the G-action, so no longitudinal contact terms arise (cf. Section 7.5.8; see also [82, 91]).

Tensor structure. In the presence of the IR metric $\bar{\Sigma}^{(\ell)}_{\mu\nu}$, the most general *symmetric* rank-2 tensor built from k^μ and $\bar{\Sigma}^{(\ell)}_{\mu\nu}$ is a linear combination of $\bar{\Sigma}^{(\ell)\mu\nu}$ and $k^\mu k^\nu$. Imposing transversality with respect to k_μ uniquely fixes the combination to be the projector $P^{\mu\nu}_{\mathrm{T}}(k;\bar{\Sigma}^{(\ell)})$ in (7.185). Hence (7.184) with a scalar form factor matrix $\Pi^{ab}_{\mathrm{T}}(k^2)$. Bose symmetry and Hermiticity of the currents imply $\Pi^{ab}_{\mathrm{T}} = \Pi^{ba}_{\mathrm{T}}$ and reality below multi-particle thresholds [91].

Källén–Lehmann form and positivity. Restricting to $\mathcal{H}_{\mathrm{phys}}$ (quartet decoupling) yields a positive-definite inner product; the usual spectral condition and locality (here implemented with band smearing) give the Källén–Lehmann representation for two-point functions of Hermitian operators [241, 82, 91]. Current conservation removes the longitudinal part, leaving the transverse projector as a kinematic factor. The spectral matrix $\rho_J^{ab}(\mu^2)$ is positive semidefinite: for any complex vector v_a, the scalar operator $J_v^\mu := v_a J_a^\mu$ has nonnegative spectral density, whence $v_a^*\,\rho_J^{ab}(\mu^2)\,v_b \geq 0$. This establishes (7.186), consistent with the general positivity statement in eq. (7.12). □

Charge action and algebra on the band. The band-limited charges $Q_a^{(\lambda_{\mathrm{UV}},\ell)} := \int d\Sigma_\mu\, J_a^\mu$ satisfy

$$[Q_a^{(\lambda_{\mathrm{UV}},\ell)},\,\mathcal{O}] = \delta_a\mathcal{O}, \qquad [Q_a^{(\lambda_{\mathrm{UV}},\ell)},\,Q_b^{(\lambda_{\mathrm{UV}},\ell)}] = i f_{ab}{}^c\,Q_c^{(\lambda_{\mathrm{UV}},\ell)}, \tag{7.187}$$

on BRST-closed, gauge-invariant composites; here $f_{ab}{}^c$ are the structure constants of G. Equation (7.180) ensures that $Q_a^{(\lambda_{\mathrm{UV}},\ell)}$ generate the same algebra as the unbanded charges, and $[Q_a^{(\lambda_{\mathrm{UV}},\ell)}, H] = 0$ at the symmetric vacuum.

Proposition 7.256 (Band-limited charge action and Lie algebra)**.** *Assume (i) global G is non-anomalous (anomaly filters hold), (ii) $[Q_a, \mathcal{D}_x] = 0$ so that band/IR operations commute with G (7.180), and (iii) the IR window renders surface terms null. Then for any BRST-closed, gauge-invariant composite $\mathcal{O}$,*

$$[Q_a^{(\lambda_{\mathrm{UV}},\ell)},\mathcal{O}] = \delta_a\mathcal{O}, \qquad [Q_a^{(\lambda_{\mathrm{UV}},\ell)},Q_b^{(\lambda_{\mathrm{UV}},\ell)}] = i f_{ab}{}^c\,Q_c^{(\lambda_{\mathrm{UV}},\ell)}.$$

Proof. Integrate the local Ward identity (7.181) over a Cauchy slice Σ_t with the IR weight. The left-hand side becomes the time derivative of the charge insertion plus a vanishing boundary term; the right-hand side produces the action of δ_a on $\mathcal{O}$. This yields $[Q_a^{(\lambda_{\mathrm{UV}},\ell)},\mathcal{O}] = \delta_a\mathcal{O}$ (the equal-time commutator form of the Ward identity) [82, 91]. For the algebra, evaluate $[Q_a^{(\lambda_{\mathrm{UV}},\ell)}, J_b^\mu]$ using the same identity with $\mathcal{O} = J_b^\mu$ and integrate; non-anomalous current algebra implies $[Q_a^{(\lambda_{\mathrm{UV}},\ell)}, Q_b^{(\lambda_{\mathrm{UV}},\ell)}] = i f_{ab}{}^c Q_c^{(\lambda_{\mathrm{UV}},\ell)}$ with no Schwinger terms. Commutation with the band projector and IR window follows from (7.180). Quartet/positivity ensures BRST-exact pieces do not contribute on $\mathcal{H}_{\mathrm{phys}}$ [442, 117]. □

Non-renormalization of conserved currents (anomaly-free case). With anomaly filters satisfied (Section 7.2.8), the conserved currents have no anomalous dimension: renormalization can at most add BRST-exact or total-derivative improvements, leaving (7.181)–(7.184) intact. In particular,

$$\mu\frac{d}{d\mu}\,J_a^\mu \sim \partial_\nu(\cdots)+\zeta(\cdots), \qquad \Rightarrow \quad \gamma_{J_a}=0 \ \text{ in } H^0(\mathcal{B}_\Gamma), \tag{7.188}$$

see [91] and [117]. Any nonzero divergence or Schwinger term would indicate an anomaly and thus violate the acceptance criteria of Section 7.3.9.

Proposition 7.257 (Algebraic non-renormalization of J_a^μ)**.** *Assume $\mathcal{S}(\Gamma)=0$ (band Slavnov identity) and exact global Ward identities on the band (non-anomalous G). Then one can choose renormalisation constants so that $Z_J=1$ and the RG flow of J_a^μ is, at most, an improvement by $\partial_\nu(\cdots)$ and a BRST-exact term $\zeta(\cdots)$. Equivalently, $\gamma_{J_a}=0$ in $H^0(\mathcal{B}_\Gamma)$.*

Proof. All statements are *on the band*; $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with BRST and with G and carry ghost number 0, so band/IR operations preserve the identities used below (cf. (7.145)). We work in the algebraic–renormalisation framework (Quantum Action Principle, QAP) with the band Slavnov identity $\mathcal{S}(\Gamma)=0$ and exact global Ward identities (non–anomalous G) [117, 91].

(1) Classification of allowed counterterms for the current insertion. Consider the insertion of the local operator J_a^μ in 1PI functionals. By the QAP, the most general renormalisation of a local insertion with the quantum numbers of J_a^μ is a linear combination of operators with the same dimension, Lorentz and G indices, modulo (i) total derivatives, (ii) equations of motion (EOM) insertions, and (iii) $\mathcal{B}_\Gamma$-exact terms (linearised BRST) [117]. Current conservation and the global Ward identities constrain the counterterm space to

$$[J_a^\mu]_R = Z_J\,J_a^\mu \;+\; \partial_\nu\,\mathfrak{I}_a^{[\nu\mu]} \;+\; \mathcal{B}_\Gamma R_a^\mu \;+\; (\mathrm{EOM})_a^\mu,$$

where $\mathfrak{I}_a^{[\nu\mu]}$ is an antisymmetric local tensor (improvement), R_a^μ is a local functional (ghost number -1), and $(\mathrm{EOM})_a^\mu$ denotes terms proportional to $\delta\Gamma/\delta\varphi$ (vanishing in physical matrix elements). Ghost number and G-covariance fix the form of the $\mathcal{B}_\Gamma$ term. No other independent local structure is compatible with conservation and the identities.

(2) Ward identity fixes the normalisation $Z_J=1$. Insert $[J_a^\mu]_R$ into the *renormalised* local Ward identity. In position space,

$$\partial_\mu^{(x)}\langle [J_a^\mu]_R(x)\,\mathcal{O}_1\cdots\mathcal{O}_n\rangle = -i\sum_j \delta^{(d)}(x-x_j)\,\langle \delta_a\mathcal{O}_j\prod_{\ell\neq j}\mathcal{O}_\ell\rangle,$$

with $\{\mathcal{O}_j\}$ BRST-closed, gauge-invariant operator insertions. Taking the divergence of the r.h.s. fixes the coefficient of the contact term uniquely in terms of the *unrenormalised* G-action δ_a (the representation matrices T_a are fixed by the Lie algebra and normalisation of the fields). On the l.h.s., $\partial_\mu(\partial_\nu\mathfrak{I}_a^{[\nu\mu]})=0$, while $\partial_\mu(\mathcal{B}_\Gamma R_a^\mu)$ and $\partial_\mu(\mathrm{EOM})_a^\mu$ give only BRST-exact or EOM contact terms that cancel against source variations and vanish in physical matrix elements.

Therefore the only term that can match the canonical contact terms is $Z_J\,\partial_\mu J_a^\mu$. Since the canonical Ward identity holds *exactly* (anomaly-free), consistency forces

$$Z_J = 1.$$

Any $Z_J \neq 1$ would either rescale the global generators on the r.h.s. (forbidden) or introduce spurious contact terms, violating the Ward identity [91].

(3) Charge algebra excludes multiplicative renormalisation. Define the renormalised charge $Q_{a,R}^{(\lambda_{\rm UV},\ell)} = \int_{\Sigma_t} d\Sigma_\mu\,[J_a^\mu]_R$. Using the equal-time Ward identity one has $[Q_{a,R}^{(\lambda_{\rm UV},\ell)},\,\mathcal{O}] = \delta_a\mathcal{O}$ on BRST-closed $\mathcal{O}$. If $Z_J \neq 1$, then $Q_{a,R}^{(\lambda_{\rm UV},\ell)} = Z_J Q_a^{(\lambda_{\rm UV},\ell)} + \cdots$ and the Lie algebra becomes $[Q_{a,R}, Q_{b,R}] = i f_{ab}{}^c\, Z_J Q_c + \cdots$, or generates a Schwinger term from the dots; both contradict the exact current algebra in the anomaly-free case. Hence $Z_J = 1$ is also required by the charge algebra on the band [82, 91].

(4) RG equation and vanishing anomalous dimension in cohomology. Let $\mathcal{C}$ be the Callan–Symanzik operator acting on renormalised 1PI functionals with an insertion of $[J_a^\mu]_R$. Using $Z_J = 1$ and the QAP,

$$\mathcal{C}\,[J_a^\mu]_R = \mu\frac{d}{d\mu}\,[J_a^\mu]_R = \partial_\nu\,\widetilde{\mathfrak{J}}_a^{[\nu\mu]} \;+\; \mathcal{B}_\Gamma \widetilde{R}_a^\mu \;+\; (\mathrm{EOM})_a^\mu,$$

i.e. the μ-variation of the insertion is, at most, an improvement plus a $\mathcal{B}_\Gamma$-exact and an EOM term (no multiplicative piece). Projecting onto the physical cohomology $H^0(\mathcal{B}_\Gamma)$ and discarding EOM terms (vanishing on $\mathcal{H}_{\rm phys}$) gives

$$\gamma_{J_a}\,[J_a^\mu]_R = 0 \quad \text{in } H^0(\mathcal{B}_\Gamma),$$

hence $\gamma_{J_a} = 0$. This is the precise sense in which the current is non-renormalised: its cohomology class is RG-invariant [117].

(5) Band/IR robustness. Because $P_x(\lambda_{\rm UV})$ and $K_{\rm IR}^{(\ell)}$ commute with BRST and with G, every step above (Ward identity, charge algebra, QAP, cohomology projection) is unchanged by band/IR embedding; surface terms are controlled by the IR window. Therefore the conclusion holds *on the band*.

Combining (1)–(5) proves the proposition. □

Implications for visibilities and plateaus. Because $P_x(\lambda_{\rm UV})$ and $K_{\rm IR}^{(\ell)}$ commute with Q_a and are BRST-closed eq. (7.30), the Ward identities (7.181)–(7.184) hold *on the band* and descend to $\mathcal{H}_{\rm phys}$. Consequently, current insertions are transverse, spectral densities are positive, and channel visibilities built from G-invariant composites inherit gauge/BRST robustness and regulator stability (cf. Sections 7.3.6 and 7.3.7). These exact identities form the baseline against which any symmetry-breaking signals in other quadrants will be contrasted [82, 91, 442, 117].

7.5.9 Slavnov–Taylor Identity and its Linearisation

Definition 7.258 (Slavnov functional and master equation (band-limited))**.** Let Γ be the band-limited 1PI effective action with sources (K_Φ, K_Θ, K_c) for the BRST variations of (Φ, Θ, c), and with antighost/auxiliary pair $(\bar{c}, b)$. Holding the UV/IR knobs fixed (they commute with BRST, cf. (7.145)), the *Slavnov functional* acts on Γ as

$$\boxed{\mathcal{S}(\Gamma) = \int d^dx \left[\frac{\delta\Gamma}{\delta\Phi}\frac{\delta\Gamma}{\delta K_\Phi} + \frac{\delta\Gamma}{\delta\Theta}\frac{\delta\Gamma}{\delta K_\Theta} + \frac{\delta\Gamma}{\delta c}\frac{\delta\Gamma}{\delta K_c} + b\,\frac{\delta\Gamma}{\delta\bar{c}} \right] = 0,} \tag{7.189}$$

which is the Zinn–Justin (Slavnov–Taylor) master equation on the band [117, 442]. The integrand has ghost number $+1$ and the functional $\mathcal{S}(\Gamma)$ vanishes identically in the anomaly-free case.

Definition 7.259 (Linearised Slavnov operator)**.** Around a solution Γ of (7.189), the *linearised* ST operator $\mathcal{B}_\Gamma$ is the graded first-order differential

$$\mathcal{B}_\Gamma = \int d^dx \left[\frac{\delta\Gamma}{\delta\Phi}\frac{\delta}{\delta K_\Phi} + \frac{\delta\Gamma}{\delta K_\Phi}\frac{\delta}{\delta\Phi} + \frac{\delta\Gamma}{\delta\Theta}\frac{\delta}{\delta K_\Theta} + \frac{\delta\Gamma}{\delta K_\Theta}\frac{\delta}{\delta\Theta} + \frac{\delta\Gamma}{\delta c}\frac{\delta}{\delta K_c} + \frac{\delta\Gamma}{\delta K_c}\frac{\delta}{\delta c} + b\,\frac{\delta}{\delta\bar{c}} \right], \tag{7.190}$$

acting on local functionals with well-defined ghost number and statistics [117].

Proposition 7.260 (Antibracket form and nilpotency)**.** *Define the BV antibracket (X, Y) in the $(\Phi, \Theta, c;\, K_\Phi, K_\Theta, K_c)$ sector (band-limited) so that*

$$\mathcal{S}(\Gamma) = \tfrac{1}{2}\,(\Gamma, \Gamma), \qquad \mathcal{B}_\Gamma X = (\Gamma, X).$$

If $\mathcal{S}(\Gamma) = 0$, then $\mathcal{B}_\Gamma^2 = 0$ and $\mathcal{B}_\Gamma$ is a graded derivation of ghost number $+1$:

$$\mathcal{B}_\Gamma^2 X = \tfrac{1}{2}\big((\Gamma, \Gamma), X\big) = 0, \qquad \mathcal{B}_\Gamma(XY) = (\mathcal{B}_\Gamma X)Y + (-1)^{|X|} X(\mathcal{B}_\Gamma Y).$$

Proof. The identities follow from the graded Jacobi identity for the antibracket and $\mathcal{S}(\Gamma) = \frac{1}{2}(\Gamma, \Gamma) = 0$; see [442, 117]. Band/IR knobs commute with the functional derivatives and carry ghost number 0, so they do not affect the algebra. □

Definition 7.261 (Physical cohomology)**.** The space of *physical* (gauge-invariant) composite operators on the band is the ghost-number zero cohomology

$$H^0(\mathcal{B}_\Gamma) := \frac{\ker(\mathcal{B}_\Gamma : \mathcal{F}^0 \to \mathcal{F}^1)}{\mathrm{im}(\mathcal{B}_\Gamma : \mathcal{F}^{-1} \to \mathcal{F}^0)},$$

where $\mathcal{F}^g$ denotes local functionals of ghost number g [117]. Representatives differing by $\mathcal{B}_\Gamma$-exact terms define the same physical matrix elements on $\mathcal{H}_{\mathrm{phys}}$ (quartet decoupling).

Proposition 7.262 (Quantum Action Principle (QAP) and stability)**.** *Suppose $\mathcal{S}(\Gamma) = 0$ (cf. eq. (7.16)) up to order $n-1$ in loops. At order n, any breaking $\Delta^{(n)}$ of ghost number $+1$ fulfils the (linearised) Wess–Zumino consistency condition*

$$\mathcal{B}_{\Gamma^{(0)}}\,\Delta^{(n)} = 0.$$

If the cohomology $H^1(\mathcal{B}_{\Gamma^{(0)}})$ is trivial in the relevant sector (anomaly filters; see Section 7.2.8), there exists a local counterterm $\mathsf{Z}^{(n)}$ with $\mathfrak{g}(\mathsf{Z}^{(n)}) = 0$ such that

$$\Delta^{(n)} = \mathcal{B}_{\Gamma^{(0)}}\, \mathsf{Z}^{(n)}.$$

Adding $-\hbar^n \mathsf{Z}^{(n)}$ (the Wess–Zumino counterterm at loop n, cf. Definition 7.25) restores $\mathcal{S}(\Gamma) = 0$ at order n. Hence the identity is stable *under renormalisation on the band [117].*

Proof. QAP locality and linearised consistency. By the Quantum Action Principle, any breaking at fixed loop order is a *local* insertion with the appropriate quantum numbers. Expanding $\Gamma = \Gamma^{(0)} + \sum_{k\geq 1} \hbar^k \Gamma^{(k)}$ and the Slavnov functional $\mathcal{S}(\Gamma)$ (cf. eq. (7.16)) gives, at order n,

$$\mathcal{S}(\Gamma) = \hbar^n \Delta^{(n)} + \mathcal{O}(\hbar^{n+1}), \qquad \Delta^{(n)} = \mathcal{B}_{\Gamma^{(0)}}\, \Gamma^{(n)} + (\text{known lower-order terms}).$$

Nilpotency of the linearised Slavnov operator $\mathcal{B}_{\Gamma^{(0)}}$ implies $\mathcal{B}_{\Gamma^{(0)}}\, \Delta^{(n)} = 0$, i.e. the linearised Wess–Zumino consistency condition.

Cohomological triviality via anomaly filters. If $H^1(\mathcal{B}_{\Gamma^{(0)}})$ is trivial in the relevant sector (anomaly filters of Section 7.2.8), then the cocycle $\Delta^{(n)}$ is a coboundary: there exists a *local* $\mathsf{Z}^{(n)}$ with $\mathfrak{g}(\mathsf{Z}^{(n)}) = 0$ such that $\Delta^{(n)} = \mathcal{B}_{\Gamma^{(0)}}\, \mathsf{Z}^{(n)}$. In the descent language this matches Definition 7.25, where the order–n anomalous variation is $\zeta\, \mathsf{Z}^{(n)}$ up to a total derivative.

Counterterm restores the identity at order n. Define the renormalised action

$$\Gamma' \;:=\; \Gamma \;-\; \hbar^n \mathsf{Z}^{(n)}.$$

Expanding $\mathcal{S}(\Gamma')$ to order n and using the linearity of the first variation yields

$$\mathcal{S}(\Gamma') \;=\; \mathcal{S}(\Gamma) - \hbar^n\, \mathcal{B}_{\Gamma^{(0)}}\, \mathsf{Z}^{(n)} + \mathcal{O}(\hbar^{n+1}) \;=\; \hbar^n \Delta^{(n)} - \hbar^n \Delta^{(n)} + \mathcal{O}(\hbar^{n+1}) \;=\; \mathcal{O}(\hbar^{n+1}),$$

so the Slavnov identity is restored at order n (cf. eq. (7.16)).

Band/IR compatibility. Since $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with BRST and preserve ghost number (band setting), locality and the above cohomological argument are unchanged on the band (see Section 7.2.8). Thus stability holds in the band framework.

This proves the proposition. □

Proposition 7.263 (Nielsen identity as a $\mathcal{B}_\Gamma$-exact variation)**.** *If the gauge parameter α_{gf} enters only through the gauge fermion $\Psi(\alpha_{\mathrm{gf}})$, then the α_{gf}-variation of Γ is $\mathcal{B}_\Gamma$-exact on the band,*

$$\partial_{\alpha_{\mathrm{gf}}} \Gamma = -\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\mathrm{gf}}} \Psi\Big),$$

so that on-shell, BRST-closed observables (masses, residues, certified visibilities) are gauge-parameter independent [117, 91].

Proof. Differentiate the path integral with respect to α_{gf}; only $\zeta\Psi$ varies. Using the antibracket representation of BRST in the source sector and performing the Legendre transform yields the stated identity; cf. the band versions in Section 7.5.5. □

Corollary 7.264 (Operational consequences)**.** *Assuming $\mathcal{S}(\Gamma) = 0$ and anomaly filters:*

(i) Unphysical modes decouple cohomologically on $\mathcal{H}_{\mathrm{phys}}$ (quartet mechanism), compatibly with Section 7.2.6.

(ii) On-shell poles and holosymmetric visibilities are gauge-parameter independent (Nielsen) [117, 91].

(iii) Renormalisation constants and counterterms satisfy algebraic constraints fixed by $\mathcal{S}(\Gamma)$ (e.g. current non-renormalisation in cohomology), see [117, 91, 82].

All statements hold on the band *since $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with BRST and with functional differentiation* (7.145).

Quantum Action Principle, anomalies, and consistency (formal). All statements below are *on the band*; the UV/IR knobs commute with BRST and carry ghost number 0, cf. (7.145). We use the antibracket form $\mathcal{S}(\Gamma) = \frac{1}{2}(\Gamma, \Gamma)$ and the linearised operator $\mathcal{B}_\Gamma X = (\Gamma, X)$.

Proposition 7.265 (QAP breaking and Wess–Zumino consistency on the band)**.** *Let $\Gamma = \sum_{\ell \geq 0} \hbar^\ell \Gamma^{(\ell)}$ with $\mathcal{S}(\Gamma^{(0)}) = 0$. At loop order $n \geq 1$, the Quantum Action Principle implies a* local *breaking $\Delta^{(n)}$ of ghost number $+1$ such that*

$$\mathcal{S}(\Gamma) = \hbar^n \, \Delta^{(n)} + \mathcal{O}(\hbar^{n+1}), \qquad \mathcal{B}_{\Gamma^{(0)}} \, \Delta^{(n)} = 0, \tag{7.191}$$

i.e. $\Delta^{(n)}$ is a BRST cocycle (Wess–Zumino consistency) [117, 442].

Proof. Expand $\mathcal{S}(\Gamma) = \frac{1}{2}(\Gamma, \Gamma)$ in powers of $\hbar$. The coefficient at order $\hbar^n$ reads

$$\sum_{k=0}^{n} (\Gamma^{(k)}, \Gamma^{(n-k)}) = 2\,(\Gamma^{(0)}, \Gamma^{(n)}) + \sum_{k=1}^{n-1} (\Gamma^{(k)}, \Gamma^{(n-k)}).$$

Define $\Delta^{(n)} := \frac{1}{2} \sum_{k=1}^{n-1} (\Gamma^{(k)}, \Gamma^{(n-k)})$, which is local by the QAP. Then $(\Gamma^{(0)}, \Gamma^{(n)}) = \Delta^{(n)}$, i.e. $\mathcal{B}_{\Gamma^{(0)}} \Gamma^{(n)} = \Delta^{(n)}$. Apply $\mathcal{B}_{\Gamma^{(0)}}$ and use the graded Jacobi identity with $(\Gamma^{(0)}, \Gamma^{(0)}) = 0$ to obtain $\mathcal{B}_{\Gamma^{(0)}} \Delta^{(n)} = 0$. Band/IR operations commute with the functional derivatives entering the antibracket and preserve locality, hence the same derivation holds on the band [117]. □

Proposition 7.266 (All-order restoration under anomaly filters)**.** *If the anomaly filters hold so that $H^1(\mathcal{B}_{\Gamma^{(0)}}) = 0$ in the relevant sector, then the breaking $\Delta^{(n)}$ is $\mathcal{B}_{\Gamma^{(0)}}$-exact:*

$$\Delta^{(n)} = \mathcal{B}_{\Gamma^{(0)}} \, \widehat{\Sigma}^{(n)} \quad \Rightarrow \quad \Gamma \;\mapsto\; \Gamma - \hbar^n \widehat{\Sigma}^{(n)} \;\; \textit{restores} \;\; \mathcal{S}(\Gamma) = 0 \;\textit{at order } n. \tag{7.192}$$

By induction, $\mathcal{S}(\Gamma) = 0$ can be imposed to all orders (algebraic renormalisation) [117, 442].

Proof. Triviality of H^1 implies existence of a local $\widehat{\Sigma}^{(n)}$ with the stated property. Adding $-\hbar^n \widehat{\Sigma}^{(n)}$ shifts $\Gamma^{(n)}$ by a solution of the inhomogeneous equation $\mathcal{B}_{\Gamma^{(0)}} \Gamma^{(n)} = \Delta^{(n)}$, cancelling the breaking at order n. Proceed by induction in n; the QAP ensures locality at each step. □

Cohomological classification of counterterms (formal).

Proposition 7.267 (Counterterms as BRST cohomology)**.** *Let Σ_{ct} be a local counterterm of ghost number 0. Requiring the renormalised action $\Gamma' = \Gamma + \epsilon\,\Sigma_{\mathrm{ct}}$ to satisfy the ST identity to first order in ϵ yields*

$$\mathcal{B}_\Gamma\,\Sigma_{\mathrm{ct}} = 0, \qquad \Sigma_{\mathrm{ct}} \sim \Sigma_{\mathrm{ct}} + \mathcal{B}_\Gamma X, \tag{7.193}$$

so admissible counterterms are classes in $H^0(\mathcal{B}_\Gamma)$, modulo BRST-exact redefinitions [117]. On the band, this cohomology is generated by the G-invariant kinetic pairings and interaction monomials compatible with eqs. (6.333) and (6.334).

Proof. Insert Γ' into $\mathcal{S}(\cdot)$ and expand to $\mathcal{O}(\epsilon)$:

$$0 = \mathcal{S}(\Gamma') = \mathcal{S}(\Gamma) + \epsilon\,\mathcal{B}_\Gamma\Sigma_{\mathrm{ct}} + \mathcal{O}(\epsilon^2) = \epsilon\,\mathcal{B}_\Gamma\Sigma_{\mathrm{ct}} + \cdots,$$

since $\mathcal{S}(\Gamma) = 0$. Thus $\mathcal{B}_\Gamma\Sigma_{\mathrm{ct}} = 0$. If $\Sigma_{\mathrm{ct}} \to \Sigma_{\mathrm{ct}} + \mathcal{B}_\Gamma X$, then $\mathcal{B}_\Gamma\Sigma_{\mathrm{ct}}$ is unchanged (nilpotency), and the change corresponds to a BRST-exact field redefinition that leaves physical matrix elements invariant. Band/IR commutation ensures the same algebraic steps apply. □

Remark 7.268 (Practical reduction of renormalisations)**.** The classification (7.193) reduces independent renormalisations to a small basis of cohomology representatives (invariant kinetic terms, gauge-invariant potentials, etc.), while gauge-fixing and BRST-exact pieces are in the trivial class. This underlies the stability results and the non-renormalisation statements used throughout (e.g. current protection, Nielsen gauge-parameter independence) [117, 91].

Vertex-level consequences and Z-factor relations. Differentiating the master equation (7.189) with respect to appropriate fields and sources, then setting sources to zero at the G-symmetric vacuum, generates the tower of Slavnov–Taylor relations among amputated 1PI kernels. In compact notation,

$$\mathcal{B}_\Gamma\,\Gamma^{(3)} \;=\; \Gamma^{(2)} \star \Gamma^{(3)} \;+\; \cdots, \tag{7.194}$$

where $\star$ denotes the standard index contraction and convolution with propagators and group factors, and the ellipsis collects additional terms from field mixing and source insertions fixed by (7.189) (see [117, 91, 82]).

Proposition 7.269 (Slavnov–Taylor constraints on renormalisation constants)**.** *Assume a multiplicatively renormalisable scheme with field renormalisations $\varphi_i^B = Z_i^{1/2}\,\varphi_i$, two-point kernels $\Gamma_i^{(2)B} = Z_{\Gamma_i^{(2)}}\,\Gamma_i^{(2)}$, and an m-leg 1PI vertex $\Gamma^{(m)B} = Z_{\Gamma^{(m)}}\,\Gamma^{(m)}$. Let Z_{int} denote the renormalisation of the corresponding (gauge-/BRST-invariant) interaction monomial in the action. Then the differentiated ST identities implied by (7.194) yield algebraic relations of the form*

$$Z_{\mathrm{int}} \;=\; \frac{Z_{\Gamma^{(3)}}}{\prod_i Z_{\Gamma_i^{(2)}}^{\alpha_i}}, \qquad \sum_i \alpha_i = \tfrac{1}{2}\,m, \tag{7.195}$$

with exponents α_i fixed by leg counting and field normalisations. In particular, for a cubic vertex built from fields $(\varphi_A, \varphi_B, \varphi_C)$ one recovers the familiar structure $Z_{\Gamma^{(3)}} = Z_{\mathrm{int}}\,Z_A^{1/2}Z_B^{1/2}Z_C^{1/2}$, and analogously for higher-point kernels once reduced by ST identities [117, 91, 82].

Sketch. Apply functional derivatives $\delta/\delta\varphi_{i_1}\cdots\delta/\delta\varphi_{i_m}$ to (7.189) and set sources to zero at the symmetric vacuum. The resulting identities express $\Gamma^{(m)}$ in terms of $\Gamma^{(2)}$ and lower vertices with fixed group-theoretic tensors. Passing to bare versus renormalised quantities and using multiplicativity, the identities can only be preserved if the overall Z-factors satisfy (7.195). The sum rule $\sum_i \alpha_i = m/2$ follows from canonical dimension/leg counting of amputated kernels. For explicit gauges (e.g. Yang–Mills), this reproduces standard relations such as $Z_g = Z_1\, Z_3^{-3/2}$, $Z_{\bar{1}} = Z_g\, Z_3^{1/2} Z_c$ for ghost–gluon, etc. [82, 91]; the abstract cohomological derivation ensures the same algebraic pattern in our setting [117]. □

Band/IR compatibility and descent to $\mathcal{H}_{\text{phys}}$.

Proposition 7.270 (Band/IR compatibility of ST identities and cohomology)**.** *If $P_x(\lambda_{\text{UV}})$ and $K_{\text{IR}}^{(\ell)}$ commute with $\hat{Q}_{\text{BRST}}$ and have ghost number* 0 (7.145)*, then the master equation* (7.189)*, its linearisation* (7.190)*, and all vertex-level consequences (including* (7.194)*–*(7.195)*) hold verbatim* on the band*. Moreover, by quartet decoupling, physical matrix elements depend only on the classes in $H^0(\mathcal{B}_\Gamma)$ on $\mathcal{H}_{\text{phys}}$ (cf. Section 7.2.6 and [117]).*

Proof. Band/IR operations commute with functional differentiation and preserve locality and ghost number. Therefore they can be pulled through the derivation of (7.189) and of its differentiated consequences; cohomology statements are unchanged because $\mathcal{B}_\Gamma$ is unaffected by multiplication with band/IR projectors of ghost number 0. □

Remark (Nielsen identity as an ST corollary). Promoting the gauge parameter α_{gf} to a BRST doublet and differentiating (7.189) yields the Nielsen master identity, i.e. $\partial_{\alpha_{\text{gf}}}\Gamma = -\,\mathcal{B}_\Gamma(\partial_{\alpha_{\text{gf}}}\Psi)$, hence on-shell, BRST-closed observables (masses, residues, certified visibilities) are α_{gf}-independent [117, 91]. In our band-limited setting, the same conclusion holds by (7.145).

7.5.10 BRST Charge, Nilpotency, and Equivalence Theorem

Definition 7.271 (BRST charge and physical Hilbert space)**.** Let $\hat{Q}_{\text{BRST}}$ be the conserved, Hermitian BRST charge on the (indefinite-metric) state space such that

$$\hat{Q}_{\text{BRST}}^2 = 0, \qquad [\hat{Q}_{\text{BRST}}, \hat{H}_0(t)] = 0, \qquad \hat{Q}_{\text{BRST}}^\dagger = \hat{Q}_{\text{BRST}}, \tag{7.196}$$

with $\hat{H}_0(t) = \int d^d x\, \hat{\mathcal{H}}_0(t,x)$ the symmetric-law Hamiltonian. The *physical* Hilbert space is the ghost-number 0 cohomology

$$\mathcal{H}_{\text{phys}} \;\cong\; \ker \hat{Q}_{\text{BRST}}/\text{im}\, \hat{Q}_{\text{BRST}}, \qquad \mathsf{P}_{\text{phys}} :\ \text{orthogonal projector onto } \ker \hat{Q}_{\text{BRST}}.$$

On $\mathcal{H}_{\text{phys}}$, positivity and unitarity are recovered by the quartet mechanism (decoupling of BRST doublets) and the Källén–Lehmann representation with positive spectral measure [442, 117, 91, 241].

Proposition 7.272 (Conservation and cohomology-preserving evolution)**.** *Let $U_0(t_2,t_1)$ be the unitary propagator generated by $\hat{H}_0(t)$. If $[\hat{Q}_{\mathrm{BRST}},\hat{H}_0(t)]=0$ for all t, then*

$$[\hat{Q}_{\mathrm{BRST}},U_0(t_2,t_1)]=0,$$
$$U_0(t_2,t_1):\ \ker\hat{Q}_{\mathrm{BRST}}\to\ker\hat{Q}_{\mathrm{BRST}},$$
$$U_0(t_2,t_1):\ \operatorname{im}\hat{Q}_{\mathrm{BRST}}\to\operatorname{im}\hat{Q}_{\mathrm{BRST}}.$$

Hence time evolution preserves BRST cohomology classes, and U_0 descends unitarily to $\mathcal{H}_{\mathrm{phys}}$.

Proof. Differentiate $U_0^\dagger Q U_0$ with respect to time and use $i\partial_t U_0=\hat{H}_0U_0$, then $d(U_0^\dagger QU_0)/dt=U_0^\dagger i[\hat{H}_0,Q]U_0=0$. The two stability statements follow from $QU_0=U_0Q$. □

Proposition 7.273 (Decoupling of BRST-exact insertions)**.** *Let $|\psi\rangle,|\phi\rangle\in\ker\hat{Q}_{\mathrm{BRST}}$ be physical states and $\hat{X}$ any (graded) operator. Then*

$$\langle\psi|\ \{\hat{Q}_{\mathrm{BRST}},\hat{X}\}\ |\phi\rangle=0,$$

so BRST-exact insertions vanish between physical states. In particular, S-matrix elements between physical asymptotic states are invariant under $\hat{\mathcal{H}}_0\mapsto\hat{\mathcal{H}}_0+\{\hat{Q}_{\mathrm{BRST}},\hat{Y}\}$ (cohomological robustness).

Proof. Use $(\hat{Q}_{\mathrm{BRST}})^\dagger=\hat{Q}_{\mathrm{BRST}}$ and $\hat{Q}_{\mathrm{BRST}}|\psi\rangle=\hat{Q}_{\mathrm{BRST}}|\phi\rangle=0$ to write $\langle\psi|\{\hat{Q},\hat{X}\}|\phi\rangle=\langle\psi|\hat{Q}\hat{X}|\phi\rangle+\langle\psi|\hat{X}\hat{Q}|\phi\rangle=0$. For the Hamiltonian deformation, Dyson-expand the time-ordered exponential; each term brings one insertion of a BRST anticommutator, which vanishes by the same argument. □

Definition 7.274 (Band/IR compatibility of the BRST charge)**.** Let $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ be the UV projector and IR window. Assume they are BRST-closed and ghost-number 0,

$$[\hat{Q}_{\mathrm{BRST}},P_x(\lambda_{\mathrm{UV}})]=0,\qquad\zeta\Big(K_{\mathrm{IR}}^{(\ell)}*\,\cdot\,\Big)=0,$$

as recalled in (7.145). Then the *band-limited* charge $Q^{(\lambda_{\mathrm{UV}},\ell)}:=P_xQP_x$ acts on the same physical cohomology and commutes with the band-limited symmetric evolution generated by $H_0^{(\lambda_{\mathrm{UV}},\ell)}$.

Proposition 7.275 (Equivalence theorem: BRST-exact deformations and field redefinitions)**.** *Consider the band-limited 1PI action Γ satisfying the Slavnov identity $\mathcal{S}(\Gamma)=0$ (7.189).*

*(i) (*BRST-exact deformations*) If $\Gamma\mapsto\Gamma'=\Gamma+\epsilon\,\mathcal{B}_\Gamma X$ with a local X (ghost number -1), then on-shell S-matrix elements of BRST-closed, gauge-invariant operators are unchanged.*

*(ii) (*Local field redefinitions*) If $\varphi\mapsto\varphi'=\varphi+\epsilon\,F(\varphi)$ is a local, invertible redefinition that preserves the asymptotic LSZ structure, then physical S-matrix elements are invariant. If $F=\mathcal{B}_\Gamma Y$ is BRST-exact, the statement follows from (i).*

Proof. (i) Using the antibracket form of the Slavnov identity (linearised BRST) one has $\delta\Gamma = \epsilon\,\mathcal{B}_\Gamma X$. Differentiating Green's functions with respect to ϵ inserts $\mathcal{B}_\Gamma X$, i.e. BRST-exact operators. After LSZ amputation and restricting to external BRST-closed asymptotic states, these insertions vanish by Proposition 7.273 (or, equivalently, by the Nielsen/Slavnov argument that $\mathcal{B}_\Gamma$-exact variations are EOM-proportional on shell) [117, 442, 91].
(ii) The standard equivalence theorem applies: local invertible redefinitions change only contact terms and wavefunction factors that cancel in properly normalised S-matrix elements; see [91]. If the redefinition is of BRST-exact type, it reduces to (i). □

Corollary 7.276 (Gauge-parameter/Nielsen invariance as a special case)**.** *If the gauge parameter α_{gf} enters only via the gauge fermion $\Psi(\alpha_{\mathrm{gf}})$, then*

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\big(\partial_{\alpha_{\mathrm{gf}}}\Psi\big),$$

so on-shell physical poles, residues, and certified visibilities are independent of α_{gf} (Nielsen identity on the band; cf. Section 7.5.5) [117, 91].

Remark 7.277 (Implications for the holosymmetric probe)**.** Because all ingredients of the probe (band-limited preparations, sector projectors, and controlled evolutions) commute with $\hat{Q}_{\mathrm{BRST}}$ and are BRST-closed on $\mathcal{H}_{\mathrm{phys}}$, Propositions 7.272–7.275 ensure that the channel visibilities are (i) insensitive to BRST-exact branches in the law channel, (ii) invariant under gauge-parameter changes (Nielsen), and (iii) stable under admissible regulator variations that preserve the cohomology class, as used throughout Section 7.4.

Equivalence theorem (BRST-exact deformations).

Theorem 7.278 (Equivalence theorem for BRST-exact deformations (band-limited))**.** *Consider the one-parameter family*

$$S_s[\varphi] = S[\varphi] + s\,\zeta\mathcal{X}[\varphi], \qquad s \in \mathbb{R},$$

with $\mathcal{X}$ local and band-limited, and let (Z_s, W_s, Γ_s) be the corresponding generating and 1PI functionals constructed with fixed UV/IR knobs (which commute with BRST and have ghost number 0, cf. (7.145)). Assume: (i) $\mathcal{S}(\Gamma_s) = 0$ (anomaly filters), (ii) the QAP applies, and (iii) LSZ asymptotics exist for the physical sector. Then there exists a local ghost-number -1 functional $\widehat{\mathcal{X}}_s$ such that

$$\frac{d}{ds}\,\Gamma_s = \mathcal{B}_{\Gamma_s}\,\widehat{\mathcal{X}}_s, \tag{7.197}$$

i.e. the s-variation of Γ_s is BRST-exact in the linearised cohomology. Consequently, for any set of physical insertions $\{\mathcal{O}_i\} \subset H^0(\mathcal{B}_{\Gamma_s})$,

$$\frac{d}{ds}\,\mathcal{M}_s(\mathcal{O}_1, \ldots, \mathcal{O}_n) = 0, \qquad \Rightarrow \quad \mathcal{S} \text{ and all } \mathcal{H}_{\mathrm{phys}} \text{ matrix elements are invariant.} \tag{7.198}$$

All statements hold on the band.

Proof. Differentiate Z_s with respect to s:

$$\frac{d}{ds}Z_s = \int \mathcal{D}\varphi\, (i\,\zeta\mathcal{X})\, e^{iS_s}, \qquad \frac{d}{ds}W_s = \langle \zeta\mathcal{X}\rangle_s.$$

Introduce band-limited sources $(\mathcal{J},\mathcal{K})$ for fields and their BRST variations (cf. Section 7.5.1) and perform the Legendre transform at fixed $\mathcal{K}$. Using the Slavnov master equation in antibracket/linearised form and the QAP, one obtains the standard algebraic–renormalisation result

$$\frac{d}{ds}\,\Gamma_s = -\,\mathcal{B}_{\Gamma_s}\Big[\partial_\epsilon \widehat{\mathcal{X}}_{s,\epsilon}\Big]_{\epsilon=0} \equiv \mathcal{B}_{\Gamma_s}\,\widehat{\mathcal{X}}_s,$$

with $\widehat{\mathcal{X}}_s$ local of ghost number -1; see [117, 91, 442]. Amputating external legs and applying on-shell LSZ to correlators with $\{\mathcal{O}_i\} \subset H^0(\mathcal{B}_{\Gamma_s})$ inserts a $\mathcal{B}_{\Gamma_s}$-exact operator, which vanishes between BRST-closed asymptotic states by cohomological decoupling (quartet mechanism) or, equivalently, because $\mathcal{B}_{\Gamma_s}$-exact variations reduce to EOM insertions on shell. Thus $d\mathcal{M}_s/ds = 0$, proving (7.198). Band/IR commutation guarantees all steps carry over unchanged on the band. □

Remark 7.279. If the anomaly filters fail so that $\mathcal{S}(\Gamma_s) \neq 0$, the QAP breaking $\Delta^{(n)}$ (ghost number $+1$) may obstruct (7.197) (cf. Proposition 7.265); in that case the deformation can affect physical amplitudes.

Operational corollaries for the holosymmetric probe.

Corollary 7.280 (Operational corollaries for the holosymmetric probe)**.** *Work on the band with BRST-closed knobs and assume the hypotheses of Theorem 7.278.*

(i) Law-branch invariance.
In Section 7.4.2 the two law branches differ by a BRST-exact deformation of the generator, $H_0 \mapsto H_0 + \zeta\Delta G$. By Theorem 7.278,

$$\frac{d}{ds}\,\Gamma_s = \mathcal{B}_{\Gamma_s}\,\widehat{\mathcal{X}}_s \quad\Longrightarrow\quad \frac{d}{ds}\,\mathcal{M}_s = 0$$

for any physical insertion; hence the branch difference cancels on $\mathcal{H}_{\mathrm{phys}}$ in the anomaly-free case, yielding the on-shell equalities at certified symmetry points

$$\mathcal{C}_{\mathrm{law}} = 1, \qquad \Lambda^{\star}_{\mathrm{law}} = 1,$$

as stated in eq. (7.121) and Section 7.4.4.

(ii) Gauge-parameter (Nielsen) independence.
Promote the gauge parameter α_{gf} to a BRST doublet and apply the same cohomological argument to the deformation $S \mapsto S + \delta\alpha_{\mathrm{gf}}\,\zeta(\partial_{\alpha_{\mathrm{gf}}}\Psi)$. Then

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma = -\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi\Big),$$

so on-shell, BRST-closed observables (poles, residues, and certified visibilities) are α_{gf}-independent (Nielsen identity on the band; cf. Section 7.2.9 and [117, 91]).

(iii) Anomaly sensitivity.
If the anomaly filters fail (Section 7.2.8), the loop-breaking $\Delta^{(n)}$ in (7.191) may represent a nontrivial class in $H^1(\mathcal{B}_{\Gamma^{(0)}})$ [117, 442]. Then the variation $\frac{d}{ds}\Gamma_s = \mathcal{B}_{\Gamma_s}\widehat{\mathcal{X}}_s$ need not be cohomologically trivial on shell, the conclusion of (7.198) can fail, and robust suppressions $|\mathcal{C}_{\mathrm{law}}| < 1$ become lawful diagnostics of symmetry violation (cf. Section 7.4.4).

Proof. (i) Apply Theorem 7.278 with the deformation generated by $\zeta\Delta G$; physical amplitudes are s-independent, hence the two branches are indistinguishable on $\mathcal{H}_{\mathrm{phys}}$. (ii) Set the deformation to $\zeta(\partial_{\alpha_{\mathrm{gf}}}\Psi)$ and invoke the Nielsen identity (band version), derived as a $\mathcal{B}_\Gamma$-exact variation; on shell, BRST-closed observables are invariant [117, 91]. (iii) Use Proposition 7.265: if $H^1(\mathcal{B}_{\Gamma^{(0)}}) \neq 0$, the breaking cannot be removed by a counterterm, so the BRST-exactness needed for invariance may fail; deviations in $\mathcal{C}_{\mathrm{law}}$ are then physically meaningful. □

Band/IR consistency and conservation.

Proposition 7.281 (Band/IR consistency and BRST conservation)**.** *Let $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ be the UV projector and IR window satisfying*

$$[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = 0, \qquad \zeta\Big(K_{\mathrm{IR}}^{(\ell)} * \cdot\Big) = 0 \quad \textit{(cf. (7.145)).}$$

Let $\hat{H}_0^{(\lambda_{\mathrm{UV}},\ell)}(t)$ be the band/IR-embedded symmetric Hamiltonian (cf. Section 7.4.3). Then

$$[\hat{Q}_{\mathrm{BRST}},\, \hat{H}_0^{(\lambda_{\mathrm{UV}},\ell)}(t)] = 0 \quad\Longrightarrow\quad \frac{d}{dt}\,\hat{Q}_{\mathrm{BRST}}(t) = i\,[\hat{H}_0^{(\lambda_{\mathrm{UV}},\ell)}(t), \hat{Q}_{\mathrm{BRST}}] = 0, \tag{7.199}$$

and the corresponding unitary propagator $U_0^{(\lambda_{\mathrm{UV}},\ell)}(t_2,t_1)$ preserves BRST cohomology classes. Consequently, all algebraic statements used in the equivalence theorem (Slavnov identity, linearisation, QAP locality) commute with the band/IR embedding, and Theorem 7.278 applies verbatim *to the holosymmetric probe constructed on the band.*

Proof. By construction (band/IR embedding of Section 7.4.3) the Hamiltonian density is obtained from its unbanded form by left/right multiplication with $P_x(\lambda_{\mathrm{UV}})$ and convolution with $K_{\mathrm{IR}}^{(\ell)}$, both BRST-closed and of ghost number 0. Since $[\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{H}}_0] = 0$ for the symmetric law, BRST-closure of the knobs implies $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_0^{(\lambda_{\mathrm{UV}},\ell)}] = 0$, yielding (7.199). The standard argument $d(U^\dagger Q U)/dt = U^\dagger i[\hat{H}_0^{(\lambda_{\mathrm{UV}},\ell)}, Q]U = 0$ shows $[Q, U_0^{(\lambda_{\mathrm{UV}},\ell)}] = 0$, hence stability of $\ker Q$ and $\operatorname{im} Q$ and preservation of cohomology. Because the knobs commute with BRST and functional differentiation, the derivations of the Slavnov–Taylor identity, its linearisation $\mathcal{B}_\Gamma$, and the QAP remain unchanged on the band [117, 442, 91]. Therefore Theorem 7.278 (and its operational corollaries) holds for the band-limited holosymmetric probe. □

Bibliography note. See [117] for the algebraic (BRST) proof of the equivalence theorem and [442, 91] for complementary treatments. For historical context on field-redefinition invariance, see Kamefuchi–O'Raifeartaigh–Salam (1961).

7.5.11 Nielsen Identities at the Symmetry Point

Definition 7.282 (Gauge-parameter BRST doublet and band/IR commutation)**.** Let $\alpha_{\rm gf}$ be a gauge-fixing parameter that appears only through the BRST-exact gauge-fermion term $\zeta\Psi(\alpha_{\rm gf})$. Promote it to a BRST doublet

$$\zeta\,\alpha_{\rm gf} = \chi, \qquad \zeta\,\chi = 0,$$

and recall the band/IR commutation with BRST,

$$[\hat{Q}_{\rm BRST}, P_x(\lambda_{\rm UV})] = 0, \qquad \zeta\Big(K^{(\ell)}_{\rm IR} * \,\cdot\,\Big) = 0, \tag{7.200}$$

so that UV projection and IR smearing carry ghost number 0 and commute with the BRST differential.

Theorem 7.283 (Nielsen (gauge-parameter) master identity on the band)**.** *Let Γ be the band-limited 1PI functional, defined at fixed antifield/source multiplet $\mathcal{K}$ and satisfying the Slavnov identity $\mathcal{S}(\Gamma) = 0$ (anomaly-free case). Then*

$$\boxed{\frac{\partial\Gamma}{\partial\alpha_{\rm gf}} = \int d^dx\, \frac{\delta\Gamma}{\delta\varphi^A(x)}\,\mathcal{N}^A(x;\alpha_{\rm gf}) \equiv \Big\langle \zeta\,\partial_{\alpha_{\rm gf}}\Psi\Big\rangle_\Gamma \cdot \frac{\delta\Gamma}{\delta\varphi}\,,}\tag{7.201}$$

where $\varphi = (\Phi, \Theta, c, \bar{c}, b)$, the dot denotes the band/IR-smeared pairing, and

$$\mathcal{N}^A(x;\alpha_{\rm gf}) \;:=\; -\,\frac{\delta}{\delta K_A(x)}\Big(\partial_{\alpha_{\rm gf}}\Psi\Big) \quad \textit{(linearised/antibracket form).} \tag{7.202}$$

Equivalently,

$$\frac{\partial\Gamma}{\partial\alpha_{\rm gf}} = -\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\rm gf}}\Psi\Big), \tag{7.203}$$

with $\mathcal{B}_\Gamma$ the linearised Slavnov operator. All statements hold on the band.

Sketch. Extend the field content by the BRST doublet $(\alpha_{\rm gf}, \chi)$ and consider the band-limited generating functional with sources $(\mathcal{J}, \mathcal{K})$ as in Section 7.5.1. The master equation $\mathcal{S}(\Gamma) = 0$ (band version of eq. (7.189)) remains valid because the knobs commute with BRST and have ghost number 0. Differentiate the functional integral with respect to $\alpha_{\rm gf}$ at fixed $\mathcal{K}$; only the gauge-fermion changes, producing the insertion $\zeta(\partial_{\alpha_{\rm gf}}\Psi)$. Passing to the 1PI functional and using the Quantum Action Principle together with the antibracket form of the Slavnov identity yields (7.203) (see [117]; [91]). Expanding the linearised operator gives (7.201) with the kernel (7.202). Band/IR commutation (7.200) ensures no extra terms arise from the knobs. □

Corollary 7.284 (On-shell gauge-parameter independence)**.** *Let $\mathcal{O}$ be a BRST-closed, gauge-invariant composite in $H^0(\mathcal{B}_\Gamma)$. Then the variation (7.201) is proportional to the equations of motion $\delta\Gamma/\delta\varphi^A$ and hence vanishes on shell. In particular, physical poles, residues, and certified holosymmetric visibilities (constructed from BRST-closed inputs) are $\alpha_{\rm gf}$-independent at the symmetry point in Quadrant I [117, 91].*

Remark 7.285 (Forms of the identity)**.** Equation (7.201) is the "equation-of-motion" (EOM) form; (7.203) is the linearised/antibracket form. The expectation-value notation in (7.201) uses the 1PI insertion map induced by Γ (at fixed $\mathcal{K}$). All forms are equivalent and commute with band/IR embedding by (7.200).

Two-point kernels and pole masses — formal treatment

Definition 7.286 (Transverse (physical) two-point kernel)**.** Let $\Gamma^{(2)}(p;\alpha_{\mathrm{gf}})$ be the 1PI two-point kernel in momentum space. With the longitudinal/transverse projectors $\Pi_{\mathrm{L}},\Pi_{\mathrm{T}}$ from Section 7.3.5, define the physical (transverse) block

$$\Gamma^{(2)}_{\mathrm{TT}}(p^2;\alpha_{\mathrm{gf}}) := \Pi_{\mathrm{T}}\,\Gamma^{(2)}(p;\alpha_{\mathrm{gf}})\,\Pi_{\mathrm{T}}, \qquad \Pi_{\mathrm{L}}\,\Gamma^{(2)}\,\Pi_{\mathrm{T}} = 0 \ \text{ on } \mathcal{H}_{\mathrm{phys}}. \tag{7.204}$$

Lemma 7.287 (Projected Nielsen identity for two-point kernels)**.** *Let Γ satisfy the band Nielsen master identity (7.201). Differentiating twice with respect to fields and projecting with Π_{T} yields*

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma^{(2)}_{\mathrm{TT}}(p^2) = \mathcal{C}(p^2;\alpha_{\mathrm{gf}})\,\Gamma^{(2)}_{\mathrm{TT}}(p^2) + \Gamma^{(2)}_{\mathrm{TT}}(p^2)\,\mathcal{C}^{\dagger}(p^2;\alpha_{\mathrm{gf}}), \tag{7.205}$$

where $\mathcal{C}$ is a local matrix functional built from 1PI insertions involving the Nielsen kernel $\mathcal{N}^A = \left\langle \zeta\,\partial_{\alpha_{\mathrm{gf}}}\Psi \right\rangle_\Gamma$ (cf. (7.202)). Equation (7.205) holds on the band.

Sketch. Differentiate (7.201) functionally with respect to the fields (twice) at vanishing sources; use the Quantum Action Principle to organise the result as a sum of local 1PI insertions. The terms proportional to $\delta\Gamma/\delta\varphi$ generate factors of $\Gamma^{(2)}$; after projection with Π_{T}, longitudinal pieces drop out on $\mathcal{H}_{\mathrm{phys}}$, leaving the bilinear form (7.205). See [117] and [91]. □

Proposition 7.288 (Gauge-parameter independence of pole masses)**.** *Let $-m_i^2(\lambda_{\mathrm{UV}},\ell)$ be a simple physical pole of the transverse 1PI kernel, i.e. there exists a nonzero vector v_i such that*

$$\Gamma^{(2)}_{\mathrm{TT}}(-m_i^2)\,v_i = 0, \qquad v_i^{\dagger}\,\Gamma^{(2)\prime}_{\mathrm{TT}}(-m_i^2)\,v_i \neq 0, \tag{7.206}$$

where $' = \partial/\partial p^2$. Then, on $\mathcal{H}_{\mathrm{phys}}$ and on the band,

$$\boxed{\partial_{\alpha_{\mathrm{gf}}}\, m_i^2(\lambda_{\mathrm{UV}},\ell) = 0.} \tag{7.207}$$

Proof. Differentiate (7.206) with respect to α_{gf}:

$$\left(\partial_{\alpha_{\mathrm{gf}}}\Gamma^{(2)}_{\mathrm{TT}}\right)(-m_i^2)\,v_i - \left(\partial_{\alpha_{\mathrm{gf}}}m_i^2\right)\Gamma^{(2)\prime}_{\mathrm{TT}}(-m_i^2)\,v_i = 0.$$

Left-multiply by $v_i^{\dagger}$ and insert (7.205) at $p^2 = -m_i^2$:

$$v_i^{\dagger}\Big[\mathcal{C}\,\Gamma^{(2)}_{\mathrm{TT}} + \Gamma^{(2)}_{\mathrm{TT}}\,\mathcal{C}^{\dagger}\Big]v_i - \left(\partial_{\alpha_{\mathrm{gf}}}m_i^2\right) v_i^{\dagger}\Gamma^{(2)\prime}_{\mathrm{TT}}v_i = 0.$$

By $\Gamma^{(2)}_{\mathrm{TT}}(-m_i^2)\,v_i = 0$ and $v_i^{\dagger}\Gamma^{(2)}_{\mathrm{TT}}(-m_i^2) = 0$, the first bracket vanishes. Using the simple-pole assumption, $v_i^{\dagger}\Gamma^{(2)\prime}_{\mathrm{TT}}(-m_i^2)v_i \neq 0$, we conclude $\partial_{\alpha_{\mathrm{gf}}}m_i^2 = 0$. This is the band/IR version of the standard Nielsen result [91]; see also [117]. □

Remark 7.289 (Residues and wavefunction factors)**.** Equation (7.207) constrains pole *positions*. Residues (wavefunction factors) can be gauge-parameter dependent; physical S-matrix elements remain gauge independent once LSZ and proper normalisations are applied (Nielsen identity at the level of amputated Green's functions) [117, 91]. Band/IR commutation with BRST ensures the same statements on $\mathcal{H}_{\mathrm{phys}}$.

Nielsen protection for Holosymmetric visibilities.

Proposition 7.290 (Nielsen protection for holosymmetric visibilities)**.** *Let the holosymmetric readout be*

$$\mathcal{C}_\alpha(\lambda_{\mathrm{UV}},\ell;T)=\frac{\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\,U_1\,\rho\,U_0^\dagger\,\mathsf{P}_{\mathrm{phys}}\Big)}{\mathrm{Tr}\Big(\mathsf{P}_{\mathrm{phys}}\rho\Big)},\qquad \Lambda_\alpha=\mathrm{Re}\Big(e^{-i\phi_\alpha}\mathcal{C}_\alpha\Big),$$

with band/IR-embedded, BRST-compatible branches $U_{0,1}$ and physical, band-limited ρ (Section 7.4.1 and eq. (7.145)). Assume the band Slavnov identity $\mathcal{S}(\Gamma)=0$ and the Nielsen master identity (7.201). Then

$$\partial_{\alpha_{\mathrm{gf}}}\mathcal{C}_\alpha=\Big\langle\mathcal{O}_\alpha\cdot\zeta\,\partial_{\alpha_{\mathrm{gf}}}\Psi\Big\rangle_{\mathcal{H}_{\mathrm{phys}}}+\Big\langle\mathcal{J}_\alpha\cdot\frac{\delta\Gamma}{\delta\varphi}\Big\rangle_{\mathcal{H}_{\mathrm{phys}}},\tag{7.208}$$

for some local, band-limited composites $\mathcal{O}_\alpha,\mathcal{J}_\alpha$ determined by the functional dependence of $U_{0,1}$ and ρ on the elementary fields.[8] *Moreover, on $\mathcal{H}_{\mathrm{phys}}$ the first term is BRST-exact and decouples by the quartet mechanism/positivity, and the second is proportional to the equations of motion; therefore,* on shell*,*

$$\boxed{\partial_{\alpha_{\mathrm{gf}}}\Lambda_\alpha(\lambda_{\mathrm{UV}},\ell)=0\quad\textit{on the band.}}\tag{7.209}$$

Sketch. Differentiate $\mathcal{C}_\alpha$ w.r.t. α_{gf}. All α_{gf}-dependence enters through $\Psi(\alpha_{\mathrm{gf}})$, hence through the fields' functionals appearing in $U_{0,1}$ and ρ. Insert the Nielsen master identity (7.201) in the EOM/linearised form to rewrite each variation as a sum of a $\zeta(\partial_{\alpha_{\mathrm{gf}}}\Psi)$ insertion and an EOM-proportional term, yielding (7.208). Because $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ commute with BRST and carry ghost number 0 (eq. (7.145)), band/IR operations do not generate extra terms. On $\mathcal{H}_{\mathrm{phys}}$, the ζ-exact contribution vanishes by quartet positivity/Källén–Lehmann positivity (Section 7.2.6 and eq. (7.12)), and the EOM contribution vanishes on shell (eqs. (6.333) and (6.334)). Taking the real part with a fixed reference phase leaves the conclusion unchanged, proving (7.209). See [117, 91]. □

Background-field Nielsen identity and Ward compatibility.

Proposition 7.291 (Background-field Nielsen identity and Ward compatibility)**.** *Adopt the background-field method and choose the gauge fermion Ψ so that background gauge invariance is manifest. Then the band-limited 1PI functional Γ satisfies, simultaneously,*

$$\mathcal{W}^a_{\mathrm{bkg}}\Gamma=0,\qquad\frac{\partial\Gamma}{\partial\alpha_{\mathrm{gf}}}=-\,\mathcal{B}_\Gamma\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi\Big)\quad\textit{(band Nielsen identity (7.201)).}$$

Consequently, the proofs of the pole-mass gauge independence (7.207) and the visibility protection (7.209) simplify: background Ward identities fix the transverse tensor structures a priori, and the Nielsen variation reduces to $\mathcal{B}_\Gamma$-exact insertions in the background-covariant basis.

[8] Concretely, $\mathcal{O}_\alpha$ collects the insertions generated by the chain rule acting on $U_{0,1}$ and ρ together with the Nielsen kernel $\mathcal{N}^A=\langle\zeta\,\partial_{\alpha_{\mathrm{gf}}}\Psi\rangle_\Gamma$; $\mathcal{J}_\alpha$ multiplies the Euler–Lagrange operators from $\delta\Gamma/\delta\varphi$. Locality follows from the QAP.

Sketch. In the BFM, the gauge-fixed action is invariant under background gauge transformations generated by $\mathcal{W}^a_{\rm bkg}$, while quantum gauge variations are controlled by BRST. Choosing Ψ background-covariant leaves $\mathcal{W}^a_{\rm bkg}\Gamma = 0$ intact [114]. The standard algebraic-renormalisation derivation of the Nielsen identity (linearised Slavnov form) carries over verbatim [91]. Transversality of current and gauge two-point functions then follows from background Ward identities, and the Nielsen variation remains an EOM- plus BRST-exact insertion, giving (7.207)–(7.209). □

Corollary 7.292 (Band/IR scope and regulator robustness)**.** *Because* $[\hat{Q}_{\rm BRST}, P_x(\lambda_{\rm UV})] = 0$ *and* $\zeta\big(K^{(\ell)}_{\rm IR} * \cdot\big) = 0$ *(cf. (7.145)), the identities (7.201)–(7.209) hold* on the band. *Moreover, under admissible regulator changes* $(P, K) \to (\tilde{P}, \tilde{K})$ *that preserve the low-energy fixed point, the induced variations of these identities are bounded by the regulator tolerance* $\varepsilon_{\rm reg}$ *from Section 7.3.7; hence the conclusions (gauge-parameter independence of pole masses and visibilities) are regulator-stable within* $\varepsilon_{\rm reg}$.

Remark 7.293 (Bibliography note)**.** For the original gauge-parameter identity, see Nielsen's paper `Nielsen1975gauge` (N. K. Nielsen, *Nucl. Phys. B* **101** (1975) 173–188). Algebraic-renormalisation treatments and proofs in the BRST framework are presented in [117], with textbook exposition in [91]. Background-field gauge and its Ward identities are reviewed in [114].

7.5.12 Callan–Symanzik Identity on the Band

Definition 7.294 (Field content and bandwise renormalisation data)**.** Throughout, we use the conventional symbols

$$\Phi \text{ (gaiamiti)}, \qquad \Theta \text{ (tantrakymon)}, \qquad c \text{ (ghost)},$$

with antifields/sources suppressed when not needed. Bandwise renormalised fields are defined by multiplicative Z-factors at fixed bare parameters,

$$\Phi_0 = Z_\Phi^{1/2}\,\Phi, \qquad \Theta_0 = Z_\Theta^{1/2}\,\Theta, \qquad c_0 = Z_c^{1/2}\,c, \tag{7.210}$$

where UV projection $P_x(\lambda_{\rm UV})$ and IR smoothing $K^{(\ell)}_{\rm IR}$ act as spectators and commute with BRST and with the RG flow (ghost number 0; cf. (7.145)). The anomalous dimensions are defined at fixed bare parameters:

$$\gamma_\Phi := \mu\,\frac{d\ln Z_\Phi}{d\mu}\Big|_{\rm bare}, \qquad \gamma_\Theta := \mu\,\frac{d\ln Z_\Theta}{d\mu}\Big|_{\rm bare}, \qquad \gamma_c := \mu\,\frac{d\ln Z_c}{d\mu}\Big|_{\rm bare}. \tag{7.211}$$

Let $\{g_r\}$ denote the set of renormalised (dimensionless) couplings, with beta functions $\beta_r(g) := \mu\,\frac{dg_r}{d\mu}\big|_{\rm bare}$. If relevant masses m_a appear, define $\gamma_{m_a} := \mu\,\frac{d\ln m_a}{d\mu}\big|_{\rm bare}$.

Definition 7.295 (Band Callan–Symanzik operator)**.** For a 1PI n-point function at the symmetric vacuum, let (n_Φ, n_Θ, n_c) be the external leg counts of (Φ, Θ, c), respectively. The band Callan–Symanzik (CS) operator acting at fixed bare parameters and fixed knobs $(\lambda_{\rm UV}, \ell)$ is

$$\mathcal{D}^{\rm band}_{\rm CS} := \mu\frac{\partial}{\partial\mu} + \sum_r \beta_r(g)\frac{\partial}{\partial g_r} - \frac{n_\Phi}{2}\gamma_\Phi - \frac{n_\Theta}{2}\gamma_\Theta - \frac{n_c}{2}\gamma_c \;\; (+\sum_a \gamma_{m_a}\, m_a\,\partial_{m_a} \text{ if masses}). \tag{7.212}$$

Theorem 7.296 (Callan–Symanzik identity on the band)**.** *Let* $\Gamma^{(n)}_{\text{band}}(\{p_i\};\mu,g)$ *be any renormalised* 1*PI n-point function computed from* (7.144) *with the scale-tagged dynamics of eqs.* (6.333) *and* (6.334) *and with the UV/IR knobs* $(\lambda_{\text{UV}},\ell)$ *held fixed. Then*

$$\boxed{\mathcal{D}^{\text{band}}_{\text{CS}}\,\Gamma^{(n)}_{\text{band}}(\{p_i\};\mu,g)=0\,,} \tag{7.213}$$

i.e. the standard Callan–Symanzik equation holds on the band. *If relevant masses* m_a *are present, include the mass terms indicated in* (7.212).

Sketch. At fixed bare parameters, the bare n-point function is μ-independent. Express it in terms of renormalised fields/couplings using (7.210). Differentiating w.r.t. μ and using the chain rule yields

$$\Big(\mu\partial_\mu+\sum_r\beta_r\partial_{g_r}\Big)\Gamma^{(n)}_{\text{band}}=\frac{1}{2}\Big(n_\Phi\,\gamma_\Phi+n_\Theta\,\gamma_\Theta+n_c\,\gamma_c\Big)\Gamma^{(n)}_{\text{band}}\ (+\ \sum_a\gamma_{m_a}\,m_a\,\partial_{m_a}\ \text{if masses}),$$

which rearranges to (7.213). Band/IR operations commute with the RG (and with BRST) by (7.145), so they do not contribute additional terms. The argument is standard (multiplicative renormalisability and RG at fixed bare parameters) [91, 82]. □

Remark 7.297 (Consistency with ST/Nielsen and scale-tagged EOM)**.** The CS identity (7.213) coexists with the band Slavnov identity and the Nielsen identities; the latter constrain gauge-parameter variations, while (7.213) governs μ-flow of renormalised amplitudes. Since $P_x(\lambda_{\text{UV}})$ and $K^{(\ell)}_{\text{IR}}$ carry ghost number 0 and commute with BRST, the algebraic relations imposed by Section 7.5.9 (and their consequences for visibilities) are compatible with (7.213). The scale-tagged equations of motion eqs. (6.333) and (6.334) fix the operator basis and ensure that all counterterms respect the band structure and the symmetric-point identities [117, 91, 82].

Composite operators and mixing — formal treatment.

Definition 7.298 (Bandwise renormalisation of composites and anomalous dimensions)**.** Let $\{\mathcal{O}_I\}$ be a local basis of BRST-closed, gauge-invariant composites representing $H^0(\mathcal{B}_\Gamma)$ at the symmetric point (fields: Φ for gaiamiti, Θ for tantrakymon, and c for ghosts). Define bandwise renormalised insertions by a finite mixing matrix $Z^{\mathcal{O}}$ at fixed bare parameters,

$$[\mathcal{O}_I]\ =\ \sum_J\big(Z^{\mathcal{O}}\big)_{IJ}\,\mathcal{O}^{\text{bare}}_J\ +\ \mathcal{B}_\Gamma(\cdots)\ +\ \partial_\mu(\cdots), \tag{7.214}$$

where the $\mathcal{B}_\Gamma$-exact and total-derivative pieces encode allowed mixings with BRST-exact and improvement operators; they decouple on $\mathcal{H}_{\text{phys}}$ (positivity/quartet mechanism). The *band anomalous-dimension matrix* is

$$\gamma_{IJ}(g)\ :=\ \Big(\big(Z^{\mathcal{O}}\big)^{-1}\,\mu\frac{d}{d\mu}\,Z^{\mathcal{O}}\Big)_{IJ}\Big|_{\text{bare}}, \tag{7.215}$$

with UV/IR knobs $(\lambda_{\text{UV}},\ell)$ commuting with BRST and with the RG flow, cf. (7.145).

Theorem 7.299 (Band Callan–Symanzik equation for composite insertions)**.** *Let a renormalised n-point 1PI function with m insertions of renormalised composites $[\mathcal{O}_{I_1}], \dots, [\mathcal{O}_{I_m}]$ be denoted by*

$$G^{(n;m)}_{\text{band}}\big(\{p\}; \mu, g\big).$$

At fixed bare parameters and fixed knobs $(\lambda_{\text{UV}}, \ell)$,

$$\Big(\mu\partial_\mu + \beta\cdot\partial_g\Big)\,[\mathcal{O}_I] \;=\; \sum_J \gamma_{IJ}\,[\mathcal{O}_J] \;+\; \mathcal{B}_\Gamma(\cdots) \;+\; \partial_\mu(\cdots), \tag{7.216}$$

and consequently

$$\Big(\mu\partial_\mu + \beta\cdot\partial_g - \tfrac{n_\Phi}{2}\gamma_\Phi - \tfrac{n_\Theta}{2}\gamma_\Theta - \tfrac{n_c}{2}\gamma_c - \sum_a \gamma_{m_a}\, m_a\partial_{m_a}\Big)\, G^{(n;m)}_{\text{band}} = \sum_{k=1}^{m}\sum_J \gamma_{I_k J}\, G^{(n;m)}_{\text{band}}(\mathcal{O}_{I_k}\to\mathcal{O}_J), \tag{7.217}$$

where the right-hand side replaces the k-th insertion by its mixed partner. The $\mathcal{B}_\Gamma$-exact and total-derivative contributions drop out of $\mathcal{H}_{\text{phys}}$ matrix elements.

Sketch. Differentiate (7.214) at fixed bare parameters; use the definition (7.215). Insert this variation into the RG equation for correlators at fixed bare parameters (the proof of Theorem 7.296) and use linearity of the insertion map defined by Γ (QAP). BRST-exact and improvement terms yield contact contributions that vanish in physical matrix elements and do not affect the 1PI kernels away from coincident points [117, 91]. □

Corollary 7.300 (Conserved currents in cohomology)**.** *If the anomaly filters hold (no gauge/mixed/gravitational anomalies) and J^μ_a is a conserved Noether current (global G), then*

$$\gamma_{J_a} = 0 \quad \text{in } H^0(\mathcal{B}_\Gamma), \tag{7.218}$$

i.e. any RG variation is an improvement plus a BRST-exact term (non-renormalisation of conserved currents), cf. (7.188) and Prop. 7.257 [117, 91].

Compatibility with Slavnov–Taylor and gauge independence — formal treatment.

Proposition 7.301 (ST stability of the RG data on the band)**.** *Assume the band Slavnov identity $\mathcal{S}(\Gamma) = 0$ and its linearisation $\mathcal{B}_\Gamma$ (Section 7.5.9). Then the RG generator $\mathcal{D}^{\text{band}}_{\text{CS}}$ (Definition 7.295) satisfies*

$$[\mathcal{D}^{\text{band}}_{\text{CS}},\, \mathcal{B}_\Gamma] = 0, \qquad \mathcal{B}_\Gamma\big(\gamma, \beta\big) = 0 \quad \textit{(cohomologically)}, \tag{7.219}$$

so the CS equations (7.213)–(7.216) are stable under BRST and their data (β, γ) are constrained by the ST cohomology (algebraic renormalisation).

Sketch. The QAP implies that $\mu\partial_\mu$ at fixed bare parameters acts by local counterterm insertions. These insertions preserve the ST identity if and only if they lie in $\ker \mathcal{B}_\Gamma$ modulo $\operatorname{im} \mathcal{B}_\Gamma$; hence $[\mathcal{D}^{\text{band}}_{\text{CS}}, \mathcal{B}_\Gamma] = 0$ and (7.219) [117]. □

Theorem 7.302 (Gauge-parameter independence of physical β-functions)**.** *Let $\alpha_{\rm gf}$ enter only through $\Psi(\alpha_{\rm gf})$, and assume the band Nielsen identity (7.201). For any* physical *coupling g_r (coupling solely to cohomology representatives in $H^0(\mathcal{B}_\Gamma)$), one has*

$$\partial_{\alpha_{\rm gf}}\beta_r(g)=0,\qquad \partial_{\alpha_{\rm gf}}\gamma_{IJ}(g)=\Big[\gamma(g),\mathcal{C}(\alpha_{\rm gf})\Big]_{IJ}\quad\textit{(similarity change of basis)},\tag{7.220}$$

where $\mathcal{C}$ is the local Nielsen kernel acting within the composite-operator space (band version of the standard result). Thus the eigenvalues *of γ in $H^0(\mathcal{B}_\Gamma)$, and all physical β-functions, are gauge-parameter independent [117, 91].*

Sketch. Apply $\partial_{\alpha_{\rm gf}}$ to (7.213)–(7.216) and use the Nielsen identity in the linearised form $\partial_{\alpha_{\rm gf}}\Gamma=-\mathcal{B}_\Gamma(\partial_{\alpha_{\rm gf}}\Psi)$. For physical couplings, the induced variations are $\mathcal{B}_\Gamma$-exact (EOM/BRST insertions), hence they cannot modify β_r. For composite operators, $\partial_{\alpha_{\rm gf}}\gamma$ is a commutator with the Nielsen kernel (basis change), leaving its spectrum in cohomology invariant. □

Corollary 7.303 (Background-field method)**.** *If the background-field method is used with a background-invariant gauge fermion, background Ward identities fix the renormalisation of gauge couplings directly from the background two-point kernel; consequently, β_g is manifestly gauge-parameter independent on the band [114, 91].*

Proposition 7.304 (RG improvement for holosymmetric visibilities)**.** *Let $\mathcal{C}_\alpha$ be the band/IR-embedded coherence amplitude and $\Lambda_\alpha=\mathrm{Re}(e^{-i\phi_\alpha}\mathcal{C}_\alpha)$ the corresponding visibility (Section 7.4.1). Assume multiplicative renormalisability on the band and the Callan–Symanzik identities (7.213)–(7.216) at fixed bare parameters. Then,* on shell *in $\mathcal{H}_{\rm phys}$,*

$$\boxed{\Big(\mu\partial_\mu+\beta\cdot\partial_g\Big)\,\mathcal{C}_\alpha(\lambda_{\rm UV},\ell;\mu,g)=0,\qquad \Big(\mu\partial_\mu+\beta\cdot\partial_g\Big)\,\Lambda_\alpha(\lambda_{\rm UV},\ell;\mu,g)=0\ ,}\tag{7.221}$$

up to $\mathcal{B}_\Gamma$-exact and total-derivative contact terms, which decouple on $\mathcal{H}_{\rm phys}$. Equivalently, $\mathcal{C}_\alpha$ and Λ_α are RG invariants whose residual scale dependence is confined to the running couplings $g(\mu)$.

Sketch. Write $\mathcal{C}_\alpha=N_\alpha/D_\alpha$ with

$$N_\alpha=\mathrm{Tr}\Big(\mathsf{P}_{\rm phys}\,U_1\,\rho\,U_0^\dagger\,\mathsf{P}_{\rm phys}\Big),\qquad D_\alpha=\mathrm{Tr}\Big(\mathsf{P}_{\rm phys}\rho\Big),$$

where $U_{0,1}$ and ρ are built from renormalised fields (Φ,Θ,c) and renormalised couplings $\{g_r\}$, with UV/IR knobs held fixed and commuting with BRST (eq. (7.145)). Applying the band CS operator (7.468) to N_α and D_α and using (7.213)–(7.216) gives two terms: (i) a piece proportional to the anomalous dimensions from field rescalings, and (ii) a piece $\beta\cdot\partial_g$. Because N_α and D_α involve identical field content (same external-leg counting in the insertion map), the anomalous-dimension contributions cancel in the ratio. The remaining BRST-exact/improvement mixings are $\mathcal{B}_\Gamma$-exact or total derivatives and thus vanish on $\mathcal{H}_{\rm phys}$ (quartet mechanism/positivity and the QAP), leaving $(\mu\partial_\mu+\beta\cdot\partial_g)\mathcal{C}_\alpha=0$. Taking a fixed reference phase does not affect RG invariance, hence (7.221) also holds for Λ_α. See [91, 82] for CS/RG, and [117] for the cohomological decoupling on physical matrix elements. □

Definition 7.305 (Band-matched renormalisation scale)**.** To minimise large logarithms in $\Gamma^{(n)}_{\text{band}}$ entering the readout, choose a *band-matched* scale

$$\mu_{\text{band}} = \mu_{\text{band}}(\lambda_{\text{UV}}, \ell)\,, \quad \text{e.g.} \quad \mu_{\text{band}} \sim \ell^{-1} \ \text{ or } \ \mu_{\text{band}} \sim \max\{|p_i|\} \text{ of the kinematics},$$

so that perturbative logs $\ln(\mu/\mu_{\text{band}})$ are small. RG-improved expressions then evaluate $\mathcal{C}_\alpha, \Lambda_\alpha$ with running couplings $g(\mu_{\text{band}})$ while keeping $(\lambda_{\text{UV}}, \ell)$ fixed (they commute with the RG), stabilising the plateau metrics under scale variations [91, 82].

Remark 7.306 (Gauge/BRST compatibility and residuals)**.** The ST/Nielsen identities ensure that the β-functions of physical couplings are gauge-parameter independent, and that any gauge-parameter variation of composite mixings is a similarity transformation in cohomology (eigenvalues invariant) [117, 91]. Therefore the RG-improved visibilities remain gauge/BRST robust on the band. Within certified plateaus (Section 7.3.9), the residual μ-dependence from higher orders is subleading and accounted for in the tolerance budget.

Trace identity (massless, anomaly-free baseline).

Proposition 7.307 (Band-local trace identity: massless, anomaly-free baseline)**.** *Work at the G-invariant symmetric point (Quadrant I) with massless renormalised fields Φ (gaiamiti), Θ (tantrakymon), and ghosts $c, \bar{c}, b$, and assume the anomaly filters hold (no gauge/mixed/-gravitational anomalies). Couple the renormalised theory to a background metric and define the renormalised energy–momentum tensor by functional differentiation of the band-limited action (sources as in (7.144)), with the UV/IR knobs $(\lambda_{\text{UV}}, \ell)$ commuting with BRST, cf. (7.145). Then the trace satisfies the RG-improved, band-local identity*

$$\boxed{\langle T^{\mu}{}_{\mu}(x)\rangle = \sum_r \beta_r(g)\,\big\langle \mathcal{O}_r(x)\big\rangle \;+\; (\text{equations of motion}) \;+\; \partial_\mu(\cdots)\,,} \tag{7.222}$$

where $\mathcal{O}_r$ are the renormalised operators coupled to the (dimensionless) couplings g_r in $S^{(\lambda_{\text{UV}},\ell)}_{\Phi,\Theta}$, and the last two terms are contact terms that vanish in $\mathcal{H}_{\text{phys}}$ matrix elements away from coincident insertions (BRST-exact/EOM improvements). Identity (7.222) holds on the band *and is regulator-stable under admissible changes of $(P_x, K^{(\ell)}_{\text{IR}})$.*

Sketch. Introduce a local Weyl (scale) variation of the background metric and use the Quantum Action Principle to represent the insertion of $T^{\mu}{}_{\mu}$ as the response of the renormalised effective action Γ to a local change of the renormalisation scale. At fixed bare parameters, $\mu\dfrac{d}{d\mu}\Gamma = 0$ implies the Callan–Symanzik generator acts on renormalised couplings and fields; translating this local RG variation into operator insertions yields the $\sum_r \beta_r \mathcal{O}_r$ term, while field rescalings produce EOM and improvement terms [91, 82]. Absence of gauge/mixed/-gravitational anomalies forbids additional local cocycles in the trace (no Weyl anomaly in the assumed baseline); any BRST-exact contributions decouple on $\mathcal{H}_{\text{phys}}$ by quartet positivity. Band/IR operations commute with BRST and preserve locality at the smearing scale by (7.145), so the same algebraic argument holds *on the band*. Regulator stability follows from Section 7.3.7. □

Lemma 7.308 (Local CS identity from the trace)**.** *Insertion of* (7.222) *into renormalised* n*-point* 1*PI functions and integration over* x *reproduces the band Callan–Symanzik equation* (7.213)*; conversely,* (7.213) *implies* (7.222) *up to EOM/improvement terms.*

Remark 7.309 (Scheme and regulator considerations)**.** (i) While β- and γ-functions depend on the renormalisation scheme beyond leading order, the *structure* of (7.222) and its Slavnov–Taylor (ST) compatibility are scheme-independent consequences of algebraic renormalisation [117, 91]. (ii) Admissible regulator changes $(P, K) \to (\tilde{P}, \tilde{K})$ preserving the low-energy fixed point leave (7.222) invariant within the tolerance $\varepsilon_{\mathrm{reg}}$ (Section 7.3.7). (iii) On $\mathcal{H}_{\mathrm{phys}}$, BRST-exact mixings and total derivatives drop out of physical observables and out of the visibilities' RG flow (positivity/decoupling), consistent with Section 7.2.6 and Section 7.5.12.

Bibliography. For CS/RG and their operator form of the trace identity, see [91, 82]. The cohomological (ST/BRST) constraints ensuring compatibility and decoupling are discussed in [117]; background-field perspectives on β-functions appear in [114].

7.5.13 Sector/Projector Compatibility and Plateau Protection

Definition 7.310 (Bandwise sector projectors)**.** Let $\{\Pi_\beta\}_{\beta\in\mathcal{B}}$ be a finite or countable family of mutually orthogonal projectors on the one–particle (or appropriate tensor) space such that

$$\Pi_\beta^\dagger = \Pi_\beta, \qquad \Pi_\beta \Pi_{\beta'} = \delta_{\beta\beta'}\Pi_\beta, \qquad \sum_\beta \Pi_\beta = \mathbb{1}.$$

Assume each Π_β is G-invariant and BRST-closed, and commutes with the band/IR knobs:

$$[\Pi_\beta, Q_a] = 0, \quad [\Pi_\beta, \hat{Q}_{\mathrm{BRST}}] = 0, \quad [\Pi_\beta, P_x(\lambda_{\mathrm{UV}})] = 0, \quad [\Pi_\beta, K_{\mathrm{IR}}^{(\ell)}] = 0, \tag{7.223}$$

where Q_a generate the global G symmetry and $P_x, K_{\mathrm{IR}}^{(\ell)}$ satisfy (7.145). For a multiplet $\varphi = (\Phi, \Theta, c, \bar{c}, b)$, define the *sector-restricted fields* $\varphi_\beta := \Pi_\beta \varphi$ and the *sector-restricted effective action*

$$\Gamma_\beta[\varphi] \;:=\; \Gamma[\Pi_\beta \varphi] \;=\; \Gamma[\varphi_\beta]. \tag{7.224}$$

Proposition 7.311 (Sectorwise Slavnov–Taylor and global Ward identities)**.** *Under* (7.223) *and at the symmetric point,*

$$\boxed{\mathcal{S}\big(\Gamma_\beta\big) = 0, \qquad \mathcal{W}_a\big(\Gamma_\beta\big) = 0,} \tag{7.225}$$

i.e. both the Slavnov functional and the global Ward operator act compatibly on each sector. In particular, the linearised ST operator about Γ_β*,*

$$\mathcal{B}_{\Gamma_\beta} X \;:=\; \frac{d}{d\epsilon}\Big|_{\epsilon=0} \mathcal{S}\big(\Gamma_\beta + \epsilon X\big),$$

is nilpotent: $\mathcal{B}_{\Gamma_\beta}^2 = 0$.

Proof. The identities $\mathcal{S}(\Gamma)=0$ and $\mathcal{W}_a(\Gamma)=0$ hold on the band by Sections 7.5.2 and 7.5.4 and commute with the insertions $P_x, K_{\mathrm{IR}}^{(\ell)}$ by (7.145). Using $[\Pi_\beta, \hat{Q}_{\mathrm{BRST}}]=[\Pi_\beta, Q_a]=0$ and the fact that Π_β has ghost number 0, one may pull Π_β through the antibracket/linearised form of $\mathcal{S}$ and through the Ward operators; thus $\mathcal{S}(\Gamma[\Pi_\beta\varphi])=0$ and $\mathcal{W}_a(\Gamma[\Pi_\beta\varphi])=0$. Nilpotency of $\mathcal{B}_{\Gamma_\beta}$ follows from the graded Jacobi identity as in the standard proof [117, 442, 91]. □

Proposition 7.312 (Cohomology factorisation and sector decomposition)**.** *Let $H^0(\mathcal{B}_\Gamma)$ denote the BRST cohomology at ghost number 0 for Γ. Then the map*

$$\bigoplus_\beta H^0(\mathcal{B}_{\Gamma_\beta}) \;\longrightarrow\; H^0(\mathcal{B}_\Gamma), \qquad \big([\mathcal{O}_\beta]\big)_\beta \;\mapsto\; \Big[\ \sum_\beta \Pi_\beta\,\mathcal{O}_\beta\ \Big],$$

is an isomorphism of vector spaces. In particular, any physical composite operator has a unique decomposition into sector components, and conversely each sector cohomology class lifts canonically to a class of the full theory.

Sketch. Orthogonality and completeness of $\{\Pi_\beta\}$ imply a direct-sum decomposition of the configuration space. Since Π_β commute with BRST, $\mathcal{B}_\Gamma$ preserves sectors and decomposes as a direct sum of $\mathcal{B}_{\Gamma_\beta}$. Exactness and closure are preserved by the direct sum, yielding the claimed isomorphism. □

Definition 7.313 (Sector-resolved readouts and weights)**.** For a channel α and interrogation time T, define the sector-resolved coherence amplitude and visibility by inserting Π_β at readout,

$$\mathcal{C}_{\alpha|\beta} := \frac{\mathrm{Tr}\Big(\Pi_\beta\,\mathsf{P}_{\mathrm{phys}}\,U_1^{(\alpha)}\,\rho_{\mathrm{phys}}\,U_0^{(\alpha)\dagger}\,\mathsf{P}_{\mathrm{phys}}\,\Pi_\beta\Big)}{\mathrm{Tr}(\Pi_\beta\,\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})}, \qquad \Lambda_{\alpha|\beta} := \mathrm{Re}\big(e^{-i\phi_\alpha}\mathcal{C}_{\alpha|\beta}\big), \tag{7.226}$$

cf. (7.133). The sector weights are $w_\beta := \mathrm{Tr}(\Pi_\beta\,\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})/\,\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})$.

Theorem 7.314 (Block-diagonality and convex additivity)**.** *If, in addition to (7.223), each branch generator is sector-compatible,*

$$[\Pi_\beta, \mathcal{H}_j^{(\alpha)}(t,x;\lambda_{\mathrm{UV}})]=0 \quad \textit{for all } (t,x),\ \beta,\ j\in\{0,1\}, \tag{7.227}$$

then the band/IR-smeared propagators $U_j^{(\alpha)}$ are block-diagonal in the sector decomposition and the aggregate amplitude decomposes as

$$\mathcal{C}_\alpha = \sum_\beta w_\beta\,\mathcal{C}_{\alpha|\beta}, \qquad \Lambda_\alpha = \sum_\beta w_\beta\,\Lambda_{\alpha|\beta}. \tag{7.228}$$

Proof. Condition (7.227) implies $U_j^{(\alpha)}=\bigoplus_\beta U_j^{(\alpha,\beta)}$, so cross-sector coherences vanish under the sector insertions. Insert the resolution of identity $\sum_\beta \Pi_\beta = \mathbb{1}$ on both sides of ρ_{phys} inside the trace and use orthogonality to obtain (7.228). □

Lemma 7.315 (Leakage bound under weak sector breaking)**.** *Suppose (7.223) holds but (7.227) is violated weakly: $\epsilon_{\mathrm{leak}} := \sup_t \sum_\beta \|[\Pi_\beta, \mathcal{H}_j^{(\alpha)}(t,\cdot;\lambda_{\mathrm{UV}})]\|_{\mathrm{op}} < \infty$. Then for the band/IR propagators (Dyson/Duhamel expansion),*

$$\big\|\Pi_\beta^{\perp}\,U_j^{(\alpha)}(T)\,\Pi_\beta\big\|_{\mathrm{op}} \;\le\; T\,\epsilon_{\mathrm{leak}}\,\exp\Big(T\,\|\mathcal{H}_j^{(\alpha)}\|_{\mathrm{op}}\Big), \tag{7.229}$$

and the deviation from (7.228) obeys

$$\Big|\Lambda_\alpha - \sum_\beta w_\beta\, \Lambda_{\alpha|\beta}\Big| \;\le\; C\,T\,\epsilon_{\mathrm{leak}} \;+\; \mathcal{O}(T^2\epsilon_{\mathrm{leak}}^2), \tag{7.230}$$

for a constant C depending on $\|\rho_{\mathrm{phys}}\|_1$ and operator norms of the sector blocks.

Sketch. Apply Duhamel's formula (7.131)–(7.132) with the decomposition $\mathcal{H}_j = \sum_\beta \Pi_\beta \mathcal{H}_j \Pi_\beta +$ (off-diagonal) and iterate the integral inequality (Gronwall). Estimate the sector off-diagonal blocks of $U_j^{(\alpha)}$ by (7.229) and insert into the trace defining $\mathcal{C}_\alpha$; normalise by $\mathrm{Tr}(\mathsf{P}_{\mathrm{phys}}\rho_{\mathrm{phys}})$ to obtain (7.230). See, e.g., [115, Sec. X.11] for operator-norm evolution bounds. □

Proposition 7.316 (Sectorwise Nielsen/Slavnov protection)**.** *The sector-restricted functionals Γ_β obey the band Nielsen identity and the linearised ST identity with the same kernels as the full theory:*

$$\partial_{\alpha_{\mathrm{gf}}}\Gamma_\beta = -\,\mathcal{B}_{\Gamma_\beta}\big(\partial_{\alpha_{\mathrm{gf}}}\Psi\big), \qquad \mathcal{B}_{\Gamma_\beta}^2 = 0.$$

Consequently, sector-resolved pole masses and visibilities are gauge-parameter independent on shell, and the sector Callan–Symanzik data (β, γ) satisfy the ST cohomological constraints as in the full theory [117, 91].

Proof. Apply the proofs of Propositions 7.229 and 7.301 and Theorem 7.302 with $\varphi \mapsto \Pi_\beta\varphi$; commutations (7.223) ensure functorial descent to each sector. □

Definition 7.317 (Sectorwise plateau protection and certification)**.** Within a certified joint plateau $\mathfrak{P}_{\{\mathrm{law,state}\}}$ (cf. Section 7.4.5), define sectorwise bounds

$$\|\nabla_{(u,v)}\Lambda_{\alpha|\beta}\| \le \varepsilon_{\mathrm{grad},\beta}, \qquad \|\mathbf{H}\Lambda_{\alpha|\beta}\|_{\mathrm{op}} \le \varepsilon_{\mathrm{curv},\beta}, \qquad \mathrm{osc}_{B_r}\,\Lambda_{\alpha|\beta} \le \varepsilon_{\mathrm{osc},\beta},$$

and a leakage tolerance $T\,\epsilon_{\mathrm{leak}} \le \varepsilon_{\mathrm{leak}}$ from (7.229). The *sectorwise certification* accepts $(\lambda_\star, \ell_\star)$ if, for all β with $w_\beta > \tau$ (weight threshold),

$$\varepsilon_{\mathrm{grad},\beta},\ \varepsilon_{\mathrm{curv},\beta},\ \varepsilon_{\mathrm{osc},\beta},\ \varepsilon_{\mathrm{leak}} \ \text{ lie below policy tolerances,}$$

and the gradient-alignment coefficient between channels (restricted to sector β) satisfies $\chi_{\star|\beta} \le \chi_{\max}$ (avoidance of near-cancellations). The aggregate plateau then inherits the bounds via (7.228) or, under weak breaking, with additive error $\mathcal{O}(\varepsilon_{\mathrm{leak}})$ by (7.230).

Corollary 7.318 (Regulator stability per sector)**.** *Under admissible changes $(P_x, K_{\mathrm{IR}}^{(\ell)}) \to (\tilde P_x, \tilde K_{\mathrm{IR}}^{(\ell)})$ preserving the low-energy fixed point, sector-resolved visibilities satisfy*

$$\big|\Lambda_{\alpha|\beta} - \tilde\Lambda_{\alpha|\beta}\big| \;\le\; \varepsilon_{\mathrm{reg},\beta},$$

with $\varepsilon_{\mathrm{reg},\beta}$ controlled as in Section 7.3.7; aggregate stability follows by summing with weights w_β (or with the leakage correction from (7.230)).

Remark 7.319 (Operational upshot)**.** Sectorwise ST/Ward/Nielsen protection (Propositions 7.311 and 7.316) guarantees that sector-resolved readouts are physically meaningful and gauge robust; block-diagonality yields exact convex additivity (7.228), while weak violations are quantitatively bounded by (7.230). These statements hold *on the band* and descend to $\mathcal{H}_{\mathrm{phys}}$ by BRST decoupling [117, 442, 91, 115].

Sectorwise Callan–Symanzik flow (formal treatment).

Proposition 7.320 (Sectorwise CS identity)**.** *Let* $\{\Pi_\beta\}$ *be the BRST-closed, G-invariant band/IR-compatible sector projectors of Section 7.5.13, commuting with the UV/IR knobs as in* (7.223)*. For the renormalised n-point* 1*PI kernels computed on the band,*

$$\Gamma^{(n)}_{\mathrm{band},\beta}(\{p_i\};\mu,g) := \Gamma^{(n)}_{\mathrm{band}}\Big[\Pi_\beta\varphi\Big](\{p_i\};\mu,g),$$

the Callan–Symanzik (CS) operator acts sectorwise with the same β*- and* γ*-functions as in Section 7.5.12:*

$$\boxed{\Big(\mu\partial_\mu + \beta\cdot\partial_g - \tfrac{n_\Phi}{2}\gamma_\Phi - \tfrac{n_\Theta}{2}\gamma_\Theta - \tfrac{n_c}{2}\gamma_c\Big)\,\Gamma^{(n)}_{\mathrm{band},\beta}(\{p_i\};\mu,g) \;=\; 0\,.} \tag{7.231}$$

Moreover, (7.231) *is compatible with the sectorwise Slavnov–Taylor and G-Ward identities* (7.225)*, so the usual cohomological constraints on counterterms hold* within each sector *[117, 91].*

Proof sketch. The CS equation on the band, (7.213), follows from RG invariance at fixed bare data in a multiplicatively renormalisable scheme [91, 82]. Since Π_β has ghost number 0 and commutes with BRST, G, and the knobs (Definition 7.310), it can be inserted either before or after renormalisation without altering renormalisation constants. Consequently, the same (β,γ) govern the sector-restricted amplitudes. Compatibility with Slavnov/Ward identities sectorwise is Proposition 7.311, ensuring stability of (7.231) under $\mathcal{S}$ and $\mathcal{W}_a$ [117, 91]. □

Smoothness in ℓ and spectral gaps (formal treatment).

Definition 7.321 (Sectoring from an IR metric)**.** Let $A(\ell)$ be a self-adjoint band/IR-local operator built covariantly from $\bar\Sigma^{(\ell)}_{\mu\nu}$ (e.g. the appropriate spin/tensor Casimir or a $\bar\Sigma^{(\ell)}$-elliptic kinetic symbol) whose spectral decomposition defines $\{\Pi_\beta(\ell)\}$. Assume a *non-crossing condition* on the scan window: there exists gap > 0 such that separated spectral clusters remain at least gap apart for all ℓ in the window.

Lemma 7.322 (Differentiability of sector projectors)**.** *Under Definition 7.321, each Riesz projector*

$$\Pi_\beta(\ell) \;=\; \frac{1}{2\pi i}\oint_{\mathcal{C}_\beta}\big(z - A(\ell)\big)^{-1}\,dz$$

is C^1 *in* ℓ *and satisfies the Kato-type bound*

$$\big\|\partial_{\ln\ell}\Pi_\beta(\ell)\big\| \;\le\; \frac{\|\,\partial_{\ln\ell}A(\ell)\,\|}{\mathrm{gap}} \;\times\; C_{\mathcal{C}_\beta}, \qquad C_{\mathcal{C}_\beta} = \sup_{z\in\mathcal{C}_\beta}\|(z-A)^{-1}\|^2, \tag{7.232}$$

where $\mathcal{C}_\beta$ *encloses only the cluster defining* Π_β*.*

Proof. This is standard analytic perturbation theory: differentiating the Riesz integral and using the resolvent identity yields (7.232); the spectral gap controls the resolvent norms [115]. □

Corollary 7.323 (Smooth sector-restricted kernels and visibilities)**.** *Let* $\Gamma^{(n)}_{\mathrm{band},\beta}$ *and the sector-resolved visibilities* $\Lambda_{\alpha|\beta}$ *be defined as in* (7.231) *and* (7.226)*. If, in addition, the embedded generators satisfy the Duhamel regularity* (7.132)*, then*

$$\partial_{\ln \ell}\Gamma^{(n)}_{\mathrm{band},\beta}, \quad \partial_{\ln \ell}\Lambda_{\alpha|\beta} \text{ exist and are continuous in } \ell,$$

with quantitative bounds of the form

$$\left|\partial_{\ln \ell}\Lambda_{\alpha|\beta}\right| \;\le\; C_1 \left\|\partial_{\ln \ell}\Pi_\beta\right\| \;+\; C_2 \int_0^T dt\, \left\|\partial_{\ln \ell} K^{(\ell)}_{\mathrm{IR}}\right\| \left\|\mathcal{H}^{(\alpha)}_j(t,\cdot;\lambda_{\mathrm{UV}})\right\|_{\mathrm{op}}, \tag{7.233}$$

for constants $C_{1,2}$ *depending on* $\|\rho_{\mathrm{phys}}\|_1$ *and operator norms of the sector blocks. Combining* (7.232) *and* (7.233) *gives*

$$\left|\partial_{\ln \ell}\Lambda_{\alpha|\beta}\right| \;\lesssim\; \frac{\|\partial_{\ln \ell}\bar{\Sigma}^{(\ell)}\|}{\mathrm{gap}} \;+\; \int_0^T dt\, \left\|\partial_{\ln \ell} K^{(\ell)}_{\mathrm{IR}}\right\| \|\mathcal{H}^{(\alpha)}_j\|_{\mathrm{op}}.$$

Proof sketch. Differentiate the definitions in (7.226) using the product rule, $\partial_{\ln \ell}\Pi_\beta$ from Lemma 7.322, and $\partial_{\ln \ell}U^{(\alpha)}_j$ from the Duhamel identity (7.132). Estimate traces by Schatten/operator norms and use unitarity of the propagators to obtain (7.233). □

Remark 7.324 (RG and cohomology inside sectors)**.** Equation (7.231) ensures that RG improvement can be carried out *per sector*. Since Π_β commute with BRST and G, the sector cohomologies $H^0(\mathcal{B}_{\Gamma_\beta})$ govern allowable counterterms and operator mixings inside each sector exactly as in the full theory (Proposition 7.312, [117, 91]). Smooth ℓ-dependence under the non-crossing hypothesis guarantees that sector plateaus and their certification metrics vary regularly across the scan window (cf. Section 7.4.5).

Plateau protection (sectorwise): formal treatment.

Proposition 7.325 (Sectorwise plateau protection)**.** *Let* $\mathfrak{P}_{\{\mathrm{law,state}\}}$ *be a certified joint plateau in the log–knob chart* $(u,v) = (\ln \lambda_{\mathrm{UV}}, \ln \ell)$*, and let* $\{\Pi_\beta(\ell)\}$ *be the BRST-closed, G-invariant sector projectors with* C^1 *dependence on* ℓ *(non-crossing hypothesis; Kato theory). For any identity functional* $\mathcal{I} \in \{\mathcal{S},\ \mathcal{W}_a,\ \text{CS operator}\}$ *and any sector* β*, define*

$$\Delta_{\mathcal{I},\beta}(u,v) := \mathcal{I}\Big[\Gamma\Big[\Pi_\beta(\ell)\,\varphi\Big]\Big](u,v), \qquad \varphi = (\Phi,\Theta,c,\bar{c},b).$$

Then on every geodesic ball $B_\rho(u_\star,v_\star) \subset \mathfrak{P}_{\{\mathrm{law,state}\}}$ *one has the quantitative bounds*

$$\|\nabla_{(u,v)}\Delta_{\mathcal{I},\beta}\| \;\le\; C_\beta\,\varepsilon_{\mathrm{grad}}\,, \qquad \|\mathbf{H}\,\Delta_{\mathcal{I},\beta}\|_{\mathrm{op}} \;\le\; C_\beta\,\varepsilon_{\mathrm{curv}}\,, \qquad \mathrm{osc}_{B_\rho}\,\Delta_{\mathcal{I},\beta} \;\le\; C_\beta\,\varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}}, \tag{7.234}$$

where C_β *depends only on sector smoothness constants* $\sup_{B_\rho}\|\partial_u\Pi_\beta\|$, $\sup_{B_\rho}\|\partial_v\Pi_\beta\|$ *(controlled by the spectral gap and* $\|\partial_{\ln \ell}\bar{\Sigma}^{(\ell)}\|$ *via Kato) and on operator norms of the Fréchet derivatives of* $\mathcal{I}$ *acting on band-limited functionals. In the exact theory,* $\Delta_{\mathcal{I},\beta} \equiv 0$ *by the sectorwise identities, and* (7.234) *quantifies the stability of* numerical/experimental *tests of these identities under UV/IR scans inside the plateau.*

Proof sketch. Step 1 (Exact sectorwise identities). Since Π_β carries ghost number 0 and commutes with BRST and G, the Slavnov functional and the global Ward operators act compatibly on sector-restricted functionals:

$$\mathcal{S}\big(\Gamma[\Pi_\beta\varphi]\big) = 0, \qquad \mathcal{W}_a\big(\Gamma[\Pi_\beta\varphi]\big) = 0,$$

and the sectorwise CS equation holds with the same (β, γ) (see eqs. (7.225) and (7.231); [117, 442, 91]). Thus, ideally, $\Delta_{\mathcal{I},\beta} \equiv 0$.

Step 2 (Differentiability and chain rule). Inside the plateau we work in knobs (u, v). The u- and v-dependence of $\Gamma[\Pi_\beta\varphi]$ comes from the embedded generators and from $\Pi_\beta(\ell)$. Duhamel formulas give band-safe expressions for ∂_u and ∂_v acting on the propagators (eqs. (7.131) and (7.132)); sector smoothness follows from the non-crossing hypothesis and Kato perturbation theory, yielding C^1 bounds for Π_β in ℓ ([115], cf. Lemma 7.322). Applying the chain rule to $\Delta_{\mathcal{I},\beta} = \mathcal{I} \circ \Gamma \circ (\Pi_\beta, \text{knobs})$ and estimating by operator norms yields

$$\|\partial_{u,v}\Delta_{\mathcal{I},\beta}\| \;\le\; \|\mathrm{D}\mathcal{I}\| \Big(\|\partial_{u,v}\Gamma\| + \|\mathrm{D}_\Gamma\Gamma\| \, \|\partial_{u,v}\Pi_\beta\| \Big).$$

Step 3 (Plateau and regulator bounds). By definition of a certified plateau, the relevant band-limited kernels/visibilities satisfy uniform gradient, curvature, and oscillation bounds (Section 7.3.5, e.g. eq. (7.137)), and admissible regulator changes obey eq. (7.67). Collecting these estimates and absorbing fixed operator norms into C_β gives the gradient and Hessian bounds in (7.234). The oscillation bound follows from the same plateau oscillation control plus ε_{reg} for permissible $(P, K) \to (\tilde{P}, \tilde{K})$ swaps.

Step 4 (Conclusion). Since the exact identities give $\Delta_{\mathcal{I},\beta} \equiv 0$, the bounds (7.234) show that *any measured deviation* within B_ρ remains uniformly small and controlled by $(\varepsilon_{\text{grad}}, \varepsilon_{\text{curv}}, \varepsilon_{\text{osc}}, \varepsilon_{\text{reg}})$, i.e. the identities are *plateau-protected* under UV/IR scans. □

Remark 7.326 (Dependence of C_β)**.** Under the spectral-gap hypothesis for the sectoring operator built from $\bar{\Sigma}^{(\ell)}_{\mu\nu}$, Kato's bound gives $\|\partial_{\ln\ell}\Pi_\beta\| \lesssim \|\partial_{\ln\ell}\bar{\Sigma}^{(\ell)}\|/\text{gap}$ [115]. Hence one may take $C_\beta = C_{\mathcal{I}}\Big(1 + \sup_{B_\rho} \|\partial_{\ln\ell}\bar{\Sigma}^{(\ell)}\|/\text{gap}\Big)$, with $C_{\mathcal{I}}$ depending only on the (fixed) operator norms associated with $\mathcal{I}$ on the band-limited function space (cf. [117, 91, 82]).

Sector-resolved visibilities and compatibility (formal treatment).

Proposition 7.327 (Nielsen independence and CS flow, sector-resolved)**.** *Let $\{\Pi_\beta\}$ be the BRST-closed, G-invariant band/IR-compatible sector projectors of Section 7.5.13, and let $\mathcal{C}_{\alpha|\beta}$ and $\Lambda_{\alpha|\beta}$ be defined by inserting Π_β at readout as in (7.133). Then, on the band and on shell,*

$$\partial_{\alpha_{\text{gf}}}\Lambda_{\alpha|\beta} = 0 \qquad \textit{(Nielsen gauge-parameter independence)}, \tag{7.235}$$

and the sector-resolved 1PI kernels obey the Callan–Symanzik flow with the same β- and γ-functions as in Section 7.5.12:

$$\Big(\mu\partial_\mu + \beta\cdot\partial_g - \tfrac{n_\Phi}{2}\gamma_\Phi - \tfrac{n_\Theta}{2}\gamma_\Theta - \tfrac{n_c}{2}\gamma_c\Big)\,\Gamma^{(n)}_{\text{band},\beta} = 0, \qquad \Gamma^{(n)}_{\text{band},\beta} := \Gamma^{(n)}_{\text{band}}\big[\Pi_\beta\varphi\big], \tag{7.236}$$

and consequently the sector-resolved visibilities inherit RG improvement on shell.

Proof sketch. Sectorwise Slavnov/Ward identities (7.225) hold because Π_β commutes with BRST and with G and carries ghost number 0 ([117, 442, 91]). The Nielsen master identity on the band (Section 7.5.11) then descends to each sector, yielding (7.235) exactly as in Section 7.3.6. Bandwise renormalisation commutes with Π_β, so the CS operator acts sectorwise with unchanged (β, γ) (Proposition 7.320 and [91, 82]); thus (7.236) follows. □

Definition 7.328 (Sector compatibility and certified point)**.** For a fixed channel α and a collection of sectors $\mathcal{B}$, define the sectorwise plateau sets $\mathfrak{P}_{\alpha|\beta}$ by the certification criteria of Sections 7.3.5 and 7.3.9 applied to $\Lambda_{\alpha|\beta}$. A *sector-compatible operating point* is any $(\lambda_\star, \ell_\star)$ such that

$$(\lambda_\star, \ell_\star) \;\in\; \bigcap_{\beta\in\mathcal{B}} \mathfrak{P}_{\alpha|\beta}. \tag{7.237}$$

Corollary 7.329 (No spurious aggregate plateaus)**.** *Assume the exact sector symmetry* $[\Pi_\beta, \mathcal{H}_j^{(\alpha)}] = 0$ *so that evolution is block-diagonal; then the aggregate visibility decomposes as a convex combination of sector visibilities,* $\Lambda_\alpha = \sum_\beta w_\beta \Lambda_{\alpha|\beta}$ *with* $w_\beta \geq 0$ *and* $\sum_\beta w_\beta = 1$ *(cf. (7.133)). On a joint plateau ball* $B_\rho(u_\star, v_\star)$*, sectorwise plateau protection (7.234) implies*

$$\|\nabla_{(u,v)}\Lambda_\alpha\| \;\leq\; \sum_\beta w_\beta \,\|\nabla_{(u,v)}\Lambda_{\alpha|\beta}\| \;\leq\; \Big(\max_\beta C_\beta\Big)\,\varepsilon_{\mathrm{grad}},$$

and analogous bounds for the Hessian and oscillation. Conversely, if an aggregate *plateau occurs while some* $\Lambda_{\alpha|\beta}$ *violates the plateau bounds, this requires near-cancellation of sector gradients; such cancellations are excluded by imposing sector coherence constraints (pairwise alignment coefficients bounded by* $\chi_{\max} < 1$*) within the certification pipeline (Section 7.3.11). Hence certified aggregate plateaus cannot arise from fragile cancellations between sectors.*

Proof sketch. The gradient/Hessian inequalities follow from linearity of differentiation and the convex decomposition, plus (7.234). The converse uses the Gram-matrix estimate for $\sum_\beta w_\beta \nabla\Lambda_{\alpha|\beta}$: if all pairwise cosine alignments are bounded by $\chi_{\max} < 1$, small aggregate gradient forces each sector gradient to be small up to a $1/(1-\chi_{\max})$ factor, contradicting a sector's plateau violation. □

Remarks. (i) Background-field implementations preserve sectorwise identities with background Ward operators, so (7.235)–(7.236) hold sector by sector [114]. (ii) If a spectral crossing in $\Pi_\beta(\ell)$ occurs, restrict to subregions where the gap is open or merge sectors to a gapped $\tilde{\beta}$; sectorwise certification and the bounds of Proposition 7.325 then apply unchanged ([115]). (iii) All statements are *on the band* and descend to $\mathcal{H}_{\mathrm{phys}}$ by positivity/decoupling (Section 7.2.6 and eq. (7.12); [241, 82]).

7.5.14 Anomaly Filters and Cohomological Triviality

Definition 7.330 (Bandwise anomaly filters)**.** On the band (UV projector $P_x(\lambda_{\mathrm{UV}})$ and IR window $K_{\mathrm{IR}}^{(\ell)}$ commuting with BRST, eq. (7.145)), impose the vanishing of the gauge, mixed, and gravitational anomaly indicators recorded in Section 7.2.8:

$$\mathfrak{A}_{\mathrm{gauge}} = \mathbf{0}, \qquad \mathfrak{A}_{\mathrm{mixed}} = \mathbf{0}, \qquad \mathfrak{A}_{\mathrm{grav}} = \mathbf{0}.$$

These conditions are understood at the G-invariant symmetry point (Quadrant I), and are stable under admissible regularisation choices that preserve the low-energy fixed point.

Proposition 7.331 (Cohomological triviality of bandwise breakings)**.** *Let Γ be the band-limited 1PI functional obeying the Quantum Action Principle (QAP). Suppose that at loop order n the Slavnov functional and global Ward operator admit a local breaking $\Delta^{(n)}$ of ghost number $+1$:*

$$\mathcal{S}(\Gamma) = \hbar^n \Delta^{(n)} + \mathcal{O}(\hbar^{n+1}), \qquad \mathcal{W}_a \Gamma = \hbar^n \Delta_a^{(n)} + \mathcal{O}(\hbar^{n+1}),$$

with the Wess–Zumino consistency conditions $\mathcal{B}_\Gamma \Delta^{(n)} = 0$ and $\mathcal{W}_a \Delta^{(n)} + \cdots = 0$. If the anomaly filters of Definition 7.330 hold, then the breaking is cohomologically trivial *on the band:*

$$\Delta^{(n)} = \mathcal{B}_\Gamma \, \widehat{\Sigma}^{(n)} + d\, \widehat{\mathcal{R}}^{(n)}, \qquad \Delta_a^{(n)} = \mathcal{W}_a \widehat{\Sigma}^{(n)} + d\, \widehat{\mathcal{J}}_a^{(n)}, \tag{7.238}$$

for some local counterterms $\widehat{\Sigma}^{(n)}$ and local currents $\widehat{\mathcal{R}}^{(n)}$, $\widehat{\mathcal{J}}_a^{(n)}$. Consequently, the redefinition

$$\boxed{\Gamma \;\mapsto\; \Gamma - \hbar^n \widehat{\Sigma}^{(n)}} \tag{7.239}$$

restores exactly*, at order n, the bandwise Slavnov–Taylor and global Ward identities:*

$$\mathcal{S}(\Gamma) = 0, \qquad \mathcal{W}_a \Gamma = 0.$$

Proof sketch. By QAP, $\Delta^{(n)}$ is a local insertion of ghost number $+1$ satisfying $\mathcal{B}_\Gamma \Delta^{(n)} = 0$ (Wess–Zumino consistency) [117, 442]. The anomaly filters imply that the relevant cohomology $H^{1,d}(\zeta \mid d)$ is trivial in the gauge, mixed, and gravitational sectors, so every consistent breaking is a sum of a $\mathcal{B}_\Gamma$-exact term and a spacetime total derivative, yielding (7.238). Subtracting the local counterterm (7.239) removes the breaking at order n. Band/IR operations commute with BRST and preserve locality at the IR scale, so the standard algebraic-renormalisation argument applies verbatim on the band [117, 443]. □

Corollary 7.332 (Law-channel identity at the symmetry point)**.** *Assume BRST nilpotency and self-adjointness (7.196), the anomaly filters of Definition 7.330, and exact bandwise Slavnov/Ward identities restored order by order via (7.239). In the* law *channel of the holosymmetric probe (Section 7.4.2), the branch difference is BRST-exact on $\mathcal{H}_{\mathrm{phys}}$, so the BRST equivalence theorem (Theorem 7.278) gives*

$$\boxed{\Lambda^\star_{\mathrm{law}} = 1, \qquad \partial_{\alpha_{\mathrm{gf}}} \Lambda^\star_{\mathrm{law}} = 0, \qquad \partial_{(\lambda_{\mathrm{UV}},\ell)} \Lambda^\star_{\mathrm{law}} \;\approx\; 0 \quad \textit{on certified plateaus.}} \tag{7.240}$$

The last bound uses the plateau metrics and regulator stability (eqs. (7.67), (7.137) and (7.138)).

Proof sketch. The law branches differ by $H_0 \mapsto H_0 + \zeta \Delta G$; by Proposition 7.331 and the quartet/positivity mechanism, this deformation is invisible on $\mathcal{H}_{\mathrm{phys}}$. Hence the overlap amplitude equals 1 and is Nielsen-protected (gauge-parameter independence on shell), yielding (7.240). Drift bounds inside certified plateaus follow from the geometric metrics and regulator tolerance established earlier. □

Remark 7.333 (State-channel baseline)**.** For the *state* channel under the infinitesimal symmetric kick (7.124), the symmetric-state expansion (7.128) gives $\Lambda^{\star}_{\text{state}} = 1 + \mathcal{O}(\epsilon^2)$. Thus any significant, regulator-stable suppression of $|\mathcal{C}_{\text{state}}|$ is a diagnostic of *state-level* tension or decoherence rather than a law-level anomaly (triage in Section 7.4.4).

7.5.15 Identity Ledger for Later SSB Analysis

At the G-invariant vacuum and on $\mathcal{H}_{\text{phys}}$, the following identities hold *on the band*. Items **I1**–**I6** are exact (cohomological/functional) identities; **I7** records baseline readouts whose reported values are exact on shell (law channel) or perturbatively controlled (state channel) and, operationally, are certified within plateau tolerances:

I1. Global Ward identities for G: position- and momentum-space forms eqs. (7.181) and (7.182) with current conservation eq. (7.183); two-point transversality eq. (7.184) and positive spectral densities eq. (7.186).

I2. Slavnov–Taylor master equation & linearisation: eqs. (7.189) and (7.190), implying cohomological decoupling of unphysical modes and Z-factor constraints at Quadrant I (vertex-level relations eq. (7.194)); any loop-level breaking is cohomologically trivial and removable by counterterms eq. (7.239) [117].

I3. BRST nilpotency and equivalence theorem: eqs. (7.196) and (7.198), ensuring invariance of $\mathcal{H}_{\text{phys}}$ matrix elements under BRST-exact deformations (including law-branch homotopies).

I4. Nielsen identities (gauge flows): master identity eq. (7.201) with on-shell gauge-parameter independence of pole masses eq. (7.207) and of visibilities/coherence amplitudes eq. (7.209).

I5. Bandwise Callan–Symanzik equation: CS identity for 1PI functions eq. (7.213) and composite-operator flow eq. (7.216), compatible with Slavnov–Taylor and gauge independence of physical β-functions.

I6. Sectorwise validity and plateau protection: sector-restricted ST/Ward identities eq. (7.225), sectorwise CS flow eq. (7.231), and stability bounds eq. (7.234) ensuring robustness of identity tests under UV/IR scans within certified plateaus.

I7. Law/state probe baselines at symmetry: law-channel unity and robustness eq. (7.240) (exact on shell and bandwise); state-channel symmetry limit from eqs. (7.126) and (7.128) with $\Lambda^{\star}_{\text{state}} = 1 + \mathcal{O}(\epsilon^2)$, and deviations interpreted via the diagnostic triage in Section 7.4.4.

These entries constitute the *baseline ledger* against which spontaneous or induced symmetry breaking (SSB) in other quadrants will be detected, certified, and quantified [117, 442, 91, 443].

7.6 Synthesis of Quadrant I: Discoveries and Baseline Status

D1. Symmetric vacuum fixed and clean EOM on the band. A G-invariant vacuum $(\bar{\Phi}, \bar{\Theta})$ has been fixed (cf. Section 7.1). The *scale-tagged*, BRST-consistent equations of motion have been established in Euler–Lagrange and in "clean" kinetic forms eqs. (6.333), (6.334) and (6.374), each defined *on the band* using the UV projector $P_x(\lambda_{\mathrm{UV}})$ and IR window $K_{\mathrm{IR}}^{(\ell)}$ Section 7.3. Band operations commute with BRST eq. (7.30), hence descend functorially to the physical sector $\mathcal{H}_{\mathrm{phys}}$ (Section 7.2).

D2. BRST health: unitarity, positivity, and causal propagation. On $\mathcal{H}_{\mathrm{phys}}$ the Kugo–Ojima quartet mechanism removes ghosts/longitudinals, yielding positive Källén–Lehmann densities for gauge-invariant observables Section 7.2.6 and eq. (7.12). The physical kinetic operator is hyperbolic with respect to $\bar{\Sigma}_{\mu\nu}^{(\ell)}$ eq. (7.15), and the physical mass operator is non-negative eqs. (7.13) and (7.14). No ghosts/tachyons occur at the symmetric point and causal propagation is well-posed (see also [442, 91, 82]).

D3. UV/IR instrumentation and certified plateaus. Families $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ have been fixed (Section 7.3.1), and the holosymmetric visibilities $\Lambda_\alpha(\lambda_{\mathrm{UV}}, \ell)$ exhibit a *non-empty joint plateau* $\mathfrak{P}_{\{\mathrm{law,state}\}}$ Section 7.3.5 and eq. (7.64). Plateau metrics satisfy the bounds eq. (7.137) and the quantitative criteria in Section 7.3.10. Regularisation stability holds across admissible (P,K) choices Section 7.3.7, and gauge/BRST robustness follows from Nielsen-type on-shell independence Section 7.3.6 and eq. (7.209). A representative operating point $(\lambda_\star, \ell_\star) \in \mathfrak{P}_{\{\mathrm{law,state}\}}$ is fixed via the certification pipeline Section 7.3.9, with bounded slope/curvature/oscillation.

D4. Holosymmetric probe instrumented and calibrated. A controlled two-path unitary U_{ctrl} has been constructed on $\mathcal{H}_{\mathrm{phys}}$ for the *law* and *state* channels Sections 7.4 and 7.4.2, yielding complex coherences $\mathcal{C}_\alpha$ and signed visibilities Λ_α Section 7.4.1. At the symmetric, anomaly-free baseline,

$$\Lambda_{\mathrm{law}}^\star = 1, \qquad \Lambda_{\mathrm{state}}^\star = 1 + \mathcal{O}(\epsilon^2) \quad (\epsilon \to 0 \text{ in eq. (7.124)}),$$

both evaluated at $(\lambda_\star, \ell_\star)$ and stable within plateau tolerances and the error budget Section 7.4.6. Deviations are diagnostic: $|\Lambda_{\mathrm{law}}| < 1$ signals law-level incoherence (e.g. anomaly or regulator pathology), whereas $|\Lambda_{\mathrm{state}}| < 1$ signals state-level symmetry tension or IR non-uniformity (triage in Section 7.4.4).

D5. Exact identities recorded as the baseline ledger. Global Ward identities for G eqs. (7.181) to (7.184), the Slavnov–Taylor master equation and its linearisation eqs. (7.189) and (7.190) (with vertex-level consequences eq. (7.194)), BRST nilpotency/equivalence eqs. (7.196) and (7.198), the Nielsen identities eqs. (7.201), (7.207) and (7.209), and the bandwise Callan–Symanzik equation eqs. (7.213) and (7.216) have been made explicit. These identities hold sectorwise with $\{\Pi_\beta\}$ Section 7.5.13, are *plateau-protected* under UV/IR scans eq. (7.234), and are compatible with BRST/gauge robustness [117, 442, 91, 114].

D6. Implications for subsequent analyses. The Quadrant I baseline is now fully specified: (i) a healthy, causal, anomaly-free physical sector; (ii) regulator- and gauge-robust visibilities anchored at a certified operating point; and (iii) an identity ledger constraining renormalisation and protecting physical conclusions. With anomaly filters enforced and potential breakings cohomologically trivial Section 7.5.14, the *law channel* obeys the unity identity eq. (7.240).

Table 7.1: Particle-like modes at the Quadrant I symmetric baseline (on $\mathcal{H}_{\text{phys}}$). All statements are plateau-certified and gauge/BRST robust; tags marked "provisional" require cross-quadrant confirmation.

Sector / origin	**Mode**	**Spin** s	**Mass / gap**	**DoF (3+1D)**
Gaiamiti $\hat{\mathbf{\Phi}}$	Tensor	2	massless	2 (helicities ± 2)
Tantrakyma $\hat{\mathbf{\Theta}}$	Gauge vector	1	massless	2 (helicities ± 1)
Scalars in $\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}}$	Scalar excitations	0	gapped ($m^2 > 0$)	1

In short: Quadrant I closes with a robust, scale-stable, and gauge-independent baseline—no ghosts, no tachyons, bright *law* and *state* channels, and the spectrum above. Any stronger particle-level tagging must now earn its status by surviving plateau tests across symmetry-broken quadrants (Sections 7.3 and 7.4).

Quadrant I baseline. Quadrant I now stands as a healthy, unbroken theory calibrated by explicit UV/IR controls (Section 7.3) and safeguarded by the full suite of BRST, Ward, and Slavnov–Taylor identities (Sections 7.2 and 7.5). *On the band*, the holosymmetric probe (Section 7.4) functions as a dial-stable interferometer: the *law* visibility is unity within plateau tolerances (eq. (7.139) and Section 7.3), excluding anomalies or regulator pathologies, and the *state* visibility is unity up to the symmetric-kick order, $\Lambda^{\star}_{\text{state}} = 1 + \mathcal{O}(\epsilon^2)$ (cf. eq. (7.128)), excluding hidden spontaneous breaking in the prepared state. Ghost and longitudinal artefacts are eliminated on $\mathcal{H}_{\text{phys}}$ by BRST cohomology and the quartet mechanism (Sections 7.2.6 and 7.5.10; [442, 108, 105, 104, 243, 82]), so the observed spectrum has the expected unbroken-phase content.

Gaiamiti (chronogeometric) sector $\hat{\mathbf{\Phi}}$*—tensor modes.* Transverse–traceless fluctuations of the *gaiamiti* field $\hat{\mathbf{\Phi}}(x)$ behave as a massless spin-2 mode with two physical polarisations in 3+1 dimensions—"graviton-like" in pattern—subject to our policy that such labels remain *provisional* until they survive symmetry-broken quadrants under plateau scans (Sections 7.3 and 7.4). BRST and Ward structures remove all non-physical pieces (Section 7.5; [243, 82]), and plateau tests ensure insensitivity to the precise UV cutoff or IR smoothing within the certified window (Section 7.3).

Tantrakyma (internal/gauge) sector $\hat{\mathbf{\Theta}}$*—vector modes.* Unbroken symmetry and the Slavnov–Taylor relations (Section 7.5; [243, 82]) yield massless transverse vectors (spin 1) from the *tantrakyma* field $\hat{\mathbf{\Theta}}(x)$. Longitudinal components and their ghost partners do not appear in

the physical cohomology (Section 7.2.6; [108, 442]). This matches the interferometric readout: bright *law* and *state* channels on the plateau (Sections 7.3 and 7.4).

Scalar content and mixing. Scalar fluctuations in both $\hat{\mathbf{\Phi}}$ and $\hat{\mathbf{\Theta}}$ are gapped at the symmetric point (positive Hessian eigenvalues; no tachyons) (Section 7.2 and eqs. (7.13) and (7.14)), and there are no Goldstones in Quadrant I. Allowed gauge-invariant gaiamiti–tantrakyma (Φ–Θ) mixings simply diagonalise into physical combinations; spurious longitudinal admixtures are removed by BRST (cf. eqs. (7.13) and (7.14), Section 7.2.6; [442, 243]).

Spin census and dimensional remark. The symmetric spectrum on $\mathcal{H}_{\text{phys}}$ thus reads: a massless spin-2 tensor (from $\hat{\mathbf{\Phi}}$, provisional), massless spin-1 gauge vectors (from $\hat{\mathbf{\Theta}}$), and massive spin-0 scalars. In 3+1 dimensions this corresponds to helicities ± 2 (tensor), ± 1 (vectors), and the usual scalar representation; in other dimensions the content reorganises under the appropriate little group but remains "spin-2 $\oplus$ spin-1 $\oplus$ spin-0" ([91, 82]). Mixing respects spin, and the BRST projection guarantees that only transverse, positive-norm modes populate $\mathcal{H}_{\text{phys}}$ (Section 7.2.6; [108, 442]).

Closing statement. Quadrant I therefore closes with a robust, scale-stable, and gauge-independent baseline: no ghosts, no tachyons, a bright *law* channel, a bright *state* channel, and a physically intuitive spectrum (Sections 7.3 to 7.5). Any stronger particle-level tagging—graviton, Higgs, apeiron, chrono–kymon—must now earn its status by surviving the plateau tests across the symmetry-broken quadrants (Sections 7.3 and 7.4; [243, 442]).

7.7 Quadrant II: Spontaneous Symmetry Breaking (SSB)

7.7.1 Hold the Law Symmetric (Keep H_0 Fixed)

Objective. In Quadrant II we probe *spontaneous* (not explicit) symmetry breaking. The *law* channel is kept strictly symmetric by using the same clean kinetic Hamiltonian H_0 (and its covariant Lagrangian counterpart) on both branches of the law interferometer (Sections 7.3 and 7.4). State preparation is free to explore asymmetric vacua; the microscopic law remains identical across branches. Thus any loss of coherence is attributed to the *state* channel, and Quadrant-II membership is preserved under branch overlay (Sections 7.4 and 7.4.1; [117, 442, 91]).

1.1 Clean symmetric baseline

We work on the BRST-closed physical sector $\mathcal{H}_{\text{phys}}$ with UV projector $P_x(\lambda_{\text{UV}})$ and IR window $K_{\text{IR}}^{(\ell)}$ chosen BRST-closed (ghost number 0) and commuting with the channel projectors (Sections 7.2 and 7.3; cf. eq. (7.30)). Concretely, the unbroken *law* is specified by the scale-tagged equations of motion

$$\mathcal{E}_{\mathbf{\Phi}}^{(\lambda_{\text{UV}},\ell)} = 0, \qquad \mathcal{E}_{\mathbf{\Theta}}^{(\lambda_{\text{UV}},\ell)} = 0,$$

as defined in eqs. (6.333) and (6.334) (BRST reading via P_{phys}; ghosts/longitudinals decouple in cohomology). Their quadratic expansion around a G-invariant background determines the band-limited Hessian $\mathbb{H}^{(\lambda_{\text{UV}},\ell)}$ with kinetic blocks $\mathcal{K}_T, \mathcal{K}_C$ and potential (mass/mixing) blocks

$\mathcal{M}_{\bullet\bullet}$ (eq. (7.10); see Section 7.2.5). On $\mathcal{H}_{\rm phys}$ only the transverse parts contribute; physical poles are read from the $\Pi_{\rm T}$-projected blocks of $\mathbb{H}^{(\lambda_{\rm UV},\ell)}$, and these are Nielsen/BRST-stable under the UV/IR scans (Section 7.5).

Hamiltonian generator. Both branches of the interferometer use the *same* relational Hamiltonian $\hat{H}_0(t;\lambda_{\rm UV},\ell)$, obtained (on the band, inside the IR window) as the Legendre transform of the covariant quadratic Lagrangian whose kernel is $\mathbb{H}^{(\lambda_{\rm UV},\ell)}$. Equivalently, the branch unitaries $U_j^{(\alpha)}(T)$ are generated by BRST-compatible Hamiltonians that coincide in the law channel and differ only by ζ-exact deformations when we change presentation (cohomologically trivial on $\mathcal{H}_{\rm phys}$); see eqs. (7.97) and (7.130). Thus "keep H_0 fixed'' means: (i) no symmetry-breaking couplings in $\mathbb{H}^{(\lambda_{\rm UV},\ell)}$; (ii) identical G-invariant kinetic/mass blocks across branches; and (iii) any branch decoration in the law channel is BRST-exact and cancels in physical matrix elements (equivalence theorem).

Explicit form (general d). Write the operator field and momentum multiplets as

$$\hat{\boldsymbol{\varphi}}^{\mathsf{T}} := \big(\hat{\boldsymbol{\Phi}},\, \hat{\boldsymbol{\Theta}}\big), \qquad \hat{\boldsymbol{\pi}}^{\mathsf{T}} := \big(\hat{\pi}_{\boldsymbol{\Phi}},\, \hat{\pi}_{\boldsymbol{\Theta}}\big),$$

where the canonical momenta are taken along a chosen foliation with unit normal n_μ via the momentum currents of Definitions 6.267 and 6.268:

$$\hat{\pi}_{\boldsymbol{\Phi}} := n_\mu\, \Pi^\mu_{\boldsymbol{\Phi}}, \quad \Pi^\mu_{\boldsymbol{\Phi}} = \bar{\Sigma}^{\mu\nu}\, \mathcal{G}_T\big(\nabla_\nu \hat{\boldsymbol{\Phi}}\big), \qquad \hat{\pi}_{\boldsymbol{\Theta}} := n_\mu\, \Pi^\mu_{\boldsymbol{\Theta}}, \quad \Pi^\mu_{\boldsymbol{\Theta}} = \bar{\Sigma}^{\mu\nu}\, \mathcal{G}_C\big(\nabla_\nu \hat{\boldsymbol{\Theta}}\big).$$

Introduce the band/IR–tagged multiplets (cf. Definition 6.282 and Section 6.12.4)

$$\hat{\boldsymbol{\varphi}}_{\lambda_{\rm UV},\ell} := \mathfrak{B}_{\lambda_{\rm UV},\ell}[\hat{\boldsymbol{\varphi}}], \qquad \hat{\boldsymbol{\pi}}_{\lambda_{\rm UV},\ell} := \mathfrak{B}_{\lambda_{\rm UV},\ell}[\hat{\boldsymbol{\pi}}].$$

Let the quadratic kernels be

$$\mathcal{K} = \begin{pmatrix} \mathcal{K}_T & 0 \\ 0 & \mathcal{K}_C \end{pmatrix}, \qquad \mathcal{M}^2 = \begin{pmatrix} \mathcal{M}^2_{\Phi\Phi} & \mathcal{M}^2_{\Phi\Theta} \\ \mathcal{M}^2_{\Theta\Phi} & \mathcal{M}^2_{\Theta\Theta} \end{pmatrix},$$

where $\mathcal{K}_T, \mathcal{K}_C$ are the positive (self-adjoint) kinetic operators induced by the pairings g_T, g_C and the background weights $\bar{\Sigma}^{(\ell)\mu\nu}$, and $\mathcal{M}^2_{\bullet\bullet}$ are the Hessian (mass/mixing) blocks from the quadratic expansion about $(\bar{\Phi},\bar{\Theta})$ (cf. Proposition 7.2). Then the law Hamiltonian used on both branches is

$$\hat{H}_0(t;\lambda_{\rm UV},\ell) = \frac{1}{2}\int d^d x \left[\big(\hat{\boldsymbol{\pi}}_{\lambda_{\rm UV},\ell}\big)^\top \mathcal{K}\, \hat{\boldsymbol{\pi}}_{\lambda_{\rm UV},\ell} \;+\; \big(\hat{\boldsymbol{\varphi}}_{\lambda_{\rm UV},\ell}\big)^\top \mathcal{M}^2\, \hat{\boldsymbol{\varphi}}_{\lambda_{\rm UV},\ell}\right] \;+\; \big\{\hat{Q}_{\rm BRST},\, \Psi_\zeta\big\}. \tag{7.241}$$

Remarks. (i) The explicit $K^{(\ell)}_{\rm IR} P_x(\lambda_{\rm UV})\,(\cdot)\, P_x(\lambda_{\rm UV}) K^{(\ell)}_{\rm IR}$ insertions are absorbed into the definitions of the tagged operators via $\mathfrak{B}_{\lambda_{\rm UV},\ell}$ (cf. Definition 6.282); expanding them out reproduces our original "UV then IR" order. (ii) No projector $\Pi_{\rm T}$ is applied here: retaining the full multiplet ensures the off-diagonal mixing $\mathcal{M}^2_{\Phi\Theta}, \mathcal{M}^2_{\Theta\Phi}$ contributes as intended. (iii) Evaluating on $\mathcal{H}_{\rm phys}$ one may insert $\mathsf{P}_{\rm phys}$ before/after $\hat{H}_0$; by Section 7.1.3, the $\{\hat{Q}_{\rm BRST}, \Psi_\zeta\}$ piece alters only unphysical sectors and leaves physical spectra/visibilities gauge-parameter independent.

Kernel (bi-local) form, without new symbols. Define the band-projected quadratic kernel

$$\begin{aligned}\widetilde{\mathbb{H}}^{(\lambda_{\mathrm{UV}},\ell)} &= \mathrm{diag}\Big(K_{\mathrm{IR}}^{(\ell)}P_x(\lambda_{\mathrm{UV}})\Pi_{\mathrm{T}}, K_{\mathrm{IR}}^{(\ell)}P_x(\lambda_{\mathrm{UV}})\Pi_{\mathrm{T}}\Big)\\ &\quad\times\begin{pmatrix}\mathcal{K} & 0\\ 0 & \mathcal{M}^2\end{pmatrix}\mathrm{diag}\Big(K_{\mathrm{IR}}^{(\ell)}P_x(\lambda_{\mathrm{UV}})\Pi_{\mathrm{T}}, K_{\mathrm{IR}}^{(\ell)}P_x(\lambda_{\mathrm{UV}})\Pi_{\mathrm{T}}\Big).\end{aligned} \tag{7.242}$$

With

$$\hat\pi(\mathbf{x}) := \begin{pmatrix}\hat\pi_{\mathbf{\Phi}}(\mathbf{x})\\ \hat\pi_{\mathbf{\Theta}}(\mathbf{x})\end{pmatrix}, \qquad \hat\varphi(\mathbf{x}) := \begin{pmatrix}\hat{\mathbf{\Phi}}(\mathbf{x})\\ \hat{\mathbf{\Theta}}(\mathbf{x})\end{pmatrix},$$

the Hamiltonian reads

$$\hat H_0(t;\lambda_{\mathrm{UV}},\ell) = \frac{1}{2}\int d^dx\, d^dy\, \begin{pmatrix}\hat\pi(\mathbf{x})\\ \hat\varphi(\mathbf{x})\end{pmatrix}^{\top}\widetilde{\mathbb{H}}^{(\lambda_{\mathrm{UV}},\ell)}(\mathbf{x},\mathbf{y})\begin{pmatrix}\hat\pi(\mathbf{y})\\ \hat\varphi(\mathbf{y})\end{pmatrix} + \big\{\hat Q_{\mathrm{BRST}},\,\Psi_\zeta\big\}. \tag{7.243}$$

Ghost/longitudinal decoupling. Gauge fixing enters as the ζ-exact term $\{\,\hat Q_{\mathrm{BRST}},\Psi_\zeta\,\}$; the Faddeev–Popov/longitudinal sectors sit in separate blocks of $\mathbb{H}^{(\lambda_{\mathrm{UV}},\ell)}$ and are killed on $\mathcal{H}_{\mathrm{phys}}$ by the quartet mechanism ($\mathsf{P}_{\mathrm{phys}}\Box_{\mathrm{FP}}\mathsf{P}_{\mathrm{phys}} = 0 = \mathsf{P}_{\mathrm{phys}}\Pi_{\mathrm{L}}\mathsf{P}_{\mathrm{phys}}$).

All band operations are BRST-closed and commute with the symmetry generators; in particular,

$$[\hat Q_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = [\hat Q_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}] = 0, \qquad [\mathsf{J}_\alpha, P_x] = [\mathsf{J}_\alpha, K_{\mathrm{IR}}^{(\ell)}] = 0 \quad (\forall\,\alpha), \tag{7.244}$$

so the scale-tagged objects descend to $\mathcal{H}_{\mathrm{phys}}$, and on-shell visibilities are gauge-parameter independent by the Nielsen identities (cf. eq. (7.115) and Section 7.5).

1.2 Law-channel branches and overlay

Introduce the ancilla two-path interferometer with branches $b \in \{1,2\}$ (Section 7.4). The *law* channel manipulates only the *presentation* of the *same* symmetric law fixed in §1.1; no explicit breaking is ever injected. Accordingly we choose branch operators $U_b^{(\mathrm{law})}$ that preserve the BRST charge, the symmetric Hamiltonian, and all G-generators:

$$\Big[U_b^{(\mathrm{law})},\,\hat H_0(t;\lambda_{\mathrm{UV}},\ell)\Big] = \Big[U_b^{(\mathrm{law})},\,\hat Q_{\mathrm{BRST}}\Big] = \Big[U_b^{(\mathrm{law})},\,\mathsf{J}_\alpha\Big] = 0 \quad (\forall\,\alpha), \tag{7.245}$$

with $\hat H_0$ as in eqs. (7.241) and (7.243). Compatibly with the scale-tagged pipeline, they also commute with the UV/IR/transverse projectors:

$$\Big[U_b^{(\mathrm{law})},\,P_x(\lambda_{\mathrm{UV}})\Big] = \Big[U_b^{(\mathrm{law})},\,K_{\mathrm{IR}}^{(\ell)}\Big] = \Big[U_b^{(\mathrm{law})},\,\Pi_{\mathrm{T}}\Big] = 0, \tag{7.246}$$

so that all band operations remain BRST-closed and G-covariant (cf. eq. (7.244) and Section 7.5). These conditions ensure that $U_b^{(\mathrm{law})}$ act as symmetry-preserving (Nielsen-compatible) reparametrisations of the same H_0.

Explicit realisations (presentation moves). It is often convenient to take $U_b^{(\mathrm{law})}$ from one (or a product) of the following classes, all of which satisfy eqs. (7.245) and (7.246) on $\mathcal{H}_{\mathrm{phys}}$:

1. **BRST-exact similarities:**
$$U_b^{(\mathrm{law})} = \exp\Big(i\{\,\hat{Q}_{\mathrm{BRST}},\,\Delta\Psi_b\,\}\Big), \tag{7.247}$$
where $\Delta\Psi_b$ is a change of the gauge-fixing fermion (e.g. a shift of ζ in Ψ_ζ); these are Nielsen-compatible on plateaus (Section 7.3; [117]).

2. **Background-field reparametrisations:** $U_b^{(\mathrm{law})}$ that reshuffle the background/quantum split without altering G or BRST structure (background-field method; [114]).

3. **Field redefinitions (equivalence moves):** local, invertible redefinitions that leave on-shell matrix elements invariant; at quadratic level these appear as orthogonal rotations within the Φ-Θ sector that commute with $\mathcal{K}$ and $\mathcal{M}^2$ (cf. eq. (7.241)).

4. **Regulator placement/order moves:** permutations of $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}, \Pi_{\mathrm{T}}$ that pairwise commute on the certified plateau window (Sections 7.3 and 7.4.5), leaving $\hat{H}_0$ isospectral.

Overlay on system⊗ancilla. With ancilla basis $\{|1\rangle, |2\rangle\}$, the controlled law overlay is
$$\mathcal{U}_{\mathrm{law}} = |1\rangle\langle 1| \otimes U_1^{(\mathrm{law})} + |2\rangle\langle 2| \otimes U_2^{(\mathrm{law})}, \tag{7.248}$$
which preserves (i) BRST-physicality and (ii) exact G-symmetry of the law on $\mathcal{H}_{\mathrm{phys}}$. Any inter-branch difference is a Nielsen-type presentation/regulator placement that leaves on-shell observables invariant on certified plateaus (Sections 7.3 and 7.4.5; [117, 114]).

Law-channel contrast (why it stays at unity in Quadrant II). Define the branch-difference unitary
$$\Delta U_{\mathrm{law}} := \Big(U_2^{(\mathrm{law})}\Big)^\dagger U_1^{(\mathrm{law})}. \tag{7.249}$$
For any BRST-physical state $|\Psi\rangle \in \mathcal{H}_{\mathrm{phys}}$ and any physical observable $\mathcal{O}$ (BRST-closed, ghost-number 0) evaluated on the plateau,
$$\langle\Psi|\mathcal{O}|\Psi\rangle = \langle\Psi|\,\Big(\Delta U_{\mathrm{law}}\Big)^\dagger\,\mathcal{O}\,\Delta U_{\mathrm{law}}\,|\Psi\rangle, \tag{7.250}$$
so the controlled-interferometer visibility in the *law* channel reduces to
$$\mathcal{V}_{\mathrm{law}} = \Big|\langle\Psi|\,\Delta U_{\mathrm{law}}\,|\Psi\rangle\Big|. \tag{7.251}$$
A convenient sufficient condition is
$$\Delta U_{\mathrm{law}} = \exp\Big(i\{\,\hat{Q}_{\mathrm{BRST}},\,\Delta\Psi\,\}\Big), \tag{7.252}$$
for which $\Delta U_{\mathrm{law}} = \mathbf{1}$ in BRST cohomology by the Nielsen identities (cf. Section 7.5), and hence
$$\mathcal{V}_{\mathrm{law}} = 1 \qquad \text{on } \mathcal{H}_{\mathrm{phys}} \text{ (plateau)}. \tag{7.253}$$
More generally, any $U_b^{(\mathrm{law})}$ satisfying eqs. (7.245) and (7.246) yields isospectral branches and identical on-shell S-matrix elements (equivalence theorem), which again implies eq. (7.253) for Quadrant II.

Anomaly caveat. If the symmetry or BRST structure were anomalous in the band of interest, eq. (7.245) would fail and a genuine law-channel contrast could appear; such cases are excluded by the admissibility checks in Section 7.4.5.

1.3 Law visibility and plateau protection

With a symmetric calibration state ρ_0 (BRST-closed, ghost number 0) the *law*-channel visibility is read from the ancilla coherence after band projection (Section 7.4.1 and eq. (7.115)):

$$\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}},\ell) = \frac{\left|\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(P_x(\lambda_{\mathrm{UV}})\,K_{\mathrm{IR}}^{(\ell)}\,U_1^{(\mathrm{law})\dagger}U_2^{(\mathrm{law})}\,\rho_0\Big)\right|}{\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(P_x(\lambda_{\mathrm{UV}})\,K_{\mathrm{IR}}^{(\ell)}\,\rho_0\Big)}\,. \tag{7.254}$$

Let $\Delta U_{\mathrm{law}} := U_1^{(\mathrm{law})\dagger}U_2^{(\mathrm{law})}$ (cf. eq. (7.249)). Using the commutation conditions from §1.2,

$$[\Delta U_{\mathrm{law}},\,\hat{Q}_{\mathrm{BRST}}] = [\Delta U_{\mathrm{law}},\,\hat{H}_0] = [\Delta U_{\mathrm{law}},\,\mathsf{J}_\alpha] = [\Delta U_{\mathrm{law}},\,P_x] = [\Delta U_{\mathrm{law}},\,K_{\mathrm{IR}}^{(\ell)}] = 0, \tag{7.255}$$

together with cyclicity of the trace on $\mathcal{H}_{\mathrm{phys}}$, the numerator of eq. (7.254) is invariant under presentation moves. In particular, if

$$\Delta U_{\mathrm{law}} = \exp\Big(i\{\hat{Q}_{\mathrm{BRST}},\eta_{\mathrm{law}}\}\Big) = \exp\Big(i\,\zeta\eta_{\mathrm{law}}\Big), \tag{7.256}$$

with $\mathfrak{g}(\eta_{\mathrm{law}}) = -1$ (hence $\mathfrak{g}(\zeta\eta_{\mathrm{law}}) = 0$), then $\Delta U_{\mathrm{law}} = \mathbf{1}$ in BRST cohomology (Nielsen identities; Section 7.5), and

$$\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}},\ell) = 1 \qquad \text{(ideal presentation invariance, certified plateau).} \tag{7.257}$$

The same conclusion holds for background-field reparametrisations and on-shell–equivalent field redefinitions that satisfy eqs. (7.245) and (7.246) (equivalence theorem).

Plateau protection and tolerances. On a finite UV/IR window, residual regulator placement and slow parameter drift introduce controlled deviations. A convenient operational budget is

$$1-\Lambda_{\mathrm{law}} = \mathcal{O}\Big(\|[U_b^{(\mathrm{law})},P_x]\| + \|[U_b^{(\mathrm{law})},K_{\mathrm{IR}}^{(\ell)}]\| + \Big\|\nabla_{(\ln\lambda_{\mathrm{UV}},\ln\ell)}\mathcal{O}_{\mathrm{phys}}\Big\| + \text{curvatures}\Big), \tag{7.258}$$

so that the certified bounds of eq. (7.137) and Section 7.4.5 yield

$$\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}},\ell) = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}}), \tag{7.259}$$

where $\varepsilon_{\mathrm{plat}}$ encodes the admissible gradients/oscillations/curvatures across the $(\ln\lambda_{\mathrm{UV}},\ln\ell)$ window. In this regime the Slavnov–Taylor/Ward/Nielsen identities (Section 7.5) ensure gauge-parameter independence of on-shell observables, and any branch dependence from $U_b^{(\mathrm{law})}$ is cohomologically trivial ([117, 442]).

Certification protocol (operational checks). To diagnose and keep $|\Lambda_{\mathrm{law}}| \approx 1$ on the plateau:

1. **Branch-swap invariance:** verify Λ_{law} is unchanged under $U_1^{(\mathrm{law})} \leftrightarrow U_2^{(\mathrm{law})}$.
2. **Gauge scan (Nielsen test):** vary the gauge parameter ζ in $\{\hat{Q}_{\mathrm{BRST}},\Psi_\zeta\}$; check
$$\partial_\zeta\Lambda_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}}). \tag{7.260}$$
3. **Regulator order test:** permute $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$, Π_{T}; confirm changes are within $\mathcal{O}(\varepsilon_{\mathrm{plat}})$.
4. **Flatness check:** ensure $\partial_{\ln\lambda_{\mathrm{UV}}}\Lambda_{\mathrm{law}}$ and $\partial_{\ln\ell}\Lambda_{\mathrm{law}}$ satisfy the plateau bounds of eq. (7.137).

Exclusion clauses. A persistent deficit $|\Lambda_{\rm law}| < 1-\delta$ with $\delta \gg \varepsilon_{\rm plat}$ signals a violation of the Quadrant II premises: (i) departure from the BRST-closed symmetric class (e.g., anomaly in the band of interest), or (ii) contamination by state-channel operations. Both are disallowed at this step (Sections 7.4 and 7.4.4; [117, 442]).

Lemma 7.334 (Plateau presentation invariance)**.** *Assume the branch-difference unitary* $\Delta U_{\rm law}$ *obeys the commutators of eq.* (7.255) *and admits a BRST-exact presentation* $\Delta U_{\rm law} = \exp\big(i\{\hat{Q}_{\rm BRST},\, \Delta\Psi\}\big)$*. Then for any BRST-closed calibration state* ρ_0 *of ghost number 0,* $\Lambda_{\rm law}(\lambda_{\rm UV}, \ell) = 1$ *on the certified plateau, i.e. eq.* (7.257) *holds.*

Proof. Start from eq. (7.254) and write the numerator $N := \mathrm{Tr}_{\mathcal{H}_{\rm phys}}\big(P_x K_{\rm IR}^{(\ell)}\, \Delta U_{\rm law}\, \rho_0\big)$. By eq. (7.255) and eq. (7.244) one has $P_x K_{\rm IR}^{(\ell)}\, \Delta U_{\rm law} = \Delta U_{\rm law}\, P_x K_{\rm IR}^{(\ell)}$. Consider $\Delta U_{\rm law}(s) := \exp\big(is\{\hat{Q}_{\rm BRST},\, \Delta\Psi\}\big)$ with $s \in [0,1]$ and $N(s) := \mathrm{Tr}_{\mathcal{H}_{\rm phys}}\big(P_x K_{\rm IR}^{(\ell)}\, \Delta U_{\rm law}(s)\, \rho_0\big)$. Then

$$\frac{dN}{ds} = i\ \mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(P_x K_{\rm IR}^{(\ell)}\, \{\hat{Q}_{\rm BRST},\, \Delta\Psi\}\, \Delta U_{\rm law}(s)\, \rho_0\Big) = 0$$

by the graded-cyclicity identity eq. (7.331) (since $P_x K_{\rm IR}^{(\ell)}$ and ρ_0 are BRST-closed). Thus $N(1) = N(0) = \mathrm{Tr}_{\mathcal{H}_{\rm phys}}\big(P_x K_{\rm IR}^{(\ell)}\, \rho_0\big)$, and $\Lambda_{\rm law} = 1$ follows from eq. (7.254). □

Corollary 7.335 (Equivalence moves)**.** *Background-field reparametrisations and on–shell–equivalent local field redefinitions that satisfy the commutator conditions eqs.* (7.245) *and* (7.246) *leave* $N = \mathrm{Tr}_{\mathcal{H}_{\rm phys}}\big(P_x K_{\rm IR}^{(\ell)}\, \Delta U_{\rm law}\, \rho_0\big)$ *invariant. Either they can be cast in the BRST-exact form eq.* (7.256) *on the physical band, or they preserve the band–projected physical algebra so that eq.* (7.331) *applies after reduction to cohomology. Consequently, by Lemma 7.334 one has* $\Lambda_{\rm law}(\lambda_{\rm UV}, \ell) = 1$ *on the certified plateau, and together with eq.* (7.259) *this gives* $\Lambda_{\rm law} = 1 + \mathcal{O}(\varepsilon_{\rm plat})$ *off the ideal limit.*

1.4 Quadrant preservation under overlay

The quadrant predicate is defined by the dyadic status of *law* vs. *state* together with their operational visibilities (table 6.1, Corollary 6.232, and Section 6.11.6). Since $\mathcal{U}_{\rm law}$ of §1.2 leaves $\hat{H}_0(t; \lambda_{\rm UV}, \ell)$, the BRST charge, and the G-action unchanged—while commuting with the UV/IR/transverse projectors—no explicit symmetry breaking is introduced and no emergent-law flow is triggered in the law channel (Sections 7.3 and 7.5). In particular, the kernels $\mathcal{K}, \mathcal{M}^2$ that define $\hat{H}_0$ remain G-invariant and identical across branches (eqs. (7.241) and (7.243)), so the overlay cannot move the system out of Quadrant II into QIV (explicit breaking) or QIII (law deformation).

Overlay acts trivially on the law kernel. From eqs. (7.245) and (7.246), the adjoint action of each branch operator leaves the band-projected Hamiltonian fixed:

$$\mathrm{Ad}_{U_b^{(\rm law)}}\Big(\hat{H}_0(t; \lambda_{\rm UV}, \ell)\Big) = \hat{H}_0(t; \lambda_{\rm UV}, \ell), \qquad \mathrm{Ad}_{U_b^{(\rm law)}}\Big(\mathbb{H}^{(\lambda_{\rm UV}, \ell)}\Big) = \mathbb{H}^{(\lambda_{\rm UV}, \ell)}\,, \tag{7.261}$$

hence the spectral data (poles, residues on $\mathcal{H}_{\rm phys}$) and the on-shell algebra generated by the $\Pi_{\rm T}$-projected blocks are unchanged. Together with eq. (7.248), this means the overlay realizes

an automorphism of the band-projected physical algebra that is trivial in BRST cohomology (Nielsen).

Proposition 7.336 (Quadrant II is preserved under law overlay)**.** *Let the branch operators $U_b^{(\mathrm{law})}$ satisfy eqs. (7.245) and (7.246). If the pre-overlay configuration lies in Quadrant II (law symmetric, state possibly asymmetric), then the post-overlay configuration also lies in Quadrant II.*

Proof. **Law symmetry.** By eq. (7.261) the kernels $\mathcal{K}, \mathcal{M}^2$ remain G-invariant and identical on both branches, and $\hat{Q}_{\mathrm{BRST}}$ is preserved. Therefore no explicit breaking or law deformation occurs.

Law visibility. On certified plateaus, eqs. (7.257) and (7.259) give $\Lambda_{\mathrm{law}} = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$, independent of the presentation (Nielsen identities, Section 7.5). Hence the law-channel signature remains that of a symmetric law.

State channel. The overlay acts only on the law presentation; state preparation and the associated order parameters/Goldstone diagnostics (defined in Section 7.4.1 and used later in the SSB analysis) are unaffected. Thus any volume-scaling loss of state visibility persists, realizing the *state-asymmetric / law-symmetric* cell. □

Corollary 7.337 (No drift to QIII/QIV)**.** *Under the hypotheses of Proposition 7.336, transitions to QIII (law deformation) or QIV (explicit breaking) would require failure of eq. (7.245) or eq. (7.246) (or a BRST/gauge anomaly in the band). These are excluded by construction and by the admissibility checks of Section 7.4.5. Hence the overlay cannot induce QII→QIII/QIV drift.*

Robustness on finite windows. On finite UV/IR windows, any deviation is bounded by the plateau budget eq. (7.258), so that

$$1 - \Lambda_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}})\,, \qquad \text{with } \varepsilon_{\mathrm{plat}} \text{ set by eq. (7.137).} \tag{7.262}$$

Thus quadrant membership is stable under overlay within certified tolerances.

Operational readout. The global map's Quadrant II signature—$|\Lambda_{\mathrm{law}}| \approx 1$ with SSB appearing solely in the state channel—follows from eqs. (7.257) and (7.259) and the interferometric readout in Section 7.4.1. This matches the standard SSB phenomenology in the state sector while keeping the microscopic law untouched ([91, 82]).

Lemma 7.338 (Converse: significant law-visibility deficit implies hypothesis failure)**.** *Assume the branch operators obey eqs. (7.245) and (7.246), the exact-identity sector is anomaly-free (Section 7.5), and the UV/IR window satisfies the plateau bounds of eq. (7.137). Then by eqs. (7.257) and (7.259) one has $|1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell)| = \mathcal{O}(\varepsilon_{\mathrm{plat}})$ on any certified window. Consequently, if on such a certified window one observes a deficit $|1 - \Lambda_{\mathrm{law}}| \geq \delta$ with $\delta \gg \varepsilon_{\mathrm{plat}}$, at least one hypothesis must be false—i.e. either a commutator in eqs. (7.245) and (7.246) fails, or the exact-identity/BRST closure fails (anomaly), or the window is not plateau-certified (violation of eq. (7.137)).*

Proof. Under the stated hypotheses, eq. (7.257) gives the ideal limit $\Lambda_{\mathrm{law}} = 1$, and eq. (7.259) refines this to the finite-window estimate $1 - \Lambda_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}})$. A measured deficit with $\delta \gg \varepsilon_{\mathrm{plat}}$ contradicts these conclusions; by contrapositive, at least one hypothesis is violated. □

Operational diagnostic. When the premise of Lemma 7.338 fails in data, localize the cause via the protocol in §1.3: (i) branch-swap invariance; (ii) Nielsen slope $\partial_\zeta \Lambda_{\mathrm{law}}$ (eq. (7.260)); (iii) regulator-order permutations; (iv) flatness checks against eq. (7.137). Persistent violations witness either law-channel contamination or loss of plateau certification.

1.5 Implementation checklist (acceptance tests)

For any operator $\mathcal{A}$ acting on the full Hilbert space, we evaluate it on the band-projected physical sector with the induced operator norm

$$\|\mathcal{A}\|_{\mathrm{phys}} := \Big\| \, \mathsf{P}_{\mathrm{phys}} \, P_x(\lambda_{\mathrm{UV}}) \, K_{\mathrm{IR}}^{(\ell)} \, \mathcal{A} \, K_{\mathrm{IR}}^{(\ell)} \, P_x(\lambda_{\mathrm{UV}}) \, \mathsf{P}_{\mathrm{phys}} \, \Big\| \,, \tag{7.263}$$

where $\|\cdot\|$ is the operator norm on $\mathcal{H}_{\mathrm{phys}}$ and $\mathsf{P}_{\mathrm{phys}}$ is the BRST projector (cf. §1.1).

- **Commutators (law/BRST/G preservation).** Verify the exact commutators eq. (7.245) on the band; when implemented numerically/operationally, enforce the quantitative tolerance

$$\Big\|[U_b^{(\mathrm{law})}, \hat{H}_0]\Big\|_{\mathrm{phys}} + \Big\|[U_b^{(\mathrm{law})}, \hat{Q}_{\mathrm{BRST}}]\Big\|_{\mathrm{phys}} + \sum_\alpha \Big\|[U_b^{(\mathrm{law})}, \mathsf{J}_\alpha]\Big\|_{\mathrm{phys}} \;\le\; \varepsilon_{\mathrm{comm}} \,, \tag{7.264}$$

  and certify that the branch difference ΔU_{law} is a presentation move:

$$\Delta U_{\mathrm{law}} = \exp\Big(i\{\hat{Q}_{\mathrm{BRST}}, \eta_{\mathrm{law}}\}\Big) = \exp\Big(i\,\zeta \eta_{\mathrm{law}}\Big) \quad \text{(cf. eqs. (7.249) and (7.256)).}$$

  This guarantees cohomological triviality on $\mathcal{H}_{\mathrm{phys}}$ (Section 7.5).

- **Band compatibility (projector commutators).** Enforces regulator–order invariance on certified plateaus (Section 7.3 and eq. (7.258))

$$\begin{aligned} \Big\|[P_x(\lambda_{\mathrm{UV}}),\, U_b^{(\mathrm{law})}]\Big\|_{\mathrm{phys}} \;+\; & \Big\|[K_{\mathrm{IR}}^{(\ell)},\, U_b^{(\mathrm{law})}]\Big\|_{\mathrm{phys}} \\ & + \Big\|[\Pi_{\mathrm{T}},\, U_b^{(\mathrm{law})}]\Big\|_{\mathrm{phys}} \le \varepsilon_{\mathrm{reg}} \,. \end{aligned} \tag{7.265}$$

- **Exact-identity sector (ST/Ward/Nielsen).** Enforce Slavnov–Taylor and Ward closures on the band (cf. Section 7.5); aggregate their residuals into an identity defect

$$\Delta_{\mathrm{id}}(\lambda_{\mathrm{UV}}, \ell) := \Delta_{\mathrm{ST}} + \Delta_{\mathrm{Ward}} \;\le\; \varepsilon_{\mathrm{id}} \,, \tag{7.266}$$

  and verify Nielsen independence of the law visibility via the gauge scan $\partial_\zeta \Lambda_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}})$ (eq. (7.260)). Any violation triggers the anomaly filter and cohomological checks (cf. §1.3 Exclusion clauses).

- **Plateau certification (flatness and robustness).** Locate windows $(\lambda_{\mathrm{UV}}, \ell)$ for which the gradient/oscillation/curvature bounds of Λ_{law} satisfy eq. (7.137), and regulator robustness holds (cf. eq. (7.258)). Record the certified budget $\varepsilon_{\mathrm{plat}}$ and verify

$$\Big|1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell)\Big| \;\le\; C_{\mathrm{plat}} \, \varepsilon_{\mathrm{plat}} \,, \tag{7.267}$$

  for a protocol-dependent constant $C_{\mathrm{plat}} \sim \mathcal{O}(1)$ (cf. eq. (7.259)).

- **Swap and ordering invariances (sanity checks).** Test branch-swap invariance and regulator ordering; accept if

$$\begin{aligned}\left|\Lambda_{\rm law}[U_1^{(\rm law)},U_2^{(\rm law)}]-\Lambda_{\rm law}[U_2^{(\rm law)},U_1^{(\rm law)}]\right|&\le\varepsilon_{\rm plat}\,,\\ \left|\Lambda_{\rm law}[\ldots P_xK_{\rm IR}\Pi_{\rm T}\ldots]-\Lambda_{\rm law}[\ldots K_{\rm IR}P_x\Pi_{\rm T}\ldots]\right|&\le\varepsilon_{\rm plat}\,,\end{aligned}\tag{7.268}$$

  consistent with eqs. (7.246) and (7.258).

- **Spectral health (physical band).** Check positivity/hyperbolicity of the $\Pi_{\rm T}$-projected Hessian blocks defining $\hat{H}_0$ on the certified window (cf. eqs. (7.241) and (7.243)). Reject if spurious longitudinal/ghost leakage is detected (quartet mechanism failure), or if poles/residues drift beyond plateau tolerances.

- **Converse trigger (escalation).** If a statistically significant deficit $|1-\Lambda_{\rm law}|\ge\delta$ with $\delta\gg\varepsilon_{\rm plat}$ is observed on a certified window, invoke the converse Lemma Lemma 7.338 and run the localization protocol of §1.3 (branch swap, Nielsen slope, regulator permutations, flatness checks).

1.6 Failure modes and diagnostics

Diagnostic decomposition (quantitative triage). Define the law-channel deficit

$$\delta_{\rm law}(\lambda_{\rm UV},\ell):=1-\Lambda_{\rm law}(\lambda_{\rm UV},\ell)\quad(\ge0).\tag{7.269}$$

On a certified window, eqs. (7.258) and (7.259) imply the schematic bound

$$\begin{aligned}\delta_{\rm law}\ \lesssim\ & C_{\rm comm}\Big(\big\|[U_b^{(\rm law)},\hat{H}_0]\big\|_{\rm phys}+\big\|[U_b^{(\rm law)},\hat{Q}_{\rm BRST}]\big\|_{\rm phys}+\sum_\alpha\big\|[U_b^{(\rm law)},\mathsf{J}_\alpha]\big\|_{\rm phys}\Big)\\ &+C_{\rm reg}\sum_{X\in\{P_x,K_{\rm IR}^{(\ell)},\Pi_{\rm T}\}}\big\|[X,U_b^{(\rm law)}]\big\|_{\rm phys}\\ &+C_{\rm id}\big(\Delta_{\rm ST}+\Delta_{\rm Ward}\big)+C_\zeta\,|\partial_\zeta\Lambda_{\rm law}|+C_{\rm plat}\,\varepsilon_{\rm plat}+C_{\rm inst}\,\varepsilon_{\rm inst}\quad(+\text{ higher orders}),\end{aligned}\tag{7.270}$$

where the norms/defects are those of eqs. (7.260) and (7.263) to (7.266), and $\varepsilon_{\rm inst}$ is set by the instrumental budget in eq. (7.271) below. This consolidates the acceptance tests of §1.5 into a single triage inequality.

- $|\Lambda_{\rm law}|<1$ **off-plateau.** The typical cause is residual regulator placement and/or an insufficiently flat UV/IR scan. Re-certify the window $(\lambda_{\rm UV},\ell)$ until the gradient/curvature/oscillation bounds of eq. (7.137) hold and regulator robustness is satisfied (Sections 7.3.3, 7.3.7 and 7.4.5). *Why:* within certified windows one has $\Lambda_{\rm law}=1+\mathcal{O}(\varepsilon_{\rm plat})$ up to regulator tolerances (eq. (7.259)), so deficits point to a plateau failure rather than genuine law incoherence.

- **Persistent** $|\Lambda_{\rm law}|<1$ **on-plateau.** This violates the Quadrant II premise (symmetric law on both branches). Perform the following triage (each line maps to a term in eq. (7.270)):

(i) *Branch commutators (§1.5).* Re-check eq. (7.245); certify ΔU_{law} is a presentation move

$$\Delta U_{\mathrm{law}} = \exp\Big(i\{\hat{Q}_{\mathrm{BRST}}, \eta_{\mathrm{law}}\}\Big) = \exp\Big(i\,\zeta\eta_{\mathrm{law}}\Big)$$

(cf. eqs. (7.249) and (7.256)). Any failure signals illicit law deformation or explicit breaking (cf. Proposition 7.336).

(ii) *Identity ledger.* Enforce ST/Ward closure on shell (Section 7.5) and bound the aggregate defect by eq. (7.266). Non-closure indicates explicit breaking or off-shell contamination.

(iii) *Anomaly filters.* Re-apply the admissibility constraints of Section 7.4.5 (gauge/mixed/-grav: trivial cohomology class; Wess–Zumino consistency). Any nontrivial class in the anomaly cohomology explains $|\Lambda_{\mathrm{law}}| < 1$; reproject to a BRST-closed scheme and retest the ledger.

(iv) *Regulator swap/robustness.* Replace $(P_x, K_{\mathrm{IR}}^{(\ell)})$ by an admissible pair; require eq. (7.265) and stability under permutations on the certified window (cf. eq. (7.268)). Deviations beyond $\varepsilon_{\mathrm{reg}}$ indicate a UV/IR mismatch rather than true law loss.

(v) *Health checks (spectral).* Re-confirm positivity/hyperbolicity of the Π_{T}–projected blocks defining $\hat{H}_0$ on the window (eqs. (7.241) and (7.243)). Pathologies (e.g. spurious longitudinal/ghost leakage, pole drift) can leak into the coherence functional and mimic law loss.

- **Gauge-parameter drift.** A nonzero Nielsen slope $\partial_\zeta \Lambda_{\mathrm{law}}$ betrays off-shell evaluation or a mis-projection. Restore the on-shell conditions used in the band-projected coherence definition (eq. (7.115)), and re-verify ST/Nielsen closures (Section 7.5 and eq. (7.260)); on shell, visibilities are gauge-parameter independent. Also re-check eq. (7.244) to ensure BRST-closure of the band operations.

- **Instrumental artefacts (false deficits).** Apparent suppressions can arise from shot noise and phase miscalibration. Track an explicit instrumental budget

$$\varepsilon_{\mathrm{inst}} \;\equiv\; \sigma_{\mathrm{shot}} + \sigma_\phi + \sigma_{\mathrm{sys}}, \tag{7.271}$$

and require the observed deviation to clear this floor before attributing physics: $|1 - \Lambda_{\mathrm{law}}| \;\gtrsim\; C_{\mathrm{inst}}\,\varepsilon_{\mathrm{inst}}$. Audit both the total uncertainty $\delta\Lambda_\alpha$ and the phase contribution $(\delta\Lambda_\alpha)_\phi$ in the readout pipeline (compare the swap/order tests in eq. (7.268)).

Converse trigger (escalation rule). On a certified window, if a statistically significant deficit $|1 - \Lambda_{\mathrm{law}}| \geq \delta$ with $\delta \gg \varepsilon_{\mathrm{plat}}$ is observed, invoke the converse lemma Lemma 7.338 and execute the localization protocol of §1.3: branch swap, Nielsen slope, regulator permutations, and flatness checks against eq. (7.137).

1.7 Summary of Step 1

We *freeze the law*: fix the band–projected Hamiltonian $\hat{H}_0(t;\lambda_{\mathrm{UV}},\ell)$ as in eqs. (7.241) and (7.243), and restrict branch manipulations to symmetry–preserving *presentations*—BRST–exact similarities, background–field reparametrisations, and on–shell–equivalent field redefinitions—implemented by $U_b^{(\mathrm{law})}$ satisfying the commutators eqs. (7.245) and (7.246) (cf. eq. (7.247)).

On certified plateaus, the law–channel visibility is presentation–invariant: $\Lambda_{\mathrm{law}} = 1$ in the ideal limit (eq. (7.257)) and $\Lambda_{\mathrm{law}} = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$ on finite windows (eq. (7.259)), with gauge–parameter independence monitored by the Nielsen slope bound eq. (7.260). The overlay acts trivially on the law kernel (eq. (7.261)) and *preserves* Quadrant II (Proposition 7.336 and Corollary 7.337). Acceptance tests eqs. (7.263) to (7.265) and (7.268) and the robustness/plateau bounds eqs. (7.259) and (7.262) certify this control; identity/closure checks are tracked in the exact-identity sector (Section 7.5). Any significant deficit triggers the converse lemma Lemma 7.338 and the localization protocol of §1.3.

With the microscopic law coherent and quadrant membership locked, **Step 2** prepares an asymmetric state on the vacuum manifold to induce genuine SSB in the *state* channel while the law remains symmetric (see the quadratic/Hessian diagnostics in Section 7.2.5 and eqs. (7.13) and (7.15); [442, 91, 82, 241]).

7.7.2 Prepare an Asymmetric State on the Vacuum Manifold

Aim. Keep the *law* symmetric as in Section 7.7.1, and prepare an *asymmetric* state that selects a point on the vacuum manifold $\mathcal{M}_{\mathrm{vac}} \cong G/H$ (Sections 7.2 and 7.5). Operationally, all manipulations occur *on the band* with the same UV/IR controls (Section 7.3), so that any deviation seen by the interferometer is unambiguously attributable to the *state* channel (cf. Section 7.4).

2.1 Vacuum manifold and selection by an infinitesimal seed

Spontaneous breaking is characterized by a nonzero gauge-invariant order parameter extracted from the prepared state ω (Section 7.5):

$$\varphi(x) \equiv \langle \Phi(x) \rangle_\omega, \qquad \text{or more generally } \langle \mathcal{O}(x) \rangle_\omega \neq 0, \\ \text{for some BRST-closed } \mathcal{O} \quad ([\hat{Q}_{\mathrm{BRST}}, \mathcal{O}] = 0). \tag{7.272}$$

To select a definite vacuum in $\mathcal{M}_{\mathrm{vac}}$, introduce an infinitesimal *seed* that tilts the potential along a coset direction $X \in \mathfrak{g}/\mathfrak{h}$. The seed couples to a gauge-invariant, BRST-closed operator $\mathcal{O}_X$ transforming as X under the *global* group G (no literal gauge-SSB; [117, 442]):

$$\Delta\mathcal{H}_{\mathrm{seed}}(\varepsilon) = -\,\varepsilon \int d^d x \; f_X(x)\, \mathcal{O}_X(x), \qquad \varepsilon > 0, \quad \varepsilon \to 0^+, \tag{7.273}$$

with f_X smooth, compactly supported, and compatible with the band projectors:

$$[\hat{Q}_{\mathrm{BRST}}, \mathcal{O}_X] = 0, \qquad \Big[P_x(\lambda_{\mathrm{UV}}), \mathcal{O}_X\Big] = \Big[K_{\mathrm{IR}}^{(\ell)}, \mathcal{O}_X\Big] = 0 \;\; \text{on } \mathcal{H}_{\mathrm{phys}} \;\; (\textit{Section 7.3}). \tag{7.274}$$

The prepared vacuum state (on branch $b \in \{1,2\}$) is defined by the ordered limits

$$\omega^{(b)}(\,\cdot\,) = \lim_{(\lambda_{\mathrm{UV}},\ell)\in\text{plateau}} \lim_{V\to\infty} \lim_{\varepsilon\to 0^+} \omega^{(b)}_{\varepsilon,V;\,\lambda_{\mathrm{UV}},\ell}(\,\cdot\,), \tag{7.275}$$

where $(\lambda_{\mathrm{UV}},\ell)$ lie in a certified plateau (Sections 7.3 and 7.4.5). The seed *does not* alter the symmetric $\hat{H}_0$ used by the law-channel interferometer; it is strictly a state-preparation device (cf. Section 7.7.1).

Two equivalent preparation routes (law unchanged). Let ρ_0 be the symmetric calibration state (ghost number 0).

1. **Imaginary-time (or adiabatic) seeding.** Prepare

$$\rho^{(b)}_{\varepsilon,V;\,\lambda_{\mathrm{UV}},\ell} = \frac{P_x K^{(\ell)}_{\mathrm{IR}}\; e^{-\beta(\hat{H}_0-\varepsilon J^{(b)}_X)}\; P_x K^{(\ell)}_{\mathrm{IR}}}{\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(P_x K^{(\ell)}_{\mathrm{IR}}\; e^{-\beta(\hat{H}_0-\varepsilon J^{(b)}_X)}\Big)}, \qquad J^{(b)}_X := \int d^d x\; f^{(b)}_X(x)\,\mathcal{O}_X(x), \tag{7.276}$$

   with β large (ground-state projection) or via an adiabatic real-time ramp that prepares the same state; then remove the seed and take $\varepsilon\to 0^+$ after $V\to\infty$ on the plateau.

2. **Unitary preparation.** Apply a BRST-physical unitary that *only* acts in the state channel,

$$\begin{aligned} \rho^{(b)}_{\varepsilon,V;\,\lambda_{\mathrm{UV}},\ell} &= U^{(b)}_{\mathrm{prep}}(\varepsilon)\,\Big(P_x K^{(\ell)}_{\mathrm{IR}}\;\rho_0\;P_x K^{(\ell)}_{\mathrm{IR}}\Big)\,U^{(b)\dagger}_{\mathrm{prep}}(\varepsilon), \\ U^{(b)}_{\mathrm{prep}}(\varepsilon) &= \mathcal{T}\exp\Big[-i\int dt\;\Delta\mathcal{H}^{(b)}_{\mathrm{seed}}(t)\Big], \end{aligned} \tag{7.277}$$

   with $[\hat{Q}_{\mathrm{BRST}}, U^{(b)}_{\mathrm{prep}}] = 0$ (BRST-closed channel), and the same ordered limits as in eq. (7.275).

Both routes are equivalent for on-shell observables by the equivalence theorem and Nielsen identities (Section 7.5; [117, 442]).

Band-compatibility and BRST admissibility. To ensure Quadrant-II integrity:

- *Gauge/BRST:* $\mathcal{O}_X$ must be BRST-closed (ghost number 0) so that $[\hat{Q}_{\mathrm{BRST}}, \Delta\mathcal{H}_{\mathrm{seed}}] = 0$ and the prepared state remains in $\mathcal{H}_{\mathrm{phys}}$ (Section 7.2).
- *Regulators:* $[P_x(\lambda_{\mathrm{UV}}), \Delta\mathcal{H}_{\mathrm{seed}}] = [K^{(\ell)}_{\mathrm{IR}}, \Delta\mathcal{H}_{\mathrm{seed}}] = 0$ on the plateau, avoiding spurious law-channel contamination (Sections 7.3 and 7.4.5).
- *Global vs. gauge.* The coset $X \in \mathfrak{g}/\mathfrak{h}$ refers to a *global* symmetry direction; gauge directions are handled cohomologically (no literal gauge-SSB; longitudinal/ghost quartets decouple) ([117, 442]).

Local coordinates on $\mathcal{M}_{\rm vac}$ and mode split. Once a vacuum $(\bar\Phi,\bar\Theta)\in\mathcal{M}_{\rm vac}$ is selected, parameterize fluctuations by NG coordinates π_a along G/H and gapped coordinates σ_i transverse to G/H:

$$\Phi(x)=\bar\Phi+\sum_a \pi_a(x)\,(T_a\cdot\bar\Phi)+\sum_i \sigma_i(x)\,n_i+\cdots,\qquad \Theta(x)=\bar\Theta+\cdots, \tag{7.278}$$

with T_a broken generators and n_i orthonormal radial/mixed directions. This NG/gapped split is consistent with the band Hessian blocks of Section 7.2.5 (cf. $\Pi_{\rm T}$-projected $\mathbb{H}^{(\lambda_{\rm UV},\ell)}$ in eqs. (7.241) and (7.243)). NG kinematics can then be read off via phase-twist interferometry along closed loops in G/H (Section 6.11.6).

Ordered limits and cluster properties. The order $\varepsilon\to 0^+$ *after* $V\to\infty$ on a certified plateau suppresses domain averaging and yields a definite vacuum sector (standard SSB construction; [91, 82]). Plateau flatness guarantees gauge-parameter independence of the resulting on-shell observables (Nielsen), and BRST cohomology removes unphysical sectors (Sections 7.2 and 7.5).

Branch usage. For later state-channel diagnostics, one may take seeds $\pm X$ on the two ancilla branches to prepare distinct vacua related by G, or the *same* vacuum on both branches for calibration. In both cases the *law* channel remains the symmetric baseline of Section 7.7.1; any visibility loss must therefore be attributed to the *state* channel (Sections 7.4 and 7.4.1).

Lemma 7.339 (Route equivalence for band–projected correlators)**.** *Consider a set of operators $\{\mathcal{O}_k\}_{k=1}^n$ that are BRST-closed, gauge-invariant, have ghost-number 0, and commute with the band projectors on $\mathcal{H}_{\rm phys}$. Define the band–projected n-point function on branch b by*

$$G_n^{(b)}[\{\mathcal{O}_k(x_k)\}]:=\frac{\mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(P_x K_{\rm IR}^{(\ell)}\,\rho^{(b)}\,P_x K_{\rm IR}^{(\ell)}\,\prod_{k=1}^n\mathcal{O}_k(x_k)\Big)}{\mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(P_x K_{\rm IR}^{(\ell)}\,\rho^{(b)}\Big)}. \tag{7.279}$$

Let $\rho^{(b)}$ be prepared either by imaginary–time seeding eq. (7.276) or by unitary seeding eq. (7.277). Then, under the ordered limits eq. (7.275) on a certified plateau and with the symmetric law fixed by eqs. (7.241) and (7.243),

$$\lim_{\text{plateau}}\lim_{V\to\infty}\lim_{\varepsilon\to 0^+} G_n^{(b)}\Big|_{\text{im. time}} = \lim_{\text{plateau}}\lim_{V\to\infty}\lim_{\varepsilon\to 0^+} G_n^{(b)}\Big|_{\text{unitary}}. \tag{7.280}$$

Proof. Step 1 (Generating functionals). Introduce a source J for the BRST–closed operator $\mathcal{O}_X$ used in eq. (7.273), and define band–projected generating functionals

$$\begin{aligned} Z_{\rm im}[J]&:=\mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(P_x K_{\rm IR}^{(\ell)}\,e^{-\beta(\hat H_0-\varepsilon J_X)}\,P_x K_{\rm IR}^{(\ell)}\Big),\\ Z_{\rm uni}[J]&:=\mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(P_x K_{\rm IR}^{(\ell)}\,U_{\rm prep}(\varepsilon;J)\,\rho_0\,U_{\rm prep}^\dagger(\varepsilon;J)\,P_x K_{\rm IR}^{(\ell)}\Big),\end{aligned} \tag{7.281}$$

with $J_X=\int d^dx\, f_X(x)\,\mathcal{O}_X(x)$ and $U_{\rm prep}=\mathcal{T}\exp[-i\int dt\,\Delta\mathcal{H}_{\rm seed}(t)]$ as in eq. (7.277). Insertion correlators eq. (7.279) are obtained by functional differentiation of $\ln Z$ w.r.t. J and then setting $J\to 0$.

Step 2 (Contour matching). Use the Schwinger–Keldysh contour with a vertical imaginary–time leg: the time–ordered evolution with U_{prep} on the real branches and the Euclidean weight $e^{-\beta(\hat{H}_0-\varepsilon J_X)}$ on the vertical leg represent the same contour–ordered object when (i) the Hamiltonian on all branches is the *same* $\hat{H}_0$ (law frozen; Section 7.7.1 and eq. (7.241)), (ii) the source couples to a BRST–closed, gauge–invariant $\mathcal{O}_X$ commuting with the band projectors eq. (7.274), and (iii) band operations commute with the symmetry/BRST generators eq. (7.244). Therefore,

$$Z_{\mathrm{im}}[J] \;=\; Z_{\mathrm{uni}}[J] \qquad \text{on the certified plateau,} \tag{7.282}$$

up to terms controlled by the plateau budget $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ (eq. (7.258)).

Step 3 (Ordered limits and cohomology). Taking $\beta \to \infty$ (ground–state projection), $V \to \infty$, and $\varepsilon \to 0^+$ in the order eq. (7.275) selects a definite vacuum sector on $\mathcal{M}_{\mathrm{vac}}$ (no domain averaging). Because the source/operator are BRST–closed and the band operations commute with $\hat{Q}_{\mathrm{BRST}}$ eq. (7.244), cohomologically exact contributions cancel in the trace (cf. the identity eq. (7.331) used in the Step 1 lemma of §1.3), and Nielsen identities guarantee gauge–parameter independence on shell (Section 7.5). Functional differentiation of eq. (7.282) thus yields equality of all band–projected, on–shell BRST–closed correlators, establishing eq. (7.280). □

Corollary 7.340 (Profile–shape robustness)**.** *Let $f_X^{(1)}, f_X^{(2)}$ be two smooth, compactly supported seed profiles along the same coset direction $X \in \mathfrak{g}/\mathfrak{h}$ that commute with the band projectors as in eq. (7.274). Then the limits eq. (7.275) of the corresponding $G_n^{(b)}$ coincide up to $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ and define the* same *vacuum sector on the plateau.*

Proof. Interpolate $f_X^{(s)} := (1-s)f_X^{(1)} + s f_X^{(2)}$ with $s \in [0,1]$, and let $J_X(s) = \int d^dx\, f_X^{(s)}(x)\, \mathcal{O}_X(x)$. By Lemma 7.339, the band–projected generating functionals for imaginary–time and unitary seeding coincide on the plateau (up to $\mathcal{O}(\varepsilon_{\mathrm{plat}})$), so it suffices to work with either route. Differentiating the (common) generating functional w.r.t. s inserts the BRST–closed operator $\int d^dx\, \delta f_X(x)\, \mathcal{O}_X(x)$, where $\delta f_X := f_X^{(2)} - f_X^{(1)}$. Because $f_X^{(s)}$ commute with the band projectors (eq. (7.274)) and $\mathcal{O}_X$ is BRST–closed and gauge–invariant, the derivative produces only plateau–suppressed terms; graded cyclicity and the cohomological identity eq. (7.331) remove BRST–exact contributions. Taking the ordered limits eq. (7.275) (which fix the vacuum sector and exclude domain averaging) gives $dG_n^{(b)}/ds = \mathcal{O}(\varepsilon_{\mathrm{plat}})$. Integrating in s yields the claim. □

Remark 7.341 (Scope)**.** The lemma applies to BRST–closed, ghost–number 0 insertions (physical operators) evaluated on the certified band. For gauge–variant or off–shell insertions, additional gauge–fixing artefacts can appear away from the plateau; these are filtered out by the acceptance tests of §1.5 and the plateau budget eq. (7.258).

2.2 Coset parameterisation and fluctuation fields

Choose a local coset chart with the CCWZ map

$$U(\pi(x)) = \exp\Big[\,\mathrm{i}\,\pi^a(x)\,T_a\Big], \qquad T_a \in \mathfrak{g}/\mathfrak{h}, \tag{7.283}$$

and write the field as a broken-phase fluctuation about the chosen vacuum vector v:

$$\Phi(x) = U(\pi(x))\Big(v + h(x)\Big), \tag{7.284}$$

where the NG coordinates π^a chart G/H and the gapped field h transforms in a (possibly reducible) linear representation of the unbroken subgroup H. In gauge theories, this parameterisation is naturally implemented in background-field gauges that preserve on-shell identities (cf. Section 7.5). BRST quartet decoupling guarantees that longitudinal/ghost sectors do not pollute $\mathcal{H}_{\rm phys}$ (Section 7.2.6).

For later kinematics it is convenient to introduce the Maurer–Cartan decomposition (with a gauge-covariant derivative D_μ when gauged)

$$-\,\mathrm{i}\,U^{-1}(\pi)\,D_\mu U(\pi) = E_\mu{}^a(\pi)\,T_a + \omega_\mu{}^i(\pi)\,H_i, \tag{7.285}$$

where $E_\mu{}^a$ is the coset "vielbein" and $\omega_\mu{}^i$ the H-connection. On the *band* (with $P_x(\lambda_{\rm UV})$, $K_{\rm IR}^{(\ell)}$, $\Pi_{\rm T}$ as in §1.1), the quadratic invariant built from π–derivatives takes the CCWZ form

$$\mathcal{L}_\pi^{(2)} = \frac{1}{2}\,(E_\mu{}^a\pi)\,G_{ab}(v)\,(E^{\mu\,b}\pi) \quad\longrightarrow\quad \frac{1}{2}\Big(\partial_\mu\pi\Big)^{\top}\mathsf{G}(v)\,\partial^\mu\pi + \mathcal{O}(\pi^3), \tag{7.286}$$

where $G_{ab}(v)$ (or $\mathsf{G}(v)$) is positive semidefinite on $\mathcal{H}_{\rm phys}$ by the positivity/hyperbolicity checks already certified on the symmetric band (eq. (7.15)).

Remarks. (i) In a BEH/Higgs realisation, some would-be NG coordinates reside in BRST quartets and are unphysical; they decouple on $\mathcal{H}_{\rm phys}$ by the quartet mechanism. (ii) All band operations commute with symmetry/BRST generators (eq. (7.244)); hence π/h observables extracted from eq. (7.284) are Nielsen-stable on certified plateaus.

2.3 Band Hessian around the broken background

Let Γ denote the band effective action. The (functional) band Hessian at the broken background φ is

$$\mathcal{H}_{\rm band}(x,y) := \left.\frac{\delta^2\Gamma}{\delta\Phi(x)\,\delta\Phi(y)}\right|_{\Phi=\varphi}, \tag{7.287}$$

and defines the inverse propagators for (π, h) after BRST projection to $\mathcal{H}_{\rm phys}$ (Section 7.2). In momentum space and on the band, the (π, h) block structure reads schematically

$$\mathbb{H}_{\rm broken}^{(\lambda_{\rm UV},\ell)}(p) = \begin{pmatrix} \mathcal{K}_{\pi\pi}(p) & \mathcal{K}_{\pi h}(p) \\ \mathcal{K}_{h\pi}(p) & \mathcal{K}_{hh}(p) \end{pmatrix} + \begin{pmatrix} \mathcal{M}^2_{\pi\pi} & \mathcal{M}^2_{\pi h} \\ \mathcal{M}^2_{h\pi} & \mathcal{M}^2_{hh} \end{pmatrix}, \tag{7.288}$$

with all objects implicitly projected by $P_x(\lambda_{\rm UV})K_{\rm IR}^{(\ell)}\Pi_{\rm T}$ and reduced to $\mathcal{H}_{\rm phys}$. Ward/Nielsen identities on the broken background imply the NG constraints

$$\mathcal{M}^2_{\pi\pi} = 0, \qquad \mathcal{K}_{\pi h}(p) = \mathcal{O}(p) \;\text{ and }\; \mathcal{K}_{\pi h}(0) = 0, \tag{7.289}$$

so that NG modes appear as massless poles (or are removed into BRST quartets in gauge realisations), while h retains a gapped mass operator $\mathcal{M}^2_{hh} \geq 0$ on $\mathcal{H}_{\rm phys}$. The principal symbol of $\mathbb{H}_{\rm broken}^{(\lambda_{\rm UV},\ell)}(p)$ remains hyperbolic and its physical mass operator non-negative by continuity from the symmetric band and the acceptance tests (eqs. (7.13) and (7.15)).

Goldstone Ward identity (on the band). Let $t_a\cdot\varphi$ be the variation of the background along a broken generator T_a. Then the band Hessian satisfies

$$\int d^d y\, \mathcal{H}_{\text{band}}(x,y)\,(T_a\cdot\varphi)(y) = 0 \qquad \text{on } \mathcal{H}_{\text{phys}}, \tag{7.290}$$

which is the on-band form of the Goldstone theorem (projected to the physical subspace); it follows from the exact identities at the symmetry point and the BRST/Nielsen machinery (Section 7.5). Equation eq. (7.290) enforces $\mathcal{M}^2_{\pi\pi} = 0$ and $\mathcal{K}_{\pi h}(0) = 0$ in eq. (7.289).

Plateau stability of the broken Hessian. Regulator stability and commutation of limits are checked on certified plateaus (Section 7.3). In particular, the band Hessian inherits the plateau robustness bounds,

$$\partial_{(\ln\lambda_{\text{UV}},\,\ln\ell)}\,\mathbb{H}^{(\lambda_{\text{UV}},\ell)}_{\text{broken}}(p) = \mathcal{O}(\varepsilon_{\text{plat}}), \tag{7.291}$$

so that the location of NG poles and the gapped spectrum of h are stable under admissible UV/IR scans (cf. eqs. (7.258) and (7.259)).

2.4 Broken Ward identities and NG structure (global G)

On the certified band (projected by $P_x(\lambda_{\text{UV}})K^{(\ell)}_{\text{IR}}\Pi_{\text{T}}$ and reduced to $\mathcal{H}_{\text{phys}}$), the Ward–Takahashi identity for a global current J^μ_a and any BRST-closed, ghost-number 0 operator $\mathcal{O}$ reads

$$\partial_\mu \left\langle T\, J^\mu_a(x)\,\mathcal{O}(y)\right\rangle_{\omega^{(b)}} = \mathrm{i}\,\delta^{(d)}(x-y)\left\langle \delta_a\mathcal{O}(y)\right\rangle_{\omega^{(b)}}, \tag{7.292}$$

with T time ordering on the band (the band projectors commute with J^μ_a and $\mathcal{O}$ on $\mathcal{H}_{\text{phys}}$, cf. eq. (7.244)). Fourier transforming eq. (7.292) and isolating the one-particle contribution gives the standard current–NG matrix element

$$\langle 0|\, J^\mu_a(0)\,|\,\pi^b(p)\rangle = \mathrm{i}\, f_{ab}\, p^\mu, \qquad f_{ab} = f_{ba} \geq 0 \text{ on } \mathcal{H}_{\text{phys}}, \tag{7.293}$$

which implies a massless pole in the current–current correlator and in any channel with nonvanishing overlap:

$$\mathrm{i}\int d^d x\, e^{\mathrm{i}k\cdot x}\left\langle T\, J^\mu_a(x) J^\nu_b(0)\right\rangle \supset \frac{f_{ac}f_{bc}\,k^\mu k^\nu}{k^2+\mathrm{i}0^+}, \qquad k^2\to 0\,. \tag{7.294}$$

Equivalently, the band Hessian at the broken background possesses zero modes along $T_a\cdot\varphi$ (Goldstone theorem on the band), cf. eqs. (7.289) and (7.290).

Soft-band Ward identity and NG soft theorem. For any insertion of BRST-closed physical operators $\{\mathcal{O}_i\}$, the $k\to 0$ limit of the current insertion reproduces the broken charge action:

$$\lim_{k\to 0} k_\mu\, \widetilde{G}^\mu_a\big(k;\{x_i\}\big) = \sum_i \left\langle \mathcal{O}_1\cdots(\delta_a\mathcal{O}_i)\cdots\mathcal{O}_n\right\rangle_{\omega^{(b)}}, \tag{7.295}$$

where $\widetilde{G}^{\mu}_{a}$ is the Fourier transform of $\langle T\, J^{\mu}_{a}(x) \prod_i \mathcal{O}_i(x_i)\rangle$. Upon LSZ reduction, this yields the NG soft theorem (Adler-type statement) on the band:

$$\mathcal{A}_{n+1}\Big(\pi^a(k),\, \Psi_1, \ldots, \Psi_n\Big) = -\,\frac{\mathrm{i}}{f_{aa}} \sum_{i=1}^{n} \mathsf{T}^{(i)}_{a}\, \mathcal{A}_n\Big(\Psi_1, \ldots, \Psi_n\Big) \;+\; \mathcal{O}(k)\,, \tag{7.296}$$

where $\mathsf{T}^{(i)}_{a}$ is the action of the broken generator on external leg i, and f_{aa} is the appropriate decay constant extracted from eq. (7.293). When the total broken charge on external states vanishes, the leading term cancels and the amplitude exhibits an Adler zero. All statements are gauge-parameter independent on certified plateaus by the Nielsen machinery (Section 7.5).

Plateau protection. The coefficients f_{ab} and the NG pole in eq. (7.294) are stable under admissible UV/IR scans:

$$\partial_{(\ln \lambda_{\mathrm{UV}},\, \ln \ell)}\, f_{ab} = \mathcal{O}(\varepsilon_{\mathrm{plat}})\,, \qquad \partial_{(\ln \lambda_{\mathrm{UV}},\, \ln \ell)}\, \mathrm{Res}_{k^2=0}\, G_{JJ}(k) = \mathcal{O}(\varepsilon_{\mathrm{plat}})\,, \tag{7.297}$$

a direct consequence of eq. (7.291) and the acceptance tests of §1.5.

2.5 BEH reorganisation (gauged G)

When the broken generators are gauged, the longitudinal gauge fields absorb the would-be NG modes (BEH mechanism). Let the covariant derivative be $D_\mu = \partial_\mu + \mathrm{i}\, g_a A^a_\mu T_a$ in the representation of Φ. Expanding $\Phi = U(\pi)(v + h)$ from eq. (7.284) to quadratic order yields the vector mass matrix

$$(M_A^2)_{ab} = g_a g_b \left\langle v \,\middle|\, \{T_a, T_b\} \,\middle|\, v \right\rangle \quad \text{(projected to } \mathcal{H}_{\mathrm{phys}}\text{)}, \tag{7.298}$$

which is positive semidefinite by eq. (7.13). The kinetic mixing between A_μ and π takes the universal derivative form

$$\mathcal{L}^{(2)}_{\mathrm{mix}} = -\, g_a\, A^{a\,\mu}\, \partial_\mu \pi^a + \cdots\,, \tag{7.299}$$

and is removed by R_ξ gauge fixing. In that gauge the unphysical scalar has mass

$$m^2_{\pi^a,\mathrm{unphys}} = \xi\, (M_A^2)_{aa}\,, \tag{7.300}$$

forming part of a BRST quartet with the Faddeev–Popov ghosts/longitudinal modes that decouple from $\mathcal{H}_{\mathrm{phys}}$ (Section 7.2). Physical poles and residues (transverse vectors and h) are gauge-parameter independent on shell by Slavnov–Taylor/Nielsen identities (Section 7.5).

Goldstone equivalence (on the band). For energies $E \gg M_A$ and on-shell external states prepared on the band,

$$\mathcal{M}\Big(A^a_L;\, \mathcal{X}\Big) = \mathcal{M}\Big(\pi^a;\, \mathcal{X}\Big) \;+\; \mathcal{O}\Big(\frac{M_A}{E}\Big)\,, \tag{7.301}$$

where A^a_L is a longitudinal vector and $\mathcal{X}$ denotes other physical insertions. The equivalence is protected by ST/Nielsen identities and the projector commutators eq. (7.244); the $\mathcal{O}(M_A/E)$ corrections are plateau-stable by eq. (7.291).

Plateau protection and provisional identifications. The spectra and residues of transverse vectors and gapped scalars h are stable under admissible UV/IR scans on the band (cf. eq. (7.291)); any "Higgs-like'' identification of h or related composites is *provisional* pending cross-quadrant certification and plateau robustness checks (policy in Section 7.4).

2.6 State visibility: volume scaling signature of SSB

Using the same readout map as in Section 7.4, define the *state* visibility from the ancilla coherence between two prepared vacua (or two preparations of the same vacuum) on the band:

$$\Lambda_{\text{state}}(\lambda_{\text{UV}},\ell;V) := \frac{\left|\operatorname{Tr}_{\mathcal{H}_{\text{phys}}}\Big(P_x(\lambda_{\text{UV}})\,K_{\text{IR}}^{(\ell)}\,U_1^{(\text{state})\dagger}U_2^{(\text{state})}\,\rho_{\text{ref}}\Big)\right|}{\operatorname{Tr}_{\mathcal{H}_{\text{phys}}}\Big(P_x(\lambda_{\text{UV}})\,K_{\text{IR}}^{(\ell)}\,\rho_{\text{ref}}\Big)}\,. \tag{7.302}$$

Here ρ_{ref} is a BRST-closed calibration state (ghost number 0); the state-channel unitaries $U_b^{(\text{state})}$ prepare the broken vacua as in eqs. (7.276) and (7.277), with the ordered limits eq. (7.275). All band operations commute with the symmetry/BRST generators (eq. (7.244)), so Λ_{state} is gauge-parameter independent on certified plateaus (Nielsen) and depends only on the prepared *state* sector (the law channel stays fixed by Section 7.7.1).

Quadrant-II signature (law vs. state). With the law frozen, Quadrant II is diagnosed by

$$|\Lambda_{\text{law}}(\lambda_{\text{UV}},\ell)| = 1+\mathcal{O}(\varepsilon_{\text{plat}}) \quad \text{(eqs. (7.257) and (7.259))}, \qquad \lim_{V\to\infty}|\Lambda_{\text{state}}(\lambda_{\text{UV}},\ell;V)| = 0, \tag{7.303}$$

with all limits taken inside a certified window (Section 7.3).

Asymptotic scaling (orthogonality of pure phases). Let $\omega^{(1)},\omega^{(2)}$ be the two branch states produced by eqs. (7.276) and (7.277) along distinct points of $\mathcal{M}_{\text{vac}}$ (or two macroscopically distinct ensembles around the same vacuum). Under standard cluster properties on the band, the overlap (obtained from eq. (7.302)) obeys a large-volume law

$$-\frac{1}{V}\log|\Lambda_{\text{state}}(\lambda_{\text{UV}},\ell;V)| \xrightarrow[V\to\infty]{} \alpha(\lambda_{\text{UV}},\ell) \;\geq 0\,, \tag{7.304}$$

with $\alpha = 0$ iff the two preparations coincide in the thermodynamic limit. Two useful regimes—both plateau-stable by eq. (7.291)—are:

1. **Gapped (short-range) regime.** If connected correlators have a finite correlation length ξ on the band, block-factorisation gives an extensive decay

$$|\Lambda_{\text{state}}| \;\leq\; \exp\Big[-\,c_{\text{gap}}\,V/\xi^{d}\Big], \qquad c_{\text{gap}}>0 \text{ set by the local overlap between phases.} \tag{7.305}$$

2. **Continuous SSB with NG modes.** For two vacua related by a small global rotation of angle θ in G/H, the zero-mode (uniform) component yields

$$|\Lambda_{\text{state}}| \;\lesssim\; \exp\Big[-\,\tfrac{1}{2}\,\rho_{\text{s}}\,\theta^2\,V\Big] \quad \text{for } \theta\ll 1, \tag{7.306}$$

where ρ_{s} is the appropriate stiffness (decay constant) extracted from eqs. (7.293) and (7.294). Thus distinct NG orientations are orthogonal as $V\to\infty$.

Estimator and plateau stability. Define the finite-volume estimator

$$\widehat{\alpha}(\lambda_{\mathrm{UV}}, \ell; V) := -\frac{1}{V} \log |\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V)| \,. \tag{7.307}$$

On certified windows,

$$\partial_{(\ln \lambda_{\mathrm{UV}}, \ln \ell)} \widehat{\alpha} = \mathcal{O}(\varepsilon_{\mathrm{plat}}) \,, \tag{7.308}$$

so the extracted macroscopic rate is insensitive to admissible UV/IR scans, mirroring eqs. (7.291) and (7.297).

Calibrations and localised contrasts. If both branches prepare the *same* vacuum sector, then $|\Lambda_{\mathrm{state}}| = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$. If the preparations differ only inside a subregion $\Omega \subset V$ (e.g., a local quench or inhomogeneous seed), the scaling in eq. (7.304) holds with V replaced by $|\Omega|$. Interface-dominated contrasts (domain walls) instead scale with boundary area and appear as $\exp[-\sigma\, \mathrm{Area}(\partial\Omega)]$, providing an operational handle to distinguish bulk vs. interface mechanisms.

Operational note. When reporting Λ_{state}, include: (i) the certified plateau window and $\varepsilon_{\mathrm{plat}}$; (ii) whether the two preparations are symmetry-related vacua or the same vacuum; (iii) the finite-volume fit to $-\log|\Lambda_{\mathrm{state}}|$ (linear in V, or area-law if applicable); and (iv) the gauge-scan confirming Nielsen stability (cf. eq. (7.260)). Coupled with eq. (7.303), this constitutes the Quadrant-II SSB fingerprint.

2.7 Acceptance and reporting for the broken-state run

The broken-state run is accepted only if *all* items below are satisfied and reported with their numerical budgets.

- **Plateaus (certification and budgets).** Certify a domain in $(\ln \lambda_{\mathrm{UV}}, \ln \ell)$ with small gradient/oscillation/curvature as in Section 7.3, and report the triple $(\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{osc}}, \varepsilon_{\mathrm{curv}})$ together with regulator robustness (Section 7.4.5). Quote the plateau budget $\varepsilon_{\mathrm{plat}}$ entering eqs. (7.259) and (7.308).
- **Identity ledger (branchwise).** Verify on-shell Slavnov–Taylor, global Ward, and Nielsen identities on each branch (Section 7.5); include anomaly filters if applicable. For global G, exhibit eq. (7.292) and the NG matrix element eq. (7.293); for gauged G, demonstrate ST/Nielsen protection of pole positions/residues together with the BEH reorganisation eqs. (7.298) to (7.301).
- **Spectrum health (band-projected).** Recheck non-negativity of the physical mass operator and hyperbolicity of the principal symbol on $\mathcal{H}_{\mathrm{phys}}$ (cf. eqs. (7.13) and (7.15)), and stability of the broken Hessian under UV/IR scans (eq. (7.291)).
- **Quadrant tests (law vs. state).** Show the law channel remains coherent on the plateau, $|\Lambda_{\mathrm{law}}| = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$ (eqs. (7.257) and (7.259)), and that the state channel exhibits

volume-suppressed visibility $\lim_{V\to\infty}|\Lambda_{\text{state}}| = 0$ (eq. (7.303)). Include finite-size scaling plots at fixed plateaus and fit the visibility via

$$-\log|\Lambda_{\text{state}}(\lambda_{\text{UV}},\ell;V)| = \alpha(\lambda_{\text{UV}},\ell)\,V + \sigma(\lambda_{\text{UV}},\ell)\,\text{Area}(\partial\Omega) + c_0 + \frac{c_1}{V} + \cdots\,, \quad (7.309)$$

reporting α (bulk decay, cf. eq. (7.304)), σ (interface cost when applicable), and uncertainties.

- **Regulator robustness and ordering.** Demonstrate stability across admissible $(P_x, K_{\text{IR}}^{(\ell)})$ choices that commute with G and BRST (cf. eq. (7.244)), enforcing

$$\left|\Lambda_{\text{state}}[U_1^{(\text{state})}, U_2^{(\text{state})}] - \Lambda_{\text{state}}[U_2^{(\text{state})}, U_1^{(\text{state})}]\right| \le \varepsilon_{\text{plat}}\,, \quad (7.310)$$

and showing insensitivity to projector ordering analogous to eq. (7.268) (with law $\to$ state replacements when applicable).

- **Route equivalence and seed profile.** Confirm that imaginary-time and unitary preparations produce identical band–projected correlators in the ordered limit (Lemma 7.339), and that the result is robust under smooth changes of the seed profile along the same coset direction (cf. Corollary 7.340). State explicitly the seed operator $\mathcal{O}_X$ and Hamiltonian $\Delta\mathcal{H}_{\text{seed}}$ used (eqs. (7.273) and (7.274)).

- **Gauge scan (Nielsen).** Report a gauge scan confirming $\partial_\zeta\Lambda_{\text{law}} = \mathcal{O}(\varepsilon_{\text{plat}})$ (eq. (7.260)) and the gauge-parameter independence of on-shell, band-projected state observables (by the same machinery; cf. Section 7.5).

- **Instrumental budget.** Quote the readout floor $\varepsilon_{\text{inst}} = \sigma_{\text{shot}} + \sigma_\phi + \sigma_{\text{sys}}$ (eq. (7.271)); ensure reported deficits/decays clear this floor with margin.

2.8 Failure modes and diagnostics

- *No NG pole (global G).* Check for (i) residual explicit breaking (violations of eq. (7.292)), (ii) improper order of limits in eq. (7.275), or (iii) off-plateau contamination (violation of Section 7.3). Revisit the seed protocol eqs. (7.273) and (7.274) and verify the Goldstone zero-mode identity eq. (7.290) and constraints eq. (7.289).

- *Gauge dependence of poles (gauged G).* A nonzero Nielsen derivative for pole positions/residues indicates off-shell mismatch. Restore on-shell conditions and band closure (eq. (7.244)) and recheck the exact-identity sector (Section 7.5).

- *Tachyon/negative modes on $\mathcal{H}_{\text{phys}}$.* The broken background is unstable. Recompute the band Hessian eq. (7.287), reselect v, and verify $\mathcal{M}^2_{\text{phys}} \ge 0$ and principal-symbol hyperbolicity (cf. eqs. (7.13) and (7.15)).

- $|\Lambda_{\text{law}}| < 1$ *at plateau.* The law channel is compromised; invoke the converse lemma Lemma 7.338 and revert to Step 1: revalidate the commutators eq. (7.245), projector compatibility eq. (7.246), and plateau certification.

- *Weak or absent volume decay of* $|\Lambda_{\text{state}}|$. If $-\log|\Lambda_{\text{state}}|$ is subextensive in V, either (i) both branches prepare the same vacuum sector (expect $|\Lambda_{\text{state}}| = 1 + \mathcal{O}(\varepsilon_{\text{plat}})$), or (ii) the contrast is interface-dominated (area law). Diagnose with the finite-size estimator eq. (7.307) and the fit eq. (7.309); if the preparations are related by a small rotation in G/H, use the NG bound eq. (7.306) to estimate the expected rate $\alpha \simeq \frac{1}{2}\rho_{\text{s}}\theta^2$.
- *Finite-size artefacts / order of limits.* Ensure $V \to \infty$ precedes $\varepsilon \to 0^+$ on a certified plateau (cf. eq. (7.275)); stabilise the extracted rate with the plateau derivative bound eq. (7.308).
- *Regulator mismatch.* If Λ_{state} or NG diagnostics drift under admissible regulator swaps, re-enforce eq. (7.265) and the ordering tests paralleling eq. (7.268) (state channel).
- *Instrumental artefacts.* Apparent deficits consistent with the floor $\varepsilon_{\text{inst}}$ (eq. (7.271)) are non-diagnostic; improve SNR or phase calibration before attributing physics.

7.7.3 Band Hessian to BRST Projection (Transverse/Longitudinal)

Aim. Starting from the asymmetric background prepared in Section 7.7.2 (with the *law* frozen as in Section 7.7.1), we construct the band Hessian, perform the transverse/longitudinal (T/L) split, and project to the BRST cohomology on $\mathcal{H}_{\text{phys}}$ so that ghosts and longitudinal artefacts decouple. All steps are performed *on the band* with the same UV/IR controls and plateau certification as in Section 7.3, and on-shell statements are protected by Slavnov–Taylor/Ward/Nielsen identities (Section 7.5; [117, 442, 91, 82]).

3.1 Band quadratic kernel about the broken background

Let Γ denote the (band) effective action including the background φ selected in Section 7.7.2 and the admissible regulator/gauge-fixing sector used in Section 7.2. The band Hessian at $\Phi = \varphi$ is the quadratic kernel (cf. eq. (7.287))

$$\mathcal{H}_{\text{band}}(x,y) := \left.\frac{\delta^2\Gamma}{\delta\Phi(x)\,\delta\Phi(y)}\right|_{\Phi=\varphi}, \tag{7.311}$$

which determines inverse propagators and mixings among fluctuations $\Psi \equiv (A_\mu, \sigma, h, \pi; c, \bar{c}, b)$. Unless stated otherwise, operators are implicitly composed with the UV projector $P_x(\lambda_{\text{UV}})$ and IR window $K_{\text{IR}}^{(\ell)}$, and traces are taken on $\mathcal{H}_{\text{phys}}$ (Sections 7.2 and 7.3).

Background stationarity and linear terms. The selected background φ is a stationary point of Γ on the certified band:

$$\left.\frac{\delta\Gamma}{\delta\Phi(x)}\right|_{\Phi=\varphi} = 0 \qquad \Rightarrow \qquad \text{no tadpoles at quadratic order,} \tag{7.312}$$

so $\mathcal{H}_{\text{band}}$ fully controls the Gaussian fluctuations about φ. For global breaking, φ lies on $\mathcal{M}_{\text{vac}}$ and satisfies the Goldstone zero–mode identity eq. (7.290).

Band filtering (shorthand). It is convenient to write the band filter as

$$\mathsf{B}_{\lambda,\ell} := K_{\mathrm{IR}}^{(\ell)}\, P_x(\lambda_{\mathrm{UV}})\,, \qquad [\mathsf{B}_{\lambda,\ell}, \hat{Q}_{\mathrm{BRST}}] = [\mathsf{B}_{\lambda,\ell}, \mathsf{J}_\alpha] = 0 \ \text{ (plateau; cf. } eq.\ (7.244)), \tag{7.313}$$

so that any quadratic form is implicitly "sandwiched" by $\mathsf{B}_{\lambda,\ell}$ when restricted to the band.

Kernel properties (symmetries and gradings). On the certified band,

$$\mathcal{H}_{\mathrm{band}}(x,y) = \mathcal{H}_{\mathrm{band}}^{\top}(y,x), \qquad \mathrm{gh}\big(\mathcal{H}_{\mathrm{band}}\big) = 0, \qquad [\hat{Q}_{\mathrm{BRST}}, \mathcal{H}_{\mathrm{band}}] = \{\hat{Q}_{\mathrm{BRST}}, \ldots\} \tag{7.314}$$

(the last relation indicates BRST variations are exact because the gauge-fixing sector is $\{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}$; gauge–parameter variations are therefore BRST–exact at the level of the physical blocks, see eq. (7.339) below §3.4).

Derivative/mass decomposition (broken background). In momentum space, each block of $\mathcal{H}_{\mathrm{band}}$ admits a principal–symbol plus mass/mixing split,

$$\mathcal{H}^{XY}_{\mathrm{band}}(p) = \mathcal{K}^{XY}_{(\varphi)}(p) + \mathcal{M}^{2,XY}_{(\varphi)}\,, \qquad X, Y \in \{T, L, h, \pi, c, \bar{c}, b\}, \tag{7.315}$$

where $\mathcal{K}^{XY}_{(\varphi)}(p)$ carries the highest-derivative (hyperbolic) structure and $\mathcal{M}^{2,XY}_{(\varphi)}$ the local mass/mixing terms evaluated at φ. Continuity from the symmetric band together with the acceptance tests implies that the principal symbol remains hyperbolic and the physical mass operator non-negative on $\mathcal{H}_{\mathrm{phys}}$ (cf. eqs. (7.13) and (7.15)).

Ward/Nielsen constraints (selection rules). Broken global symmetries enforce (on the band) the NG constraints in the scalar sector,

$$\mathcal{M}^2_{\pi\pi} = 0, \qquad \mathcal{K}_{\pi h}(p) = \mathcal{O}(p), \qquad \mathcal{K}_{\pi h}(0) = 0, \tag{7.316}$$

as stated in eq. (7.289), while gauge realizations reorganize would-be NG modes into BRST quartets (see §2.5). Dependence on the gauge parameter ζ is BRST–exact on the physical blocks (Nielsen corollary eq. (7.339)).

Block structure (schematic). In the fluctuation basis Ψ,

$$\mathcal{H}_{\mathrm{band}} = \begin{pmatrix} \mathcal{H}^{TT} & \mathcal{H}^{TL} & \mathcal{H}^{Th} & \mathcal{H}^{T\pi} & 0 & 0 & 0 \\ \mathcal{H}^{LT} & \mathcal{H}^{LL} & \mathcal{H}^{Lh} & \mathcal{H}^{L\pi} & \star & \star & \star \\ \mathcal{H}^{hT} & \mathcal{H}^{hL} & \mathcal{H}^{hh} & \mathcal{H}^{h\pi} & 0 & 0 & 0 \\ \mathcal{H}^{\pi T} & \mathcal{H}^{\pi L} & \mathcal{H}^{\pi h} & \mathcal{H}^{\pi\pi} & 0 & 0 & 0 \\ 0 & \star & 0 & 0 & 0 & \mathcal{H}^{c\bar{c}} & 0 \\ 0 & \star & 0 & 0 & \mathcal{H}^{\bar{c}c} & 0 & 0 \\ 0 & \star & 0 & 0 & 0 & 0 & \mathcal{H}^{bb} \end{pmatrix}, \tag{7.317}$$

where the T/L superscripts refer to the transverse/longitudinal decomposition of A_μ (defined in §3.2). The starred entries implement the BRST doublet structure tying the longitudinal sector to $(c, \bar{c}, b)$; these ensure quartet decoupling on $\mathcal{H}_{\mathrm{phys}}$ (Sections 7.2.6 and 7.5). Gauge/BRST invariance implies that mixings with one longitudinal leg vanish at zero momentum,

$$\mathcal{H}^{TL}(p) \text{ and } \mathcal{H}^{LT}(p) \ \propto\ p \quad \Rightarrow \quad \mathcal{H}^{TL}(0) = \mathcal{H}^{LT}(0) = 0\,, \tag{7.318}$$

consistent with the ST/Ward identities and with the Schur-reduction in §3.4.

Plateau robustness (band response). Within a certified window in $(\ln \lambda_{\rm UV}, \ln \ell)$,

$$\partial_{(\ln \lambda_{\rm UV},\, \ln \ell)}\, \mathcal{H}_{\rm band}(p) = \mathcal{O}(\varepsilon_{\rm plat})\,, \tag{7.319}$$

as already stated in eq. (7.291). Hence eigenvalues/eigenvectors associated with NG directions and gapped modes vary only within plateau tolerances, and all subsequent on-shell reductions (T/L split and BRST projection in §3.2–3.4) inherit the same stability.

3.2 Transverse/longitudinal split and band commutation

In momentum space (Minkowski signature $\eta_{\mu\nu}$; Euclidean continuation is straightforward), define

$$\Pi_{\rm T}^{\mu\nu}(p) = \eta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}\,, \qquad \Pi_{\rm L}^{\mu\nu}(p) = \frac{p^\mu p^\nu}{p^2}\,, \tag{7.320}$$

with the understanding that $p^2 = 0$ singularities are regulated inside the certified IR window $K_{\rm IR}^{(\ell)}$ (and never probed outside it).

Algebra and kinematics. The projectors obey, for $p^2 \neq 0$,

$$\Pi_{\rm T}^2 = \Pi_{\rm T},\quad \Pi_{\rm L}^2 = \Pi_{\rm L},\quad \Pi_{\rm T}\Pi_{\rm L} = 0,\quad \Pi_{\rm T} + \Pi_{\rm L} = \mathbb{1},\qquad p_\mu \Pi_{\rm T}^{\mu\nu} = 0,\quad \Pi_{\rm L}^{\mu\nu} v_\nu = \frac{p^\mu\, p\cdot v}{p^2}. \tag{7.321}$$

Accordingly we decompose any vector A_μ as $A_\mu = A_\mu^{\rm T} + A_\mu^{\rm L}$, with

$$A_\mu^{\rm T}(p) = \Pi_{\rm T}{}_\mu^{\ \nu}(p)\, A_\nu(p), \qquad A_\mu^{\rm L}(p) = \Pi_{\rm L}{}_\mu^{\ \nu}(p)\, A_\nu(p). \tag{7.322}$$

Real–space (Helmholtz) form on the band. Define the IR–regulated inverse d'Alembertian on the band by the kernel

$$\big(\Delta_\ell^{-1} f\big)(x) := -\int \frac{d^d p}{(2\pi)^d}\, \frac{K_{\rm IR}^{(\ell)}(p)}{p^2}\, e^{{\rm i} p\cdot x}\, \tilde f(p), \tag{7.323}$$

so that $-\Box\, \Delta_\ell^{-1} \approx \mathbb{1}$ on the support of $K_{\rm IR}^{(\ell)}$. Then the band–restricted Helmholtz decomposition reads

$$A_\mu^{\rm L} = \partial_\mu\, \Delta_\ell^{-1}(\partial\cdot A), \qquad A_\mu^{\rm T} = A_\mu - \partial_\mu\, \Delta_\ell^{-1}(\partial\cdot A), \tag{7.324}$$

which reproduces eq. (7.322) after Fourier transform and automatically inherits the IR regularisation.

Band commutation and symmetry/BRST compatibility. On the certified band, the UV projector $P_x(\lambda_{\rm UV})$ and the IR window $K_{\rm IR}^{(\ell)}$ act as scalar multipliers in momentum space (functions of p^2), while $\Pi_{{\rm T}/L}$ act only on Lorentz indices. Hence

$$\Big[P_x(\lambda_{\rm UV}), \Pi_{{\rm T}/L}\Big] = \Big[K_{\rm IR}^{(\ell)}, \Pi_{{\rm T}/L}\Big] = 0, \qquad \Big[\hat Q_{\rm BRST}, \Pi_{{\rm T}/L}\Big] = \Big[\mathsf{J}_\alpha, \Pi_{{\rm T}/L}\Big] = 0, \tag{7.325}$$

as advertised (cf. eq. (7.244)). The last two commutators hold because $\Pi_{{\rm T}/L}$ depend only on p^μ and are blind to internal/gauge indices on which $\hat Q_{\rm BRST}$ and J_α act.

Zero–mode handling ($p^2 \to 0$) and finite volume. In a finite box $V = L^d$ with periodic boundary conditions, the smallest nonzero momentum is $\sim 2\pi/L$; within the IR window the regulated kernel Δ_ℓ^{-1} in eq. (7.323) is well defined provided $L \gg \ell$. If an exact zero mode is present (e.g. strict spatially uniform mode in a massless sector), replace $1/p^2$ by its Moore–Penrose pseudoinverse on the band, or equivalently define $\Delta_{\ell,V}^{-1}$ by projecting out the zero eigenspace before inversion:

$$\Delta_{\ell,V}^{-1} := -\left(\Box|_{\text{band}\ominus\ker\Box}\right)^{-1} K_{\text{IR}}^{(\ell)}\,, \qquad \Pi_{\text{L}} = \partial\,\Delta_{\ell,V}^{-1}\,\partial, \quad \Pi_{\text{T}} = \not\Vdash - \Pi_{\text{L}}. \tag{7.326}$$

All identities used later (idempotence, orthogonality, and the commutators in eq. (7.325)) continue to hold on the orthogonal complement of $\ker\Box$.

Mixing constraints at zero momentum. Gauge/ST identities imply that any mixing carrying a single longitudinal leg is $\mathcal{O}(p)$; thus

$$\mathcal{H}^{TL}(p),\, \mathcal{H}^{LT}(p) \;\propto\; p \quad \Rightarrow \quad \mathcal{H}^{TL}(0) = \mathcal{H}^{LT}(0) = 0, \tag{7.327}$$

consistent with the Schur reduction in §3.4 and the NG/BEH structure discussed in §2.4–2.5.

Multiple gauge sectors and color structure. For nonabelian groups, $\Pi_{\text{T}/L}$ act trivially on color indices: $(\Pi_{\text{T}/L})^{\mu\nu}\delta^{ab}$. Consequently they commute with global/gauge generators and BRST differentials acting in the internal space, ensuring the projector identities used in the BRST decoupling and in the physical block construction (§3.3–3.4).

Plateau stability. Since $\Pi_{\text{T}/L}$ are independent of λ_{UV} and ℓ (the dependence sits only in the band filter and Δ_ℓ^{-1}), the T/L split is stable under admissible UV/IR scans; any residual ℓ-dependence enters only through the regulated Green's operator in eq. (7.324) and is bounded within the plateau budget (cf. eq. (7.319)).

With eqs. (7.322), (7.324) and (7.325) in hand, we will form the physical inverse two-point blocks by combining the T/L split with the BRST doublet structure (quartet mechanism) in §3.3 and the Schur reduction in §3.4.

3.3 BRST doublets and quartet decoupling

BRST algebra near the broken background (band form). Let the gauge–fixing sector be generated by a fermion Ψ_ζ so that $S_{\text{gf+gh}} = \{\hat{Q}_{\text{BRST}}, \Psi_\zeta\}$. Linearised about the background φ (with background–covariant derivative $\bar{D}_\mu$), the BRST variations on the band read schematically

$$\begin{aligned} [\hat{Q}_{\text{BRST}},\, A_\mu^{\text{L}}] &= \bar{D}_\mu c + \mathcal{O}(\text{nonlin}),\\ \{\hat{Q}_{\text{BRST}},\, \bar{c}\} &= b,\\ [\hat{Q}_{\text{BRST}},\, b] &= 0,\\ \{\hat{Q}_{\text{BRST}},\, c\} &= 0, \end{aligned} \tag{7.328}$$

with ghost numbers $\text{gh}(c) = +1$, $\text{gh}(\bar{c}) = -1$, $\text{gh}(b) = 0$, and $\hat{Q}_{\text{BRST}}^2 = 0$. The transverse field A_μ^{T} and the matter sector (h, π) transform covariantly but do not form BRST doublets; their cohomology carries the physical poles.

Doublets and trivial cohomology. A pair (u, v) with $\{\hat{Q}_{\mathrm{BRST}}, u\} = v$ and $[\hat{Q}_{\mathrm{BRST}}, v] = 0$ is a BRST *doublet*. By eq. (7.328), the longitudinal/ghost/Nakanishi–Lautrup variables assemble into two doublets $(\bar{c}, b)$ and $(A^{\mathrm{L}}, \bar{D}c)$. The standard doublet lemma implies that the cohomology in the algebra generated by doublet variables is trivial: any BRST–closed functional of doublets is BRST–exact. Consequently, insertions made of $(A^{\mathrm{L}}, c, \bar{c}, b)$ alone do not contribute to physical matrix elements.

Band gauge fixing and the longitudinal block. Since $S_{\mathrm{gf+gh}} = \{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}$, its quadratic expansion about φ yields the ghost/longitudinal part of the band Hessian. Hence there exists a band operator $\mathcal{K}_{\mathrm{dbl}}$ (depending on Ψ_ζ and the background) such that

$$\mathcal{H}^{LL} \oplus \mathcal{H}^{c\bar{c}} \oplus \mathcal{H}^{\bar{c}c} \oplus \mathcal{H}^{bb} = \left\{\hat{Q}_{\mathrm{BRST}},\, \mathcal{K}_{\mathrm{dbl}}\right\} \qquad \text{(on the band)}. \tag{7.329}$$

In particular, mixings that carry one longitudinal leg $(TL, LT, Lh, L\pi)$ arise from the same BRST–exact sector and are proportional to a single momentum insertion (cf. eq. (7.318)).

Physical projector and graded cyclicity. Let $\mathsf{P}_{\mathrm{phys}}$ denote the projector onto the BRST cohomology (ghost number 0) on the band; by construction,

$$\mathsf{P}_{\mathrm{phys}}\hat{Q}_{\mathrm{BRST}} = \hat{Q}_{\mathrm{BRST}}\mathsf{P}_{\mathrm{phys}} = 0, \qquad [\mathsf{P}_{\mathrm{phys}},\, P_x(\lambda_{\mathrm{UV}})] = [\mathsf{P}_{\mathrm{phys}},\, K_{\mathrm{IR}}^{(\ell)}] = 0. \tag{7.330}$$

Therefore, for any BRST–closed, ghost–number 0 operator $\mathcal{O}$ (or between physical states), graded cyclicity gives the band identity

$$\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathcal{O}\,\{\hat{Q}_{\mathrm{BRST}}, X\}\Big) = 0, \qquad \langle\psi_{\mathrm{phys}}|\,\{\hat{Q}_{\mathrm{BRST}}, X\}\,|\phi_{\mathrm{phys}}\rangle = 0, \tag{7.331}$$

for any band operator X. Combining eq. (7.329) with eq. (7.331) yields the cohomological vanishing restated in eq. (7.332):

$$\mathsf{P}_{\mathrm{phys}}\left(\mathcal{H}^{LL} \oplus \mathcal{H}^{c\bar{c}} \oplus \mathcal{H}^{\bar{c}c} \oplus \mathcal{H}^{bb}\right)\mathsf{P}_{\mathrm{phys}} \;\simeq\; 0 \qquad \text{(in BRST cohomology)}. \tag{7.332}$$

Quartet mechanism (band version). The two doublets $(\bar{c}, b)$ and $(A^{\mathrm{L}}, \bar{D}c)$ combine into a Kugo–Ojima *quartet*. Off shell, members of a quartet come in norm–indefinite pairs; on the band and on shell, their contributions cancel in any physical matrix element by eq. (7.331). Thus the spectrum and residues relevant to observables are carried entirely by the transverse gauge block and the matter block, as used in §3.4.

Gauge–parameter independence and plateaus. Because the entire doublet sector is BRST–exact on the band, a gauge–parameter variation ∂_ζ acts as a BRST commutator on the physical blocks (Nielsen corollary eq. (7.339)). Moreover, since all band projectors commute with BRST and with the T/L projectors (cf. eq. (7.325)), the quartet decoupling is stable under admissible UV/IR scans within a certified window (plateau robustness $\mathcal{O}(\varepsilon_{\mathrm{plat}})$).

Consequence for the physical Hessian. Equations eqs. (7.329) and (7.331) imply that the Schur–complement subtractions used to eliminate longitudinal mixings are themselves BRST–exact and therefore drop from physical matrix elements; this is formalised and used in §3.4 to obtain the on–shell simplifications eq. (7.336).

3.4 Physical block matrix and on-shell reduction

The band-projected *physical* inverse two-point kernel is obtained by restricting eq. (7.317) to the BRST cohomology and eliminating unphysical mixings. At the operator level, a convenient gauge-invariant construction uses Schur complements:

$$\mathcal{H}^{TT}_{\mathrm{phys}} := \Pi_{\mathrm{T}}\Big(\mathcal{H}^{TT} - \mathcal{H}^{TL}\,(\mathcal{H}^{LL})^{-1}\,\mathcal{H}^{LT}\Big)\Pi_{\mathrm{T}}\,, \tag{7.333}$$

and similarly for the matter block

$$\mathcal{H}^{\mathrm{mat}}_{\mathrm{phys}} := \begin{pmatrix}\mathcal{H}^{hh} & \mathcal{H}^{h\pi}\\ \mathcal{H}^{\pi h} & \mathcal{H}^{\pi\pi}\end{pmatrix} - \begin{pmatrix}\mathcal{H}^{hL}\\ \mathcal{H}^{\pi L}\end{pmatrix}(\mathcal{H}^{LL})^{-1}\begin{pmatrix}\mathcal{H}^{Lh} & \mathcal{H}^{L\pi}\end{pmatrix}, \tag{7.334}$$

all understood on the band and on $\mathcal{H}_{\mathrm{phys}}$.

Lemma 7.342 (BRST-exactness of Schur subtractions on the band)**.** *Let the longitudinal and $(c,\bar c,b)$ sectors form BRST doublets as in eq. (7.328), and assume the band-closure commutators eq. (7.325). Then there exist band operators $\mathcal{B}_T, \mathcal{B}_{\mathrm{mat}}$ such that*

$$\begin{aligned}\Pi_{\mathrm{T}}\,\mathcal{H}^{TL}(\mathcal{H}^{LL})^{-1}\mathcal{H}^{LT}\,\Pi_{\mathrm{T}} &= \{\hat Q_{\mathrm{BRST}},\,\mathcal{B}_T\},\\ \begin{pmatrix}\mathcal{H}^{hL}\\ \mathcal{H}^{\pi L}\end{pmatrix}(\mathcal{H}^{LL})^{-1}\begin{pmatrix}\mathcal{H}^{Lh} & \mathcal{H}^{L\pi}\end{pmatrix} &= \{\hat Q_{\mathrm{BRST}},\,\mathcal{B}_{\mathrm{mat}}\}.\end{aligned} \tag{7.335}$$

Consequently, for any BRST-closed, ghost-number 0 insertion $\mathcal{O}$ (and likewise between physical states), the Schur subtractions vanish:

$$\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathcal{O}\,\Pi_{\mathrm{T}}\mathcal{H}^{TL}(\mathcal{H}^{LL})^{-1}\mathcal{H}^{LT}\Pi_{\mathrm{T}}\Big) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathcal{O}\,\{\hat Q_{\mathrm{BRST}},\mathcal{B}_T\}\Big) = 0,$$

and similarly for the matter block, by the cohomological identity eq. (7.331).

Proof. By eq. (7.328), the longitudinal/ghost/Nakanishi–Lautrup sector is a sum of BRST doublets; variations of Γ with respect to these fields therefore lie in the image of $\hat Q_{\mathrm{BRST}}$ (see [117, 442]). In particular, the "constraint'' operator that maps longitudinal fluctuations to gauge variations, and the inverse longitudinal kernel $(\mathcal{H}^{LL})^{-1}$ generated by the gauge-fixing term $\{\hat Q_{\mathrm{BRST}}, \Psi_\zeta\}$, are BRST-exact on the band. The mixing blocks $\mathcal{H}^{TL}, \mathcal{H}^{LT}, \mathcal{H}^{hL}, \mathcal{H}^{Lh}, \dots$ arise from this gauge-fixing sector and carry one longitudinal leg; composing them with $(\mathcal{H}^{LL})^{-1}$ keeps the result in the BRST image. Commutators eq. (7.325) ensure that inserting Π_{T} and the band projectors does not spoil exactness. Thus both Schur subtractions in eqs. (7.333) and (7.334) are $\hat Q_{\mathrm{BRST}}$-exact operators of ghost number 0, establishing eq. (7.335). The vanishing of their physical traces then follows from eq. (7.331). □

Corollary 7.343 (On-shell simplification of physical blocks)**.** *Using Lemma 7.342, one has, in BRST cohomology and on shell,*

$$\mathcal{H}^{TT}_{\rm phys} \;\simeq\; \Pi_{\rm T}\,\mathcal{H}^{TT}\,\Pi_{\rm T}\,, \qquad \mathcal{H}^{\rm mat}_{\rm phys} \;\simeq\; \begin{pmatrix} \mathcal{H}^{hh} & \mathcal{H}^{h\pi} \\ \mathcal{H}^{\pi h} & \mathcal{H}^{\pi\pi} \end{pmatrix}. \tag{7.336}$$

Proof. Start from the Schur-reduced definitions eqs. (7.333) and (7.334). By Lemma 7.342, the Schur subtractions are $\hat{Q}_{\rm BRST}$-exact band operators. Thus, when sandwiched by the physical projector or inserted in band traces with BRST-closed, ghost-number 0 operators, they vanish by the cohomological identity eq. (7.331). This yields the stated equivalences in BRST cohomology. On shell, longitudinal mixings are momentum-suppressed or BRST-exact (cf. eq. (7.318)), so the TT and matter blocks above furnish the physical poles/residues. □

Global vs. gauged G. For *global* breaking, the NG constraints eq. (7.289) hold in the matter block, so that $\mathcal{M}^2_{\pi\pi} = 0$ and $\mathcal{K}_{\pi h}(0) = 0$, and NG poles emerge (cf. eq. (7.290)). If the broken generators are *gauged* (BEH realisation), the would-be NGs enter BRST quartets and decouple from $\mathcal{H}_{\rm phys}$; the physical spectrum is carried by $\mathcal{H}^{TT}_{\rm phys}$ (massive transverse vectors) and the gapped scalar block for h (cf. eqs. (7.298), (7.300) and (7.301)).

Physical propagators and positivity/hyperbolicity. The band-projected physical propagator is

$$\mathbb{G}^{(\lambda_{\rm UV},\ell)}_{\rm phys}(p) := \Big(\mathbb{H}^{(\lambda_{\rm UV},\ell)}_{\rm phys}(p)\Big)^{-1}, \qquad \mathbb{H}^{(\lambda_{\rm UV},\ell)}_{\rm phys} := \mathcal{H}^{TT}_{\rm phys} \oplus \mathcal{H}^{\rm mat}_{\rm phys}, \tag{7.337}$$

with non-negativity of the mass operator and hyperbolicity of the principal symbol guaranteed by eqs. (7.13) and (7.15) (continuity from the symmetric band and the acceptance tests).

Plateau stability. Under admissible UV/IR scans within a certified window, the physical blocks inherit the robustness bounds

$$\partial_{(\ln\lambda_{\rm UV},\,\ln\ell)}\,\mathbb{H}^{(\lambda_{\rm UV},\ell)}_{\rm phys}(p) = \mathcal{O}(\varepsilon_{\rm plat}), \tag{7.338}$$

as a direct corollary of eq. (7.291) and the projector commutators eq. (7.325).

Corollary 7.344 (Nielsen: gauge–parameter independence on the band)**.** *Differentiating the BRST–exact Schur subtractions eq. (7.335) with respect to the gauge parameter ζ (the gauge–fixing sector is $\{\hat{Q}_{\rm BRST}, \Psi_\zeta\}$) gives*

$$\partial_\zeta\,\mathbb{H}^{(\lambda_{\rm UV},\ell)}_{\rm phys}(p) = \Big\{\hat{Q}_{\rm BRST},\, \mathcal{N}^{(\lambda_{\rm UV},\ell)}_\zeta(p)\Big\} \qquad \textit{(on the certified band)}, \tag{7.339}$$

for some band operator $\mathcal{N}_\zeta$. Hence, for any BRST–closed, ghost–number 0 insertion $\mathcal{O}$ (or between physical states),

$$\partial_\zeta\;\mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(\mathcal{O}\,\mathbb{H}_{\rm phys}\Big) = \mathrm{Tr}_{\mathcal{H}_{\rm phys}}\Big(\mathcal{O}\,\{\hat{Q}_{\rm BRST}, \mathcal{N}_\zeta\}\Big) = 0 \quad \textit{by eq. (7.331)}.$$

Therefore physical poles and residues extracted from $\mathbb{G}_{\rm phys} = (\mathbb{H}_{\rm phys})^{-1}$ are ζ-independent (Nielsen identity), matching the gauge–scan criteria in eqs. (7.343) and (7.347) and the visibility test eq. (7.260). Combined with eq. (7.338), this independence is stable under admissible UV/IR scans on the plateau.

Proof. By Lemma 7.342, the Schur subtractions are BRST–exact band operators. Since the gauge–fixing sector is $\{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}$, differentiating w.r.t. ζ preserves BRST exactness, yielding eq. (7.339). Inserting a BRST–closed, ghost–number 0 $\mathcal{O}$ and using graded cyclicity on $\mathcal{H}_{\mathrm{phys}}$ (eq. (7.331)) gives zero for the derivative of any band trace, which implies the ζ-independence of on-shell poles and residues. On finite plateaus, residuals are bounded as in eqs. (7.343) and (7.347), with UV/IR stability from eq. (7.338). □

Summary. Equations eqs. (7.320), (7.325), (7.328) and (7.332) implement the (T/L) split and BRST projection on the band. The resulting physical inverse two-point kernel eqs. (7.333), (7.334) and (7.336) furnishes the correct poles/residues for on-shell observables, with NG/BEH structure as appropriate and with plateau-stable UV/IR response eq. (7.338).

3.5 Gauge-parameter independence (Nielsen) and ST identities

Master Nielsen identity on the band. Gauge fixing enters through a BRST-exact term $\{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}$. On the certified band the gauge–parameter derivative of the 1PI functional is itself BRST-exact:

$$\partial_\zeta \Gamma = \left\{\hat{Q}_{\mathrm{BRST}},\, \mathcal{N}_\zeta\right\} \qquad (\text{band; } \mathsf{B}_{\lambda,\ell}\text{-projected}) \,, \tag{7.340}$$

for some band operator $\mathcal{N}_\zeta$ built from Ψ_ζ and the background (cf. the Hessian version eq. (7.339)). Therefore, any BRST-closed, ghost-number 0 matrix element of $\partial_\zeta\Gamma$ vanishes on $\mathcal{H}_{\mathrm{phys}}$ by eq. (7.331).

Pole locations are ζ-independent (Nielsen). Let physical poles be defined by the zeros of the band-projected determinant $\det \mathbb{H}_{\mathrm{phys}}(p^2, \zeta) = 0$ at $p^2 = m_n^2(\zeta)$. Differentiating and using left/right eigenvectors L_n, R_n of $\mathbb{H}_{\mathrm{phys}}$ at the pole gives

$$\partial_\zeta m_n^2 = -\,\frac{L_n^\top \left(\partial_\zeta \mathbb{H}_{\mathrm{phys}}\right) R_n}{L_n^\top \left(\partial_{p^2} \mathbb{H}_{\mathrm{phys}}\right) R_n} \,. \tag{7.341}$$

By eq. (7.339), $\partial_\zeta \mathbb{H}_{\mathrm{phys}} = \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}_\zeta^{(2)}\}$ on the band, so the numerator is a BRST-exact physical matrix element and vanishes by eq. (7.331). Hence

$$\partial_\zeta m_n^2 = 0 \qquad (\text{Nielsen identity on the band}). \tag{7.342}$$

On finite plateaus, residual deviations are bounded by the plateau budget (cf. eq. (7.338)), yielding the acceptance criterion

$$\left|\partial_\zeta m_n^2\right| = \mathcal{O}(\varepsilon_{\mathrm{plat}}) \,. \tag{7.343}$$

Residues are ζ-independent. Let the residue (wavefunction factor) be

$$Z_n^{-1} = L_n^\top (\partial_{p^2} \mathbb{H}_{\mathrm{phys}}) R_n \Big|_{p^2 = m_n^2}$$

Differentiating and using eqs. (7.331) and (7.339) again shows $\partial_\zeta Z_n = 0$ on the band (and $\partial_\zeta Z_n = \mathcal{O}(\varepsilon_{\mathrm{plat}})$ on finite windows).

From poles to S-matrix (LSZ + Nielsen). Band-projected amputated Green functions inherit eq. (7.340). Combining with LSZ reduction (which uses m_n^2 and Z_n) gives gauge–parameter independence of on-shell S-matrix elements on the band:

$$\partial_\zeta \mathcal{S}_{\rm phys} = 0 \qquad (\text{and } = \mathcal{O}(\varepsilon_{\rm plat}) \text{ on finite plateaus}). \tag{7.344}$$

Slavnov–Taylor identities (constraints and transversality). The ST identity is the functional statement of BRST invariance of Γ and, after differentiation, constrains 1PI kernels and vertices. In particular:

$$\begin{aligned} p_\mu\, \Gamma^{\mu\nu}_{AA}(p) \;&=\; 0 \\ \Rightarrow \quad \Gamma^{\mu\nu}_{AA}(p) &= \Pi^{\mu\nu}_{\rm T}(p)\, \Gamma^{TT}_{AA}(p) \end{aligned} \tag{7.345}$$

(transversality of the physical gauge block),

and for matter–gauge mixing,

$$p_\mu\, \Gamma^{\mu}_{A\Phi\Phi}(p; q, -q-p) = \Gamma_{\Phi\Phi}(q+p) - \Gamma_{\Phi\Phi}(q) \tag{7.346}$$

(tree Ward form; background-field version is identical with $A \to \widehat{A}$).

Equations eqs. (7.345) and (7.346) ensure that the physical TT block used in eq. (7.333) is the only gauge block contributing on shell, and that longitudinal mixings are either momentum–suppressed (cf. eq. (7.318)) or BRST-exact (cf. §3.3).

Background-field gauge (optional strengthening). If a background-field gauge is used, background Ward identities imply manifest gauge covariance of background amplitudes and fix renormalisation relations among couplings and field strengths (e.g., $Z_g = Z_{\widehat{A}}^{-1/2}$), tightening the ST constraints without altering the on-band conclusions above.

Operational acceptance (gauge scans). For each reported physical pole m_n^2 and residue Z_n at a fixed plateau, perform a gauge scan $\zeta \mapsto (\, m_n^2(\zeta), Z_n(\zeta)\,)$ and verify

$$\left|\partial_\zeta m_n^2\right| \le \varepsilon_{\rm plat}, \qquad \left|\partial_\zeta Z_n\right| \le \varepsilon_{\rm plat}, \tag{7.347}$$

together with a law-channel check $\partial_\zeta \Lambda_{\rm law} = \mathcal{O}(\varepsilon_{\rm plat})$ (cf. eq. (7.260)). Passing eq. (7.347) certifies that pole locations/residues and the derived on-shell observables are gauge-parameter independent within the plateau tolerance.

3.6 Practical algorithm (run-sheet)

1. **Choose the broken background φ.** Prepare φ as in Section 7.7.2 (seed protocol and ordered limits). Check stationarity on the band, $\delta\Gamma/\delta\Phi|_{\Phi=\varphi} = 0$ (eq. (7.312)), and record the coset direction(s) used (cf. $\mathcal{O}_X$ in Step 2).

2. **Assemble $\mathcal{H}_{\rm band}$.** Compute the quadratic kernel $\mathcal{H}_{\rm band}$ (eq. (7.311)), keeping explicit dependence on the band filter $\mathsf{B}_{\lambda,\ell} = K_{\rm IR}^{(\ell)} P_x(\lambda_{\rm UV})$ (eq. (7.313)) and on gauge parameters ζ (for Nielsen scans). Decompose each block into principal symbol and mass/mixing pieces (eq. (7.315)).

3. **T/L decomposition (vector sector).** In momentum space apply the projectors $\Pi_{\mathrm{T}/L}$ (eq. (7.320)) and rewrite $A_\mu = A^T_\mu + A^L_\mu$ (eq. (7.322)); in real space use the IR-regulated Helmholtz form (eq. (7.324)) and handle zero modes via $\Delta^{-1}_{\ell,V}$ (eq. (7.326)). Verify band commutators (eq. (7.325)).

4. **BRST sort (doublets & quartets).** Identify the BRST doublets $(\bar{c}, b)$ and $(A^{\mathrm{L}}, \bar{D}c)$ via the linearised algebra (eq. (7.328)); confirm that the ghost/longitudinal kernel is BRST-exact (eq. (7.329)) and that single-L mixings vanish at $p = 0$ (eq. (7.318)). Cross-check quartet decoupling with Section 7.2.6.

5. **Project to $\mathcal{H}_{\mathrm{phys}}$ and form physical blocks.** Apply the physical projector properties (eq. (7.330)) and construct the Schur-reduced kernels $\mathcal{H}^{TT}_{\mathrm{phys}}$ and $\mathcal{H}^{\mathrm{mat}}_{\mathrm{phys}}$ (eqs. (7.333) and (7.334)). Use the lemma Lemma 7.342 to drop BRST-exact subtractions and adopt the on-shell simplification (eq. (7.336)). The band-projected physical propagator is then $\mathbb{G}_{\mathrm{phys}} = (\mathbb{H}_{\mathrm{phys}})^{-1}$ (eq. (7.337)).

6. **Health checks (band-projected).** Verify principal-symbol hyperbolicity and non-negativity of the physical mass operator (continuity from Step 1; eqs. (7.13) and (7.15)). For bookkeeping, define the minimal hyperbolicity margin and mass gap

$$\delta_{\mathrm{hyp}} := \inf_{|p|\gg 1} \lambda_{\min}\Big(\operatorname{sym} \mathcal{K}_{\mathrm{phys}}(p)\Big), \qquad m^2_{\min} := \min_n m^2_n \geq 0, \tag{7.348}$$

   and require $\delta_{\mathrm{hyp}} > 0$ and $m^2_{\min} \geq 0$ on the plateau.

7. **Nielsen & ST verification.** Perform a gauge-parameter scan $\zeta \mapsto \mathbb{H}_{\mathrm{phys}}$ and confirm $\partial_\zeta \mathbb{H}_{\mathrm{phys}} = \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}^{(2)}_\zeta\}$ (eq. (7.339)), whence $\partial_\zeta m^2_n = 0$ and $\partial_\zeta Z_n = 0$ within tolerance (eqs. (7.343) and (7.347)). Check ST identities for two- and three-point structures (eqs. (7.345) and (7.346)).

8. **Plateau certification and robustness.** Confirm small band derivatives of the reduced kernel (eq. (7.338)) and compliance with the visibility/plateau bounds (eq. (7.137)). Where applicable, swap admissible regulators and verify stability (cf. eq. (7.325)).

Outputs to report. List: (i) chosen φ and seed profile, (ii) certified plateau window and $\varepsilon_{\mathrm{plat}}$, (iii) m^2_n, Z_n with gauge-scan slopes, (iv) hyperbolicity/mass margins (eq. (7.348)), and (v) any residual BRST-exact diagnostics observed (all should vanish within numerical tolerance).

3.7 Acceptance tests (physics-facing)

- **Quartet decoupling (null test).** Using a BRST-closed, ghost-number 0 probe $\mathcal{O}$ on the band, verify

$$\Big|\operatorname{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathcal{O}\,(\mathcal{H}^{LL} \oplus \mathcal{H}^{c\bar{c}} \oplus \mathcal{H}^{\bar{c}c} \oplus \mathcal{H}^{bb})\Big)\Big| \leq \varepsilon_{\mathrm{plat}} \qquad \text{(expected = 0 by eq. (7.332))}. \tag{7.349}$$

- **Transverse dominance (spin-1 sector).** Define the transversality ratio for the band-projected two-point function

$$\mathcal{T}(p) := \frac{p_\mu \, \mathbb{G}^{\mu\nu}_{AA}(p) \, p_\nu}{p^2 \, \mathrm{tr}\Big(\Pi_{\mathrm{T}} \, \mathbb{G}_{AA}(p)\Big)} \,, \tag{7.350}$$

  and require $|\mathcal{T}(p)| \le \varepsilon_{\mathrm{plat}}$ across the plateau support. Equivalently, the Källén–Lehmann (band) weight carries no A^L component, consistent with eq. (7.345) and the construction in eq. (7.333).

- **Gauge independence (Nielsen scans).** For every reported pole m_n^2 and residue Z_n,

$$\Big|\partial_\zeta m_n^2\Big| \le \varepsilon_{\mathrm{plat}}, \qquad \Big|\partial_\zeta Z_n\Big| \le \varepsilon_{\mathrm{plat}} \tag{7.351}$$

  (cf. eqs. (7.343) and (7.347)); also check the law-channel slope $\partial_\zeta \Lambda_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}})$ (eq. (7.260)) as a control.

- **Mass/hyperbolicity.** The physical mass operator is non-negative and the principal symbol hyperbolic on the band: compliance with eqs. (7.13) and (7.15), and margins $\delta_{\mathrm{hyp}} > 0$, $m^2_{\mathrm{min}} \ge 0$ (eq. (7.348)) are reported.

- **Plateau robustness.** Derivatives of the reduced kernel and of extracted observables w.r.t. $(\ln \lambda_{\mathrm{UV}}, \ln \ell)$ are within $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ (eq. (7.338)); regulator permutations that commute with G and BRST leave results invariant within tolerance (cf. eq. (7.325)).

3.8 Failure modes and diagnostics

- *Residual longitudinal leakage in physical correlators.* **Symptom:** nonzero longitudinal weight in band-projected two-point functions. **Test:** the transversality ratio $\mathcal{T}(p)$ in eq. (7.350) fails to stay within $\varepsilon_{\mathrm{plat}}$, or the quartet null test eq. (7.349) is violated. **Likely cause:** BRST misalignment or off-shell evaluation. **Fix:** re-enforce on-shell ST/Nielsen conditions (cf. eqs. (7.339) and (7.345)), recompute the BRST sort (eqs. (7.328) and (7.329)), and redo the Schur reduction (§3.4) using the lemma Lemma 7.342. Confirm $\mathsf{P}_{\mathrm{phys}}$ commutators eq. (7.330) and band commutators eq. (7.325).

- *Gauge-parameter drift of physical poles/residues.* **Symptom:** $|\partial_\zeta m_n^2|, |\partial_\zeta Z_n| \not\le \varepsilon_{\mathrm{plat}}$ (cf. eqs. (7.343) and (7.351)). **Likely cause:** evaluation off a certified plateau or missing/incorrect counterterms in Γ. **Fix:** restore plateau conditions (eq. (7.338)) and check algebraic renormalisation constraints (Nielsen master identity eq. (7.340) and ST relations eqs. (7.345) and (7.346)); update the gauge-fixing fermion Ψ_ζ if needed.

- *Schur instability / singular $\mathcal{H}^{LL}$.* **Symptom:** ill-conditioned or non-invertible longitudinal block obstructs the Schur step. **Diagnostic:** monitor the condition number

$$\kappa_{LL} := \frac{\lambda_{\max}(\mathcal{H}^{LL\dagger}\mathcal{H}^{LL})}{\lambda_{\min}(\mathcal{H}^{LL\dagger}\mathcal{H}^{LL})} \,. \tag{7.352}$$

  Likely cause: inadequate IR treatment of zero modes or an incompatible gauge choice. **Fix:** handle zero modes with the band pseudoinverse $\Delta^{-1}_{\ell,V}$ (eq. (7.326)), switch to an

admissible R_ξ family, and re-verify $\mathcal{H}^{TL/LT}(0) = 0$ (eq. (7.318)); then reapply eqs. (7.333) and (7.334).

- *Tachyonic/elliptic pathologies.* **Symptom:** violation of mass non-negativity or hyperbolicity ($m^2_{\min} < 0$ or $\delta_{\rm hyp} \le 0$; cf. eq. (7.348)). **Likely cause:** unstable background φ or seed/order-of-limits error. **Fix:** revisit the background preparation protocol (Step 2), correct seed ordering, and test regulator stability as in eq. (7.319); if needed, reselect v and recompute $\mathcal{H}_{\rm band}$ (eq. (7.311)).

- *Uncontrolled h–π mixing (global G).* **Symptom:** finite $\mathcal{K}_{\pi h}(0)$ or $\mathcal{M}^2_{\pi\pi} \neq 0$ contradicting the NG constraints eq. (7.316). **Likely cause:** broken Ward identity mishandled or coset parameterisation inconsistent with the chosen vacuum. **Fix:** recheck global Ward identities (§2.4) and the coset chart (cf. §2.2), then re-enforce the constraints eq. (7.316) at the level of $\mathcal{H}^{\rm mat}_{\rm phys}$ (eq. (7.336)).

- *Plateau drift / regulator-order sensitivity.* **Symptom:** derivatives $\partial_{(\ln\lambda_{\rm UV},\,\ln\ell)}\mathbb{H}_{\rm phys}$ exceed $\mathcal{O}(\varepsilon_{\rm plat})$ (eq. (7.338)), or results vary with admissible permutations of band projectors beyond tolerance. **Diagnostic:** define the ordering sensitivity

$$\Delta_{\rm ord} := \left\| \mathbb{H}^{(P_x K_{\rm IR})}_{\rm phys} - \mathbb{H}^{(K_{\rm IR} P_x)}_{\rm phys} \right\|_{\rm phys} \le \varepsilon_{\rm plat}\,, \tag{7.353}$$

  and check commutators eq. (7.325). **Fix:** tighten the plateau window, retune regulator profiles, and ensure all band operations commute with BRST and symmetry generators.

- *Anomalous identity ledger (rare).* **Symptom:** persistent violation of Ward/ST checks not cured by plateau/gauge fixes. **Likely cause:** anomaly contamination in the probed band. **Fix:** revisit the exact-identity sector (Section 7.5) and exclude the anomalous window before re-running the reduction.

Outcome. After these diagnostics, the quadratic dynamics *on the band* is reduced to the BRST-physical blocks with well-posed propagation and gauge-parameter–independent on-shell content: $\mathbb{H}_{\rm phys}$ and $\mathbb{G}_{\rm phys} = (\mathbb{H}_{\rm phys})^{-1}$ (eq. (7.337)) satisfy eqs. (7.338), (7.339) and (7.345). This furnishes the input for Step 4 (readout of visibilities and NG soft structure), where the block-reduced kernel links to interferometric diagnostics (Section 7.4).

7.7.4 Read Visibilities: Verify $|\Lambda_{\rm law}| \approx 1$; Volume Decay of $|\Lambda_{\rm state}|$; Phase–twist Interferometry for NG Soft Limits

Aim. Having frozen the law (Section 7.7.1) and prepared an asymmetric state (Section 7.7.2), and with the band Hessian reduced to physical blocks (Section 7.7.3), we now execute the interferometric readout on certified plateaus (Section 7.3). The goals are: (i) confirm the law–channel coherence $|\Lambda_{\rm law}| \simeq 1$ within plateau tolerances (eqs. (7.137) and (7.139)); (ii) demonstrate *volume–decay* of the state visibility $|\Lambda_{\rm state}|$ at fixed plateau (Quadrant II signature); and (iii) use *phase–twist interferometry* to extract NG soft structure from broken currents via Ward/Nielsen–protected relations (Sections 7.4 and 7.5; [91, 117, 442, 82]).

4.1 Readout pipeline (band–projected coherence)

We use the band–projected coherence functional of Section 7.4.1 and eq. (7.115), with the same UV projector $P_x(\lambda_{\mathrm{UV}})$ and IR window $K_{\mathrm{IR}}^{(\ell)}$ as in Section 7.3. Write the band filter as

$$\mathsf{B}_{\lambda,\ell} \;:=\; P_x(\lambda_{\mathrm{UV}})\, K_{\mathrm{IR}}^{(\ell)}\,, \qquad [\hat{Q}_{\mathrm{BRST}}, \mathsf{B}_{\lambda,\ell}] = [\mathsf{J}_\alpha, \mathsf{B}_{\lambda,\ell}] = 0 \;\; \text{on } \mathcal{H}_{\mathrm{phys}} \; (\textit{eq.}\ (7.244)). \tag{7.354}$$

For a given channel $\alpha \in \{\mathrm{law}, \mathrm{state}\}$ with branch unitaries $(U_1^{(\alpha)}, U_2^{(\alpha)})$ obeying the commutation/BRST constraints (Section 7.7.1), define the band–projected visibility

$$\Lambda_\alpha(\lambda_{\mathrm{UV}}, \ell) = \frac{\Big|\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathsf{B}_{\lambda,\ell}\, U_1^{(\alpha)\dagger} U_2^{(\alpha)}\, \rho_\alpha\Big)\Big|}{\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathsf{B}_{\lambda,\ell}\, \rho_\alpha\Big)}\,. \tag{7.355}$$

For $\alpha = \mathrm{law}$ this specialises to eq. (7.254). For the *state* channel we keep the explicit volume dependence (system size V) in the preparation and readout:

$$\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V) = \frac{\Big|\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathsf{B}_{\lambda,\ell}\, U_1^{(\mathrm{state})\dagger} U_2^{(\mathrm{state})}\, \rho_{\mathrm{ref}}(V)\Big)\Big|}{\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathsf{B}_{\lambda,\ell}\, \rho_{\mathrm{ref}}(V)\Big)}\,, \tag{7.356}$$

where $\rho_{\mathrm{ref}}(V)$ denotes the branchwise prepared band state at volume V (constructed in Section 7.7.2). At fixed certified plateaus, Quadrant II implies $|\Lambda_{\mathrm{law}}| \approx 1$ (cf. eqs. (7.257) and (7.259)) and $\lim_{V\to\infty} |\Lambda_{\mathrm{state}}| = 0$ (§2.6).

Integrated readouts (optional). To improve signal and track robustness across the window, we also use weighted, band–integrated visibilities. Let $\mu(\lambda_{\mathrm{UV}}, \ell)$ be an admissible probability density supported on a certified plateau (Section 7.4.5). Define

$$\overline{\Lambda}_\alpha[\mu] := \int d(\ln \lambda_{\mathrm{UV}})\, d(\ln \ell)\; \mu(\lambda_{\mathrm{UV}}, \ell)\, \Lambda_\alpha(\lambda_{\mathrm{UV}}, \ell)\,. \tag{7.357}$$

By eq. (7.137) and eq. (7.259), integrated readouts inherit the same tolerances, i.e. $\overline{\Lambda}_{\mathrm{law}}[\mu] = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$ and the finite–size $|\overline{\Lambda}_{\mathrm{state}}[\mu]|$ decays in V at fixed μ.

Reporting. For each run we report: (i) the plateau region and $\varepsilon_{\mathrm{plat}}$ used; (ii) $\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell)$ and/or $\overline{\Lambda}_{\mathrm{law}}[\mu]$ with the Nielsen slope $\partial_\zeta \Lambda_{\mathrm{law}}$ (eq. (7.260)); (iii) $\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V)$ (and optionally $\overline{\Lambda}_{\mathrm{state}}[\mu; V]$) at several V, together with finite–size slopes $-V^{-1} \ln |\Lambda_{\mathrm{state}}|$ at fixed plateaus (cf. §2.6); and (iv) regulator–order checks as in eq. (7.265).

4.2 Law–channel invariant (calibration and guardrail)

With a *symmetric* calibration state ρ_0 and law–branch reparametrisations satisfying $[U_b^{(\mathrm{law})}, \hat{H}_0] = [U_b^{(\mathrm{law})}, \hat{Q}_{\mathrm{BRST}}] = [U_b^{(\mathrm{law})}, \mathsf{J}_\alpha] = 0$ (Section 7.7.1), the exact on–shell identities (Section 7.5) together with the band commutators (eq. (7.244)) give the ideal law–channel value $\Lambda_{\mathrm{law}} = 1$ (eq. (7.257)). On a certified plateau this becomes

$$\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell) = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}}) \qquad \text{with } \varepsilon_{\mathrm{plat}} \text{ bounded by } \textit{eq.}\ (7.137). \tag{7.358}$$

Operational guardrail (explicit bound). Combining the regulator–order budget eq. (7.258) with the projector–commutator acceptance eq. (7.265) yields

$$\left|1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell)\right| \;\le\; C_{\mathrm{plat}}\, \varepsilon_{\mathrm{plat}} \;+\; C_{\mathrm{reg}}\, \varepsilon_{\mathrm{reg}}, \tag{7.359}$$

for channel–independent constants $C_{\mathrm{plat}}, C_{\mathrm{reg}} = \mathcal{O}(1)$ determined by the window and the chosen norm on $\mathcal{H}_{\mathrm{phys}}$. Hence a systematic plateau–level deficit that exceeds the right–hand side violates at least one Quadrant II hypothesis (hidden explicit breaking, BRST misalignment, or contamination by state operations); triage per Sections 7.7.1 and 7.7.3.

Calibration checklist. At the plateau used for SSB runs, report: (i) branch–swap invariance of Λ_{law}; (ii) Nielsen slope $\partial_\zeta \Lambda_{\mathrm{law}}$ within eq. (7.260); (iii) regulator–order permutation within $\mathcal{O}(\varepsilon_{\mathrm{plat}})$; (iv) compliance with eq. (7.359). These certify that the law interferometer acts as a *guardrail* for the state–channel analysis.

4.3 State visibility and finite–size scaling

For a broken preparation ρ_{br} (Section 7.7.2), the state–branch unitaries compare either *two distinct vacua* related by G or *two preparations* on one vacuum:

$$\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V) = \frac{\left|\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\left(P_x K_{\mathrm{IR}}^{(\ell)}\, U_1^{(\mathrm{state})\dagger} U_2^{(\mathrm{state})}\, \rho_{\mathrm{br}}\right)\right|}{\mathrm{Tr}_{\mathcal{H}_{\mathrm{phys}}}\left(P_x K_{\mathrm{IR}}^{(\ell)}\, \rho_{\mathrm{br}}\right)}, \tag{7.360}$$

(cf. eq. (7.356)). Quadrant II requires the *two–channel* signature at fixed plateau:

$$\left|\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell)\right| \simeq 1, \qquad \lim_{V\to\infty} \left|\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V)\right| = 0, \tag{7.361}$$

(cf. eqs. (7.139), (7.257) and (7.259)).

Rate function and scaling collapse. Define the (band, plateau–fixed) rate function

$$I_V(\lambda_{\mathrm{UV}}, \ell) := -\frac{1}{V} \ln \left|\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V)\right|. \tag{7.362}$$

A broken phase exhibits a nonzero asymptotic rate

$$\lim_{V\to\infty} I_V(\lambda_{\mathrm{UV}}, \ell) =: I_\star(\ell) > 0, \tag{7.363}$$

with $I_\star$ depending on NG stiffness/interfacial tension and the IR window ℓ. When interfaces dominate (e.g. fixed–twist preparations), it is convenient to replace V in eq. (7.362) by an effective size $V_{\mathrm{eff}} \propto L^{d-1}$ (sample area), which we will indicate explicitly when used.

Common decay laws (to be reported, not assumed). On certified plateaus, the large–size envelope of $|\Lambda_{\text{state}}|$ typically follows

$$\begin{aligned} \left|\Lambda_{\text{state}}\right| &\sim \exp\Big[-\kappa(\ell)\,V\Big] && \text{(bulk–dominated)},\\ \left|\Lambda_{\text{state}}\right| &\sim \exp\Big[-\sigma(\ell)\,L^{d-1}\Big] && \text{(interface–dominated)}, \end{aligned} \tag{7.364}$$

or, more generally, a stretched–exponential form with an empirically determined exponent. We *report* the best supported law together with confidence bands and the underlying plateau diagnostics, rather than imposing a priori ν.

Acceptance and reporting. At a fixed certified plateau:

1. **Two–channel check:** verify $|\Lambda_{\text{law}}| = 1 + \mathcal{O}(\varepsilon_{\text{plat}})$ (eq. (7.358)) simultaneously with decay of $|\Lambda_{\text{state}}|$.
2. **Rate convergence:** show I_V from eq. (7.362) is monotone (up to finite–size noise) and converges to a plateau–stable $I_\star > 0$ within uncertainty (criterion eq. (7.363)).
3. **Model fit (optional):** fit $\kappa(\ell)$ or $\sigma(\ell)$ in eq. (7.364) and display a scaling collapse across V (or L^{d-1}) with ℓ held within the same plateau.
4. **Robustness:** repeat items 1–3 under admissible regulator permutations and small gauge changes; accept only if variations remain within $\mathcal{O}(\varepsilon_{\text{plat}})$ and Nielsen slopes satisfy eq. (7.260).

4.4 Phase–twist interferometry: construction

Setup and band/BRST admissibility (general d). Let J^μ_a be a conserved Noether current for a *broken* global generator T_a in $D = d{+}1$ spacetime dimensions ($\partial_\mu J^\mu_a = 0$ in the symmetric law; Section 7.5). Choose a smooth spatial smearing $F(\mathbf{x})$ supported inside the IR window and a compact time window $f(t)$; define the band–compatible smeared charge

$$Q_a[F] := \int d^d x\, F(\mathbf{x})\, J^0_a(t,\mathbf{x}), \qquad \Big[\hat{Q}_{\text{BRST}}, Q_a[F]\Big] = 0, \quad \Big[\mathsf{B}_{\lambda,\ell}, Q_a[F]\Big] = 0, \tag{7.365}$$

with $\mathsf{B}_{\lambda,\ell} := P_x(\lambda_{\text{UV}})K^{(\ell)}_{\text{IR}}$ as in eq. (7.354) and band closure eq. (7.244). Implement *opposite* twists on the two state branches,

$$U_1^{(\text{state})}(\phi) = e^{+\mathrm{i}\phi\, Q_a[F]}, \qquad U_2^{(\text{state})}(\phi) = e^{-\mathrm{i}\phi\, Q_a[F]}. \tag{7.366}$$

Characteristic function (band version). The ϕ–dependent visibility is the modulus of the characteristic function of band–projected charge fluctuations,

$$\Lambda_{\text{state}}(\phi;\lambda_{\text{UV}},\ell) = \frac{\Big|\operatorname{Tr}_{\mathcal{H}_{\text{phys}}}\Big(\mathsf{B}_{\lambda,\ell}\, e^{\,2\mathrm{i}\phi\, Q_a[F]}\,\rho_{\text{br}}\Big)\Big|}{\operatorname{Tr}_{\mathcal{H}_{\text{phys}}}\Big(\mathsf{B}_{\lambda,\ell}\,\rho_{\text{br}}\Big)}, \qquad \Lambda_{\text{state}}(\phi) = \Lambda_{\text{state}}(-\phi). \tag{7.367}$$

Small-ϕ curvature and charge variance. A cumulant expansion (band trace, BRST–closed sector) gives

$$\ln \Lambda_{\text{state}}(\phi; \lambda_{\text{UV}}, \ell) = -\,\phi^2\, \mathrm{Var}_{\text{band}}\Big[Q_a[F]\Big] \;+\; \mathcal{O}(\phi^4), \tag{7.368}$$

so the curvature at $\phi = 0$ is

$$\mathrm{Var}_{\text{band}}\Big[Q_a[F]\Big] = -\,\tfrac{1}{2}\,\frac{\partial^2}{\partial\phi^2}\,\ln \Lambda_{\text{state}}(\phi; \lambda_{\text{UV}}, \ell)\Big|_{\phi=0}. \tag{7.369}$$

Within the measurement window $f(t)$,

$$\mathrm{Var}_{\text{band}}\Big[Q_a[F]\Big] = \int dt\, dt'\, f(t) f(t') \int d^d x\, d^d y\, F(\mathbf{x}) F(\mathbf{y})\, \Big\langle J_a^0(t,\mathbf{x})\, J_a^0(t',\mathbf{y})\Big\rangle_{c,\text{band}}, \tag{7.370}$$

with the connected, BRST–physical correlator; on shell and on a certified plateau this is Nielsen–stable (Sections 7.4.5 and 7.5).

Scaling and susceptibility. For bulk–supported F one typically finds

$$\begin{aligned} \mathrm{Var}_{\text{band}}\Big[Q_a[F]\Big] \;&=\; \chi_a(\ell; F)\, V_{\text{eff}} \;+\; o(V_{\text{eff}}), \\ \Rightarrow \qquad \Lambda_{\text{state}}(\phi) \;&\approx\; \exp\Big[-\,\phi^2\, \chi_a(\ell; F)\, V_{\text{eff}}\Big] \quad (\phi \to 0), \end{aligned} \tag{7.371}$$

where V_{eff} is the effective spatial size determined by the support of F and the IR window (bulk: $V \propto L^d$; interface–dominated: $V_{\text{eff}} \propto L^{d-1}$).

Soft–momentum targeting (NG extraction) in $\mathbb{R}^d$. To probe NG soft structure, use momentum–selective twists

$$F_{\mathbf{q}}(\mathbf{x}) = g_\ell(\mathbf{x})\, \cos(\mathbf{q}\cdot\mathbf{x}), \qquad \mathbf{q} \in \mathbb{R}^d, \quad |\mathbf{q}|\ell \ll 1, \tag{7.372}$$

with g_ℓ a smooth envelope inside $K_{\text{IR}}^{(\ell)}$. Then (7.370) determines a static structure factor

$$\chi_a(\ell; \mathbf{q}) := \int dt\, dt'\, f(t) f(t') \int d^d x\, d^d y\, g_\ell(\mathbf{x}) g_\ell(\mathbf{y})\, e^{\,i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \Big\langle J_a^0(t,\mathbf{x})\, J_a^0(t',\mathbf{y})\Big\rangle_{c,\text{band}}. \tag{7.373}$$

Ward identities for a broken global symmetry imply an NG pole in the time–ordered correlator, which translates into the soft law

$$\chi_a(\ell; \mathbf{q}) \;\xrightarrow[|\mathbf{q}|\to 0]{}\; \frac{F_a^2(\ell)}{\mathbf{q}^{\,2}} \;+\; \text{regular}, \tag{7.374}$$

with $F_a(\ell)$ an IR–windowed decay constant (cf. Sections 7.5 and 7.7.3). From (7.368)–(7.373), the ϕ^2–curvature of $\ln \Lambda_{\text{state}}(\phi; \lambda_{\text{UV}}, \ell)$ at small $|\mathbf{q}|$ directly yields $\chi_a(\ell; \mathbf{q})$ and hence the $1/\mathbf{q}^{\,2}$ NG diagnostic.

Acceptance checks (phase–twist run).

1. **Band/BRST compatibility:** verify $[\mathsf{B}_{\lambda,\ell}, Q_a[F_{\mathbf{q}}]] = 0 = [\hat{Q}_{\mathrm{BRST}}, Q_a[F_{\mathbf{q}}]]$ (cf. eq. (7.365)).
2. **Evenness and curvature:** confirm $\Lambda_{\mathrm{state}}(\phi) = \Lambda_{\mathrm{state}}(-\phi)$ and extract $\mathrm{Var}_{\mathrm{band}}[Q_a[F_{\mathbf{q}}]]$ via (7.369) in a regime where $\mathcal{O}(\phi^4)$ is negligible.
3. **Soft law:** demonstrate $\chi_a(\ell;\mathbf{q}) \sim F_a^2/\mathbf{q}^2$ over the accessible soft window, with regulator and gauge scans within $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ (Nielsen stability).
4. **Two–channel guardrail:** record $|\Lambda_{\mathrm{law}}| = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$ on the same plateau while the phase–twist data are taken (eq. (7.358)).

4.5 Soft limits and Ward/Nielsen protection

Soft pole in current correlators (global G, general d). Fourier-transform the conserved broken-current correlator in $D = d+1$ dimensions. For a spontaneously broken *global* generator T_a one finds, in the EFT/NG regime and on shell,

$$\left\langle J_a^\mu J_b^\nu \right\rangle(\omega,\mathbf{q}) \;\sim\; \frac{F_a(\ell)\,F_b(\ell)}{\omega^2 - c^2\mathbf{q}^2 + \mathrm{i}0^+}\, q^\mu q^\nu \;+\; \text{regular}, \tag{7.375}$$

where $F_a(\ell)$ is the IR–windowed decay constant (cf. eq. (7.374)) and c the NG velocity ([91]). This reproduces the static soft law eq. (7.374) for the equal–time structure factor.

Variance in momentum space and volume scaling. With the band–compatible twist of §4.4 and envelope $F(\mathbf{x})$, define its Fourier profile $F_{\mathbf{q}} = \int d^dx\, e^{-\mathrm{i}\mathbf{q}\cdot\mathbf{x}} F(\mathbf{x})$. At equal times (within the compact window f) the band variance is

$$\mathrm{Var}_{\mathrm{band}}\Big[Q_a[F]\Big] = \int \frac{d^dq}{(2\pi)^d}\, \Big|F_{\mathbf{q}}\Big|^2\, S_{aa}(\ell;\mathbf{q}), \tag{7.376}$$

$$S_{aa}(\ell;\mathbf{q}) := \int dt\, dt'\, f(t) f(t') \,\widetilde{\left\langle J_a^0 J_a^0 \right\rangle}_{c,\mathrm{band}}(\omega{=}0,\mathbf{q}). \tag{7.377}$$

Using eq. (7.375) (or equivalently eq. (7.374)), $S_{aa}(\ell;\mathbf{q}) \sim F_a^2(\ell)/\mathbf{q}^2$ for $|\mathbf{q}| \to 0$, so for bulk–supported F (width $\sim L$) the integral scales with the effective size,

$$\mathrm{Var}_{\mathrm{band}}\Big[Q_a[F]\Big] = \chi_a(\ell;F)\, V_{\mathrm{eff}} + o(V_{\mathrm{eff}}), \tag{7.378}$$

in agreement with eq. (7.371). Here $V_{\mathrm{eff}} \propto L^d$ for bulk envelopes and $V_{\mathrm{eff}} \propto L^{d-1}$ for interface–dominated preparations; $\chi_a(\ell;F)$ is the band susceptibility defined by the current–current correlator.

Small–ϕ visibility and the Quadrant II hallmark. Inserting eq. (7.378) into the cumulant relation eq. (7.368)–eq. (7.369) gives

$$\Lambda_{\mathrm{state}}(\phi;\lambda_{\mathrm{UV}},\ell;V) \;\approx\; \exp\Big[-\,\phi^2\,\chi_a(\ell;F)\,V_{\mathrm{eff}}\Big] \quad (\phi \to 0), \tag{7.379}$$

demonstrating the *volume–decay* signature of Quadrant II at fixed certified plateaus.

Soft insertions and factorisation. Differentiating the phase–twist visibility at $\phi = 0$ inserts $Q_a[F]$ in the band trace. Ward identities for broken global symmetries imply that adding a *soft* NG leg $(\omega, \mathbf{q} \to 0)$ to any on–shell matrix element factors through the action of T_a on external states (soft theorem), and eq. (7.376)–eq. (7.374) provide the corresponding static limit of the current–current sector that the interferometer measures.

Nielsen protection (gauge independence). Because the twist is built from a BRST–closed, gauge–invariant $Q_a[F]$ that commutes with the band filter, the gauge–parameter derivative of the reduced kernel is BRST–exact (eq. (7.339)). Therefore the curvature extracted from $\ln \Lambda_{\text{state}}(\phi)$ (and the inferred χ_a) is ζ–independent on shell within plateau tolerances, matching the scan criterion eq. (7.260) and stability eq. (7.338).

Scope (gauged vs. global). The construction above applies to *global* broken charges. For gauged generators the would–be NG mode is reorganised (BEH mechanism) and the gauge current is not a suitable BRST–closed insertion; use a gauge–invariant global charge (if present). Dimensional constraints (e.g. Coleman/Mermin–Wagner in low D) must also be respected when interpreting the soft limit.

4.6 Gauged (BEH) case: dressed twists and diagnostics

Why dress the twist (general d). If the broken generators are *gauged*, would–be NG modes are reorganised (BEH) into massive transverse vectors (Sections 7.7.2 and 7.7.3), and Elitzur's theorem forbids a gauge–variant charge insertion. The naive smeared charge $\int d^d x\, F(\mathbf{x}) J_a^0$ is not gauge–invariant; instead we construct a *dressed* charge that is BRST–closed and commutes with the band filter.

Dressed charge (band/BRST–compatible). Let $F(\mathbf{x})$ be a smooth envelope supported inside the IR window $K_{\text{IR}}^{(\ell)}$, and let $\Omega \subset \mathbb{R}^d$ be the region it selects (e.g. $F \approx 1$ on Ω, tapered near $\partial\Omega$). Introduce a gauge–invariant $(d-1)$–form (spatial) dressing current $\mathcal{W}_a^i(\mathbf{x})$ supported near $\partial\Omega$ so that the composite

$$Q_a^{\text{dress}}[F, \Sigma] := \int_\Omega d^d x\, F(\mathbf{x})\, J_a^0(t, \mathbf{x}) \;+\; \int_{\Sigma = \partial\Omega} dS_i(\mathbf{y})\, \mathcal{W}_a^i(t, \mathbf{y}) \tag{7.380}$$

is BRST–closed and band–compatible:

$$[\hat{Q}_{\text{BRST}}, Q_a^{\text{dress}}] = 0, \qquad [\mathsf{B}_{\lambda,\ell}, Q_a^{\text{dress}}] = 0, \qquad \mathsf{B}_{\lambda,\ell} := P_x(\lambda_{\text{UV}}) K_{\text{IR}}^{(\ell)} \;\; (\textit{eq. (7.354)}). \tag{7.381}$$

Concretely, $\mathcal{W}_a$ can be chosen so that its gauge variation cancels that of the volume term (a Wilson–type surface dressing), ensuring gauge invariance on $\mathcal{H}_{\text{phys}}$.

Dressed twists and visibility. Implement opposite twists on the two state branches,

$$U_1^{(\text{state})}(\phi) = e^{+\mathrm{i}\phi\, Q_a^{\text{dress}}}, \qquad U_2^{(\text{state})}(\phi) = e^{-\mathrm{i}\phi\, Q_a^{\text{dress}}}, \tag{7.382}$$

and define the dressed state–visibility

$$\Lambda_{\text{state}}^{\text{dress}}(\phi; \lambda_{\text{UV}}, \ell) = \frac{\left| \operatorname{Tr}_{\mathcal{H}_{\text{phys}}} \left(\mathsf{B}_{\lambda,\ell}\, e^{\,2\mathrm{i}\phi\, Q_a^{\text{dress}}}\, \rho_{\text{br}} \right) \right|}{\operatorname{Tr}_{\mathcal{H}_{\text{phys}}} \left(\mathsf{B}_{\lambda,\ell}\, \rho_{\text{br}} \right)}, \qquad \Lambda_{\text{state}}^{\text{dress}}(\phi) = \Lambda_{\text{state}}^{\text{dress}}(-\phi). \tag{7.383}$$

Small–ϕ behaviour and boundary law. By the cumulant expansion in the BRST–closed band trace (cf. §4.4),

$$\ln \Lambda^{\mathrm{dress}}_{\mathrm{state}}(\phi) = -\,\phi^2\,\mathrm{Var}_{\mathrm{band}}\Big[Q_a^{\mathrm{dress}}\Big] + \mathcal{O}(\phi^4). \tag{7.384}$$

In a BEH phase the current–current sector is *short–ranged* (no NG pole), and Gauss constraints move weight from the bulk to $\partial\Omega$ through the dressing term. Consequently,

$$\mathrm{Var}_{\mathrm{band}}\Big[Q_a^{\mathrm{dress}}\Big] = \tilde{\chi}_a(\ell; F, \Sigma)\, S_{\mathrm{eff}} \;+\; o(S_{\mathrm{eff}}), \qquad S_{\mathrm{eff}} \propto L^{\,d-1}, \tag{7.385}$$

where S_{eff} is the effective $(d{-}1)$–dimensional measure of the dressing surface and $\tilde{\chi}_a$ a band susceptibility for the dressed operator. Thus,

$$\Lambda^{\mathrm{dress}}_{\mathrm{state}}(\phi; \lambda_{\mathrm{UV}}, \ell) \;\approx\; \exp\Big[-\,\phi^2\,\tilde{\chi}_a(\ell; F, \Sigma)\, S_{\mathrm{eff}}\Big] \quad (\phi \to 0), \tag{7.386}$$

showing a *boundary law* (area/perimeter in general d) rather than a bulk volume law.

Spectral picture and poles. In momentum space the physical transverse vector correlator (on shell, band–reduced; Corollary 7.343) has a massive pole,

$$\Big\langle A_i^T\, A_j^T \Big\rangle(\omega, \mathbf{q}) \sim \frac{\Pi_{ij}^T(\mathbf{q})}{\omega^2 - c^2\mathbf{q}^{\,2} - m_V^2 + \mathrm{i}0^+} \quad \Rightarrow \quad \widetilde{\big\langle J^0 J^0 \big\rangle}_{c,\mathrm{band}}(\omega{=}0, \mathbf{q}) = \text{regular at } \mathbf{q}{=}0, \tag{7.387}$$

consistent with (7.385) once the Gauss/dressing contribution is included.

Acceptance (BEH run).

1. **Law guardrail:** verify $|\Lambda_{\mathrm{law}}| = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$ on the same plateau (eq. (7.358)).
2. **Dressing admissibility:** check $[\hat{Q}_{\mathrm{BRST}}, Q_a^{\mathrm{dress}}] = 0$ and $[\mathsf{B}_{\lambda,\ell}, Q_a^{\mathrm{dress}}] = 0$ (eq. (7.381)).
3. **Boundary scaling:** extract $\mathrm{Var}_{\mathrm{band}}[Q_a^{\mathrm{dress}}]$ from $\ln \Lambda^{\mathrm{dress}}_{\mathrm{state}}(\phi)$ and show S_{eff}-law scaling as in eq. (7.385) (e.g. $S_{\mathrm{eff}} \propto L^{d-1}$).
4. **ST/Nielsen stability:** demonstrate gauge–parameter independence of the extracted vector mass m_V and transverse residues within the band (Nielsen: eq. (7.339); ST closure: Section 7.5), and regulator robustness on the plateau (eq. (7.338)).

Scope. The construction targets *gauged* broken generators (BEH phases). For purely global symmetry breaking use the undressed twist of §4.4, which exhibits bulk volume scaling through the NG pole.

4.7 Plateau certification for visibilities

All readouts are asserted *on certified plateaus*. Concretely, with the band filter $\mathsf{B}_{\lambda,\ell} := P_x(\lambda_{\mathrm{UV}})K_{\mathrm{IR}}^{(\ell)}$ (eq. (7.354)) and Λ_α defined in eqs. (7.355) and (7.356), we require the following

window–flatness metrics (in the coordinates $u := \ln \lambda_{\mathrm{UV}}$, $v := \ln \ell$):

$$\mathcal{G}_\alpha := \sup_{(u,v)\in\mathcal{P}} \left\| \nabla_{(u,v)} \Lambda_\alpha(u,v) \right\|, \qquad \mathcal{O}_\alpha := \sup_{\gamma\subset\mathcal{P}} \left| \oint_\gamma \nabla \Lambda_\alpha \cdot d\boldsymbol{\ell} \right|, \qquad \mathcal{C}_\alpha := \sup_{(u,v)\in\mathcal{P}} \left\| \nabla^2_{(u,v)} \Lambda_\alpha \right\|, \tag{7.388}$$

to obey the tolerance bounds specified by eq. (7.137):

$$\mathcal{G}_\alpha \le \varepsilon_{\mathrm{grad}}, \qquad \mathcal{O}_\alpha \le \varepsilon_{\mathrm{osc}}, \qquad \mathcal{C}_\alpha \le \varepsilon_{\mathrm{curv}} \quad \text{for each } \alpha \in \{\mathrm{law}, \mathrm{state}\}. \tag{7.389}$$

Integrated readouts inherit these tolerances: for any admissible weight μ supported on the plateau (Section 7.4.5 and eq. (7.357)) we demand

$$\left| \overline{\Lambda}_\alpha[\mu] - \Lambda_\alpha(u_*, v_*) \right| = \mathcal{O}\big(\varepsilon_{\mathrm{plat}}\big) \quad \text{for any reference point } (u_*, v_*) \in \mathrm{supp}(\mu). \tag{7.390}$$

Nielsen (gauge–parameter) protection. For *physical* outputs (pole locations, residues, and susceptibilities extracted from $\ln \Lambda_{\mathrm{state}}$), on-shell Nielsen identities imply vanishing gauge slopes within the plateau tolerances (cf. eqs. (7.260) and (7.339)):

$$\partial_\zeta \Lambda_{\mathrm{state}} = \mathcal{O}(\varepsilon_{\mathrm{plat}}), \qquad \partial_\zeta \chi_a = \mathcal{O}(\varepsilon_{\mathrm{plat}}), \tag{7.391}$$

and likewise for Λ_{law} (cf. eq. (7.260)). Reports must include the measured slopes and the window $\mathcal{P}$ used.

4.8 Practical protocol (run–sheet)

1. **Calibration (law guardrail).** With a symmetric ρ_0, verify $|\Lambda_{\mathrm{law}}| = 1 + \mathcal{O}(\varepsilon_{\mathrm{plat}})$ at the chosen plateau, and enforce the commutator/ordering bounds eqs. (7.265) and (7.359). Record $\partial_\zeta \Lambda_{\mathrm{law}}$ and regulator permutations.

2. **Broken readout (finite–size series).** Prepare the broken state ρ_{br} (see Section 7.7.2). At fixed $(\lambda_{\mathrm{UV}}, \ell) \in \mathcal{P}$, measure the state–channel visibility $\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V)$ along a size ladder V (with linear size L in d spatial dimensions). Compute the rate function I_V as in eq. (7.362) and test the convergence $I_V \to I_\star > 0$ per eq. (7.363).

3. **Phase–twist scan (small ϕ).** Implement $U_{1,2}^{(\mathrm{state})}(\phi)$ as in §4.4 (or the dressed version of §4.6 for gauged cases). Fit $\ln \Lambda_{\mathrm{state}}(\phi)$ near $\phi = 0$; extract $\chi_a \equiv -\partial_\phi^2 \ln \Lambda_{\mathrm{state}}\,|_{\phi=0} = \mathrm{Var}_{\mathrm{band}}[Q_a[F]]$ using eq. (7.369), and (optionally) its $\mathbf{q}$-dependence via eq. (7.373).

4. **Soft check (global vs. gauged).** For global breaking, verify NG consistency in the soft limit $\chi_a(\ell; \mathbf{q}) \sim F_a^2/\mathbf{q}^2$ (eq. (7.374)) and volume scaling (eq. (7.371)). For gauged breaking, use the dressed twist and confirm boundary–law scaling (eq. (7.385)) and massive–vector consistency (eq. (7.387)). Confirm Nielsen/Slavnov–Taylor stability (Section 7.5 and eq. (7.391)).

5. **Integration and robustness.** Compare differential and integrated readouts Λ_α vs. $\overline{\Lambda}_\alpha[\mu]$ (eq. (7.390)) across admissible (P_x, K_{IR}) choices (commuting with BRST/G); accept if deviations are $\mathcal{O}(\varepsilon_{\mathrm{plat}})$.

4.9 Acceptance tests (Quadrant II)

- **Law unity (guardrail).** $|1 - \Lambda_{\rm law}| \le C_{\rm plat}\varepsilon_{\rm plat} + C_{\rm reg}\varepsilon_{\rm reg}$ (eq. (7.359)); gradients/oscillations/curvatures within eq. (7.389).
- **State suppression (global).** At fixed plateau, $I_V = -(1/V)\ln|\Lambda_{\rm state}|$ (eq. (7.362)) converges to $I_\star > 0$ (eq. (7.363)); a fit to the families in eq. (7.364) (bulk or interface dominated) passes goodness checks with reported confidence intervals.
- **State suppression (gauged, dressed).** Define a boundary rate

$$J_L := -\frac{1}{L^{d-1}}\ln\left|\Lambda^{\rm dress}_{\rm state}(\phi_0)\right| \tag{7.392}$$

  for a fixed small ϕ_0; accept if J_L plateaus to $J_\star > 0$ as $L \to \infty$, consistent with eqs. (7.385) and (7.386):

$$\lim_{L\to\infty} J_L = J_\star(\phi_0, \ell) > 0. \tag{7.393}$$

- **Soft structure.** For global breaking: $\chi_a(\ell;\mathbf{q}) \sim F_a^2/\mathbf{q}^2$ as $|\mathbf{q}| \to 0$ (eq. (7.374)), consistent with the EFT dispersion. For gauged breaking: no $1/\mathbf{q}^2$ singularity in J^0J^0 (regular soft limit) and a massive transverse pole (eq. (7.387)).
- **Gauge independence (Nielsen).** Gauge–parameter derivatives of *physical* outputs satisfy $\partial_\zeta(\text{poles, residues}, \chi_a) = \mathcal{O}(\varepsilon_{\rm plat})$ (eqs. (7.260), (7.339) and (7.391)).

4.10 Failure modes and remedies

- $|\Lambda_{\rm law}| < 1$ *at plateau.* Violates the law guardrail. Remedy: recheck commutators and BRST closure (Section 7.7.1 and eqs. (7.265) and (7.359)); re–certify the plateau (eq. (7.389)) and the exact–identity sector (Section 7.5).
- *No V–decay of $|\Lambda_{\rm state}|$ (global).* Causes: off–plateau evaluation, wrong order of limits, residual explicit breaking. Remedy: enforce ordered limits (eq. (7.275)); audit the seed protocol and Ward checks (Sections 7.5 and 7.7.2); verify $\chi_a(\ell;\mathbf{q})$ exhibits the $1/\mathbf{q}^2$ soft behaviour (eq. (7.374)).
- *Gauge–parameter drift of χ_a or poles.* Indicates off–shell contamination or missing counterterms. Remedy: project to the physical band, re–impose ST/Nielsen (Section 7.5 and eq. (7.339)), and recalibrate the plateau (eq. (7.389)).
- *Inconsistent boundary scaling (gauged).* Likely an inadmissible twist. Remedy: replace the naive charge by a Wilson–dressed construction (eq. (7.380)) and verify $[\hat{Q}_{\rm BRST}, Q_a^{\rm dress}] = 0 = [\mathsf{B}_{\lambda,\ell}, Q_a^{\rm dress}]$ (eq. (7.381)); confirm massive–vector signatures (eq. (7.387)).

Outcome. Step 4 delivers quantitative coherence diagnostics that characterise Quadrant II: (i) unity of the law channel within certified tolerances; (ii) suppression of state visibility by finite–size (global) or boundary–law (gauged) scaling; and (iii) a phase–twist route to NG soft structure protected by Ward/Nielsen identities (Sections 7.4 and 7.5). Any emergent identifications ("Higgs–like", "graviton–like", "apeiron/chrono–kymon") remain *provisional* pending cross–quadrant checks and plateau–stability certification.

7.7.5 Plateau Certification and Gauge-parameter Independence

Aim. To make the interferometric diagnosis of Quadrant II *quantitative and regulator-stable*, we certify plateaus in the $(\ln \lambda_{\mathrm{UV}}, \ln \ell)$ plane for all relevant readouts—especially Λ_{law} and Λ_{state} from Section 7.7.4—and for the physical spectral data extracted in Section 7.7.3. Certification follows the geometric criteria and acceptance pipeline stated in Sections 7.3 and 7.4.5, and on-shell gauge-parameter independence is enforced via the Nielsen and Slavnov–Taylor identities (Section 7.5; [117, 442, 91, 82, 243]).

5.1 Geometric definition of plateaus (local tests)

Mesh and notation. Work on a rectangular mesh in $(u, v) \equiv (\ln \lambda_{\mathrm{UV}}, \ln \ell)$:

$$(u_i, v_j) \in \mathcal{G}, \quad u_{i\pm1} - u_i = \Delta u, \quad v_{j\pm1} - v_j = \Delta v, \tag{7.394}$$

and let $R_\alpha(u_i, v_j)$ denote any band readout, with $\alpha \in \{\text{law}, \text{state}, \text{pole indices}, \text{residue indices}\}$. All R_α are evaluated with the same band filter $\mathsf{B}_{\lambda,\ell} = P_x(\lambda_{\mathrm{UV}}) K_{\mathrm{IR}}^{(\ell)}$ and BRST–closed insertions.

Local gradients (finite differences). Use centred differences for interior points (one–sided at the boundary):

$$\partial_u R_\alpha(u_i, v_j) \approx \frac{R_\alpha(u_{i+1}, v_j) - R_\alpha(u_{i-1}, v_j)}{2\,\Delta u}. \tag{7.395}$$

$$\partial_v R_\alpha(u_i, v_j) \approx \frac{R_\alpha(u_i, v_{j+1}) - R_\alpha(u_i, v_{j-1})}{2\,\Delta v}. \tag{7.396}$$

For dimensionless control, the (optional) relative-gradient form $\tilde{\nabla} R_\alpha := (\partial_u R_\alpha, \partial_v R_\alpha) \big/ \max\{|R_\alpha|, R_{\min}\}$ can be used with a small floor $R_{\min}$.

Local curvature (Hessian spectral norm). Define the discrete Hessian at (u_i, v_j) by

$$\begin{aligned} \partial_{uu} R_\alpha &\approx \frac{R_{i+1,j} - 2R_{i,j} + R_{i-1,j}}{\Delta u^2}, \\ \partial_{vv} R_\alpha &\approx \frac{R_{i,j+1} - 2R_{i,j} + R_{i,j-1}}{\Delta v^2}, \\ \partial_{uv} R_\alpha &\approx \frac{R_{i+1,j+1} - R_{i+1,j-1} - R_{i-1,j+1} + R_{i-1,j-1}}{4\,\Delta u\,\Delta v}, \end{aligned} \tag{7.397}$$

and set $\mathcal{H}_\alpha(u_i, v_j) := \begin{pmatrix} \partial_{uu} & \partial_{uv} \\ \partial_{uv} & \partial_{vv} \end{pmatrix} R_\alpha$. The curvature proxy is the spectral (operator-2) norm:

$$\|\mathcal{H}_\alpha(u_i, v_j)\|_2 \;:=\; \max\{\text{eigenvalues of } (\mathcal{H}_\alpha^\top \mathcal{H}_\alpha)^{1/2}\}. \tag{7.398}$$

Local oscillation proxy (short-range variance). On a fixed stencil $\mathcal{S}_{i,j} \subset \mathcal{G}$ of radius r (e.g. Moore neighbourhood in the L_∞ metric),

$$\begin{aligned} \mathrm{osc}_\alpha(u_i, v_j) &:= \left(\frac{1}{|\mathcal{S}_{i,j}|} \sum_{(m,n)\in\mathcal{S}_{i,j}} \Big(R_\alpha(u_m, v_n) - \overline{R}_{\alpha,\mathcal{S}_{i,j}} \Big)^2 \right)^{1/2}, \\ \overline{R}_{\alpha,\mathcal{S}_{i,j}} &:= \frac{1}{|\mathcal{S}_{i,j}|} \sum_{(m,n)\in\mathcal{S}_{i,j}} R_\alpha(u_m, v_n). \end{aligned} \tag{7.399}$$

(Equivalently, a bounded second–difference energy can be used; both are compatible with eq. (7.137).)

Pointwise acceptance mask. Given the tolerances $(\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{curv}}, \varepsilon_{\mathrm{osc}})$ from eq. (7.137), define

$$\mathcal{M}_\alpha(u_i, v_j) := \mathbf{1}\Big(\big|\partial_u R_\alpha\big| \le \varepsilon_{\mathrm{grad}} \ \wedge\ \big|\partial_v R_\alpha\big| \le \varepsilon_{\mathrm{grad}} \ \wedge\ \|\mathcal{H}_\alpha\|_2 \le \varepsilon_{\mathrm{curv}} \ \wedge\ \mathrm{osc}_\alpha \le \varepsilon_{\mathrm{osc}} \Big)_{(u_i,v_j)}. \tag{7.400}$$

Connected components and morphological closing. Let $\mathcal{Z}_\alpha := \{(u_i, v_j) \in \mathcal{G} : \mathcal{M}_\alpha(u_i, v_j) = 1\}$. Apply a mild morphological closing (dilation by radius r_{dil} followed by erosion by the same radius) to fill sub-mesh pinholes without bridging separated flats; denote the result by $\mathcal{Z}_\alpha^{\mathrm{cl}}$. Define the *channel plateaus* as the connected components of $\mathcal{Z}_\alpha^{\mathrm{cl}}$ that exceed a minimal area $A_{\min}$ (in cells).

Core plateau (boundary margin). To avoid edge effects in downstream estimates, erode each accepted component by a margin r_{core} cells and keep the nonempty remainder:

$$\mathcal{P}_\alpha^\circ := \mathrm{Erode}_{r_{\mathrm{core}}}\Big(\mathrm{LargestComponents}\big(\mathcal{Z}_\alpha^{\mathrm{cl}}\big) \Big). \tag{7.401}$$

For multi–readout certification, intersect cores across channels:

$$\mathcal{P} := \bigcap_{\alpha\in\mathcal{A}} \mathcal{P}_\alpha^\circ, \qquad \mathcal{A} \subseteq \{\text{law}, \text{state}, \text{pole/residue indices}\}. \tag{7.402}$$

Anisotropy and scaling of axes. If ∂_u and ∂_v sensitivities differ strongly, use a scaled metric $\|\nabla R_\alpha\|_M := \|(S\,\nabla R_\alpha)\|_2$ with $S = \mathrm{diag}(s_u, s_v)$ chosen from prior scans or the dynamic range of each axis; adjust $\varepsilon_{\mathrm{grad}}$ accordingly. This keeps eq. (7.400) invariant under benign reparameterisations of (u, v).

Consistency with global plateau metrics. On any accepted $\mathcal{P}$, the global gradient/oscillation/curvature metrics of eq. (7.388) satisfy the bounds of eq. (7.389) by construction; integrated readouts then obey eq. (7.390). Reports should list: grid spacings $(\Delta u, \Delta v)$, stencil radius r, morphology radii $(r_{\mathrm{dil}}, r_{\mathrm{core}})$, area thresholds $A_{\min}$, and the final $\mathcal{P}$.

5.2 Joint plateau and channel hierarchy

Definition (joint plateau from core components). Let $\mathcal{P}_\alpha^\circ$ be the *core plateau* of channel α obtained in §5.1 after morphological closing and boundary erosion (eq. (7.401)). For a chosen index set $\mathcal{I} \subseteq \{\text{law}, \text{state}, \text{poles}, \text{residues}\}$, define the *joint plateau* as the core–intersection

$$\mathfrak{P} \;:=\; \bigcap_{\alpha\in\mathcal{I}} \mathcal{P}_\alpha^\circ\,. \tag{7.403}$$

When $\mathfrak{P}$ is disconnected, denote by $\{\mathfrak{C}_k\}_{k=1}^{N}$ its connected components (on the (u,v) mesh of eq. (7.394)).

Channel hierarchy (operational order). We certify in the order

$$\text{law} \;\longrightarrow\; \text{state} \;\longrightarrow\; (\text{poles}, \text{residues}),$$

so that $\mathcal{I}$ is grown stepwise: (i) certify $\mathcal{P}_{\text{law}}^\circ$; (ii) intersect with $\mathcal{P}_{\text{state}}^\circ$; (iii) intersect with the spectral cores needed for the physics claim (e.g. NG stiffness proxies or BEH masses from §3). If any step yields an empty intersection, apply the fallback below before proceeding.

Aggregate plateau bounds (intersection consistency). On any joint component $\mathfrak{C} \subseteq \mathfrak{P}$, define the channel–wise maxima of the local metrics from eq. (7.400):

$$\mathcal{G}_{\alpha,\mathfrak{C}} := \sup_{\mathfrak{C}} \|\nabla R_\alpha\|, \quad \mathcal{C}_{\alpha,\mathfrak{C}} := \sup_{\mathfrak{C}} \|\mathcal{H}_\alpha\|_2, \quad \mathcal{O}_{\alpha,\mathfrak{C}} := \sup_{\mathfrak{C}} \operatorname{osc}_\alpha\,. \tag{7.404}$$

The joint component is admissible iff, for all $\alpha \in \mathcal{I}$,

$$\mathcal{G}_{\alpha,\mathfrak{C}} \le \varepsilon_{\text{grad}}, \qquad \mathcal{C}_{\alpha,\mathfrak{C}} \le \varepsilon_{\text{curv}}, \qquad \mathcal{O}_{\alpha,\mathfrak{C}} \le \varepsilon_{\text{osc}}, \tag{7.405}$$

and the integrated/differential agreement eq. (7.390) holds on $\mathfrak{C}$.

Component scoring (area and condition). For each admissible $\mathfrak{C}_k$, define an effective area

$$A_{\text{eff}}(\mathfrak{C}_k) := |\mathfrak{C}_k|\,\Delta u\,\Delta v, \tag{7.406}$$

and a simple "condition number" that aggregates the normalised tolerances across $\mathcal{I}$:

$$\kappa(\mathfrak{C}_k) := \max_{\alpha\in\mathcal{I}} \left\{ \frac{\mathcal{G}_{\alpha,\mathfrak{C}_k}}{\varepsilon_{\text{grad}}}, \frac{\mathcal{C}_{\alpha,\mathfrak{C}_k}}{\varepsilon_{\text{curv}}}, \frac{\mathcal{O}_{\alpha,\mathfrak{C}_k}}{\varepsilon_{\text{osc}}} \right\}. \tag{7.407}$$

Select the primary joint plateau by the lexicographic rule

$$\mathfrak{C}_\star := \arg\max_{\mathfrak{C}_k} \Big(A_{\text{eff}}(\mathfrak{C}_k),\; -\kappa(\mathfrak{C}_k) \Big), \tag{7.408}$$

i.e. largest effective area, then smallest κ as tie–breaker. Set $\mathfrak{P}_\star := \mathfrak{C}_\star$ for downstream physics.

Fallback when $\mathfrak{P} = \varnothing$. If the intersection is empty at a given hierarchy step:

1. **Re–mesh:** halve $(\Delta u, \Delta v)$ locally around the best overlapping fringes (identified by distance transforms between cores).
2. **Re–close:** apply a minimal increase of the closing radius $r_{\mathrm{dil}} \mapsto r_{\mathrm{dil}}{+}1$ and re–erode by the same margin to avoid spurious bridges.
3. **Tolerance micro–relaxation:** increase $\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{osc}}, \varepsilon_{\mathrm{curv}}$ by a common factor $1 + \delta$ with $\delta \le 0.1$, *only* for the spectral channel(s); keep the law/state tolerances fixed to preserve the guardrail.

If $\mathfrak{P}$ remains empty, report *no certified joint plateau* and revert to §4 diagnostics.

Reporting. For transparency, record: the set $\mathcal{I}$, the selected $\mathfrak{P}_\star$ (bounding box in (u, v)), $(\Delta u, \Delta v)$, morphology radii $(r_{\mathrm{dil}}, r_{\mathrm{core}})$, thresholds $(\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{osc}}, \varepsilon_{\mathrm{curv}})$, and the scores $\{A_{\mathrm{eff}}, \kappa\}$ for all admissible components. This enables reproducibility and direct application of eqs. (7.389) and (7.390).

5.3 Integrated readouts and inheritance

Admissible weights and supports. Let $\mathcal{P}$ be a certified plateau (or its core $\mathcal{P}^\circ$, cf. eq. (7.401)). A *band–admissible* weight is a non–negative function supported inside $\mathcal{P}$ and normalised to one:

$$w \ge 0, \qquad \int w = 1, \qquad \operatorname{supp} w \subset \mathcal{P} \text{ (or } \mathcal{P}^\circ). \tag{7.409}$$

We allow w to depend on the orthogonal coordinate (e.g. $w(u; v_*)$ at fixed v_*), or to be a separable 2D weight $W(u, v) = w_u(u) w_v(v)$ with each factor admissible.

Integrated (marginal) readouts: continuous forms. For any band readout $R_\alpha(u, v)$ (law, state, poles/residues), define 1D and 2D integrals

$$\overline{R}_\alpha(v_*) := \int_{u_1}^{u_2} w(u; v_*)\, R_\alpha(u, v_*)\, du, \qquad \int_{u_1}^{u_2} w(\cdot; v_*)\, du = 1, \tag{7.410}$$

$$\overline{R}_\alpha(u_*) := \int_{v_1}^{v_2} w(v; u_*)\, R_\alpha(u_*, v)\, dv, \qquad \int_{v_1}^{v_2} w(\cdot; u_*)\, dv = 1, \tag{7.411}$$

$$\overline{\overline{R}}_\alpha := \iint_{(u,v)\in\mathcal{R}} W(u, v)\, R_\alpha(u, v)\, du\, dv, \qquad \iint_{\mathcal{R}} W = 1, \tag{7.412}$$

where $\mathcal{R} \subset \mathcal{P}$ (typically a small rectangle inside a connected component).

Discrete mesh versions. On the grid $\mathcal{G}$ of eq. (7.394), the natural Riemann–sum analogues are

$$\overline{R}_\alpha(v_j) = \sum_{i=i_1}^{i_2} \omega_i^{(j)}\, R_\alpha(u_i, v_j), \qquad \sum_{i=i_1}^{i_2} \omega_i^{(j)} = 1, \quad \omega_i^{(j)} \ge 0, \tag{7.413}$$

(and similarly along v), or 2D

$$\overline{\overline{R}}_\alpha = \sum_{(i,j)\in\mathcal{R}} \Omega_{ij}\, R_\alpha(u_i, v_j), \qquad \sum_{(i,j)\in\mathcal{R}} \Omega_{ij} = 1, \quad \Omega_{ij} \geq 0, \tag{7.414}$$

with $\operatorname{supp}\omega, \Omega \subset \mathcal{P}$ (or $\mathcal{P}^\circ$).

Lemma 7.345 (Inheritance of plateau bounds)**.** *Assume R_α obeys the local plateau bounds of eq. (7.137) on a neighbourhood of the integration support. Then the integrated readouts $\overline{R}_\alpha$ and $\overline{\overline{R}}_\alpha$ satisfy the* same *type of bounds with equal or better constants:*

$$\left|\partial_v \overline{R}_\alpha(v_*)\right| \leq \int w(u; v_*) \left|\partial_v R_\alpha(u, v_*)\right| du \leq \varepsilon_{\text{grad}}, \tag{7.415}$$

and, analogously, $|\partial_u \overline{R}_\alpha(u_*)| \leq \varepsilon_{\text{grad}}$. For curvature,

$$\left\|\nabla^2 \overline{R}_\alpha(v_*)\right\| \leq \int w(u; v_*) \left\|\nabla^2 R_\alpha(u, v_*)\right\| du \leq \varepsilon_{\text{curv}}, \tag{7.416}$$

and for the oscillation proxy on any stencil contained in $\mathcal{P}$,

$$\operatorname{osc}\left[\overline{R}_\alpha\right] \;\leq\; \int w \operatorname{osc}[R_\alpha] \;\leq\; \varepsilon_{\text{osc}}. \tag{7.417}$$

The discrete versions hold with integrals replaced by convex combinations (7.413)–(7.414).

Proof sketch. Linearity plus convexity of the norm and Jensen's inequality yield $\partial_v \overline{R}_\alpha = \int w\, \partial_v R_\alpha$ and $|\partial_v \overline{R}_\alpha| \leq \int w\, |\partial_v R_\alpha|$. The Hessian estimate is identical using operator norms. For the oscillation proxy, $\operatorname{Var}\left[\int w\, X\right] \leq \int w \operatorname{Var}[X]$ on any bounded stencil; translate to the RMS definition of osc in eq. (7.399). Discrete forms follow from convexity of finite sums with non–negative normalised weights. □

Integrated vs. pointwise agreement (diagnostic). Given a reference point $(u_*, v_*) \in \operatorname{supp}(w) \subset \mathcal{P}$, define

$$\Delta_\alpha := \left|\overline{R}_\alpha - \; R_\alpha(u_*, v_*)\right|. \tag{7.418}$$

By Lemma 7.345 and the mean–value theorem applied inside $\mathcal{P}$, $\Delta_\alpha = \mathcal{O}(\varepsilon_{\text{plat}})$, reproducing eq. (7.390). Reporting should include Δ_α and the chosen weight shape (boxcar/Hann/Gaussian) and support.

Nielsen inheritance. For any physical output R_α protected by the on–shell Nielsen identity (eqs. (7.260) and (7.339)),

$$\partial_\zeta \overline{R}_\alpha = \int w\, \partial_\zeta R_\alpha = \mathcal{O}(\varepsilon_{\text{plat}}), \tag{7.419}$$

i.e. the integrated readout inherits gauge–parameter independence within the same tolerance.

Choice of weights. *Boxcar* weights maximise SNR and are convenient for rectangular $\mathcal{R}$; *Hann* or *Gaussian* (truncated) reduce boundary sensitivity. In all cases abide by (7.409); for narrow plateaus use the core $\mathcal{P}^\circ$ to avoid leakage across $\partial\mathcal{P}$ (cf. eq. (7.401)).

5.4 Regulator robustness and commutation of limits

Admissible families and notation. Let $\mathcal{R}_{\mathrm{adm}} = \{(P^{(i)}, K^{(i)})\}_{i=1}^{N}$ be an admissible family of band operators: each pair is BRST–closed and G–compatible on the certified window,

$$[\hat{Q}_{\mathrm{BRST}}, P^{(i)}] = [\hat{Q}_{\mathrm{BRST}}, K^{(i)}] = [\mathsf{J}_\alpha, P^{(i)}] = [\mathsf{J}_\alpha, K^{(i)}] = 0, \qquad i = 1, \dots, N,$$

and (on plateau) either commute or have commutators bounded within the regularisation stability budget (cf. Section 7.3 and eq. (7.67)). For any readout R_α we write $R_\alpha^{(i)}$ for the value obtained with $(P^{(i)}, K^{(i)})$.

Regulator robustness (uniform envelope over the joint plateau). On the joint plateau $\mathfrak{P}$ (eq. (7.403)), define the regulator envelope

$$\Delta_{\mathrm{reg}}[R_\alpha] := \max_{i,j} \sup_{(u,v)\in\mathfrak{P}} \left| R_\alpha^{(i)}(u,v) - R_\alpha^{(j)}(u,v) \right|. \tag{7.420}$$

Acceptance requires

$$\Delta_{\mathrm{reg}}[R_\alpha] \;\le\; \varepsilon_{\mathrm{reg}}, \tag{7.421}$$

with $\varepsilon_{\mathrm{reg}}$ bounded as in eq. (7.67). The same bound applies to integrated readouts (eqs. (7.410) and (7.412)); by convexity, $\Delta_{\mathrm{reg}}[\overline{R}_\alpha] \le \Delta_{\mathrm{reg}}[R_\alpha]$.

Ordering invariance (placement and permutation test). For each $(P^{(i)}, K^{(i)})$ and any fixed physical operator $\mathcal{O}$, compare admissible placements (e.g. $P^{(i)}K^{(i)}$, $K^{(i)}P^{(i)}$, and versions with Π_{T} interleaved on certified bands). Define the ordering defect

$$\Delta_{\mathrm{ord}}[R_\alpha^{(i)}] := \sup_{(u,v)\in\mathfrak{P}} \max_{\text{admissible orders } o,o'} \left| R_\alpha^{(i);o}(u,v) - R_\alpha^{(i);o'}(u,v) \right|, \tag{7.422}$$

and require $\Delta_{\mathrm{ord}}[R_\alpha^{(i)}] \le C_{\mathrm{ord}}\, \varepsilon_{\mathrm{reg}}$ for a modest constant C_{ord} (typically $C_{\mathrm{ord}} \sim 1$). This is the operational counterpart of the projector–commutator bound eq. (7.265).

Kernel-level robustness (physical blocks). For spectral claims based on the reduced kernel $\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$ (Section 7.7.3), impose

$$\sup_{(u,v)\in\mathfrak{P}} \left\| \mathbb{H}_{\mathrm{phys}}^{(i)}(p;u,v) - \mathbb{H}_{\mathrm{phys}}^{(j)}(p;u,v) \right\| \;\le\; \varepsilon_{\mathrm{reg}} \tag{7.423}$$

uniformly on the momentum region used to extract poles/residues. By eq. (7.339) and the quartet decoupling (eq. (7.336)), this bound propagates to poles and residues themselves.

Commutation of limits (band scans and preparations). On $\mathfrak{P}$ we test that relevant pairs of limits commute within a budget $\varepsilon_{\mathrm{comm}}$:

(i) UV/IR scan limits. For any reference $(u_*, v_*) \in \mathfrak{P}$,

$$\Delta_{\mathrm{comm}}^{(u,v)}[R_\alpha; u_*, v_*] := \left| \lim_{u\to u_*} \lim_{v\to v_*} R_\alpha(u,v) - \lim_{v\to v_*} \lim_{u\to u_*} R_\alpha(u,v) \right| \;\le\; \varepsilon_{\mathrm{comm}}. \tag{7.424}$$

A discrete proxy is the mixed–increment bound

$$\Big| R_\alpha(u{+}\Delta u, v{+}\Delta v) - R_\alpha(u{+}\Delta u, v) - R_\alpha(u, v{+}\Delta v) + R_\alpha(u, v) \Big| \;\le\; C\,\varepsilon_{\mathrm{comm}} \quad (\text{small } \Delta u, \Delta v). \tag{7.425}$$

(ii) Thermodynamic vs. seed limit (SSB preparation). With V the spatial volume and $\varepsilon \to 0^+$ the seed strength (Section 7.7.2),

$$\Delta^{(V,\varepsilon)}_{\mathrm{comm}}[R_\alpha] := \Big| \lim_{V\to\infty} \lim_{\varepsilon\to 0^+} R_\alpha - \lim_{\varepsilon\to 0^+} \lim_{V\to\infty} R_\alpha \Big| \;\le\; \varepsilon_{\mathrm{comm}}. \tag{7.426}$$

(iii) Ground–state projection vs. seed (imaginary time). For $\beta \to \infty$ in the imaginary–time route,

$$\Delta^{(\beta,\varepsilon)}_{\mathrm{comm}}[R_\alpha] := \Big| \lim_{\beta\to\infty} \lim_{\varepsilon\to 0^+} R_\alpha - \lim_{\varepsilon\to 0^+} \lim_{\beta\to\infty} R_\alpha \Big| \;\le\; \varepsilon_{\mathrm{comm}}. \tag{7.427}$$

Violations of (7.424)–(7.427) trigger window tightening or exclusion of the affected region from $\mathfrak{P}$.

Algorithmic notes (how to check in practice).

1. *Envelope:* evaluate $R^{(i)}_\alpha$ on the mesh $\mathcal{G}$ (eq. (7.394)) for all $(P^{(i)}, K^{(i)})$; compute $\Delta_{\mathrm{reg}}[R_\alpha]$ via eq. (7.420).
2. *Ordering:* for each i, build $R^{(i);o}_\alpha$ across admissible operator orders; compute $\Delta_{\mathrm{ord}}[R^{(i)}_\alpha]$ via eq. (7.422).
3. *Limits:* along monotone sequences $u_n \to u_*$, $v_m \to v_*$ inside $\mathfrak{P}$, estimate $\Delta^{(u,v)}_{\mathrm{comm}}$ by Richardson extrapolation or the mixed–increment proxy eq. (7.425). Repeat for (V,ε) and (β,ε) using the same preparation protocol as in Section 7.7.2.
4. *Kernel:* compare $\mathbb{H}^{(i)}_{\mathrm{phys}}$ across regulators as in eq. (7.423); propagate to poles/residues.

Acceptance and reporting. Report the triplet $\big(\Delta_{\mathrm{reg}}[R_\alpha],\, \max_i \Delta_{\mathrm{ord}}[R^{(i)}_\alpha],\, \Delta^{(\cdot)}_{\mathrm{comm}}[R_\alpha]\big)$ together with the family $\mathcal{R}_{\mathrm{adm}}$, the joint plateau $\mathfrak{P}$ (bounding box), and the budgets $(\varepsilon_{\mathrm{reg}}, \varepsilon_{\mathrm{comm}})$. Acceptance requires (7.421), $\Delta_{\mathrm{ord}} \le C_{\mathrm{ord}}\varepsilon_{\mathrm{reg}}$, and (7.424)–(7.427). By eq. (7.338) and Nielsen/ST protection (Section 7.5 and eq. (7.339)), accepted bounds are stable for physical outputs.

5.5 Gauge-parameter independence (Nielsen tests)

Set-up (multi-parameter gauges). Let $\boldsymbol{\xi} = (\xi_1, \dots, \xi_M)$ denote a set of admissible gauge parameters (e.g. covariant gauge ζ, background-field gauge weights, etc.), varied within a domain $\mathcal{X}_{\mathrm{adm}}$ where BRST/ST identities hold and the band projectors remain BRST-closed (cf. Sections 7.3 and 7.5). On the certified joint plateau $\mathfrak{P}$ (eq. (7.403)), any *physical* output O_{phys} (pole mass, residue, stiffness proxy extracted from Λ_{state}, etc.) must satisfy the on-shell Nielsen condition

$$\sup_{(u,v)\in\mathfrak{P}} \sup_{\|\mathbf{e}\|_2=1} \Big| \partial_{\mathbf{e}} O_{\mathrm{phys}}(u, v; \boldsymbol{\xi}) \Big| \;\le\; \varepsilon_{\mathrm{gauge}}, \qquad \partial_{\mathbf{e}} := \sum_{r=1}^{M} e_r\, \partial_{\xi_r}, \tag{7.428}$$

with $\varepsilon_{\text{gauge}}$ chosen no larger than the plateau tolerances in eq. (7.137). Equation eq. (7.428) is the observable-level consequence of the Hessian identity $\partial_{\xi_r}\mathbb{H}_{\text{phys}} = \{\hat{Q}_{\text{BRST}}, \mathcal{N}_{\xi_r}\}$ on the band (eq. (7.339)) combined with $\mathrm{Tr}_{\mathcal{H}_{\text{phys}}}(\mathcal{O}\{\hat{Q}, X\}) = 0$.

Local slope maps (differential test). Define, for each parameter direction ξ_r,

$$\mathcal{S}_r(u,v) \;:=\; \Big|\partial_{\xi_r} O_{\text{phys}}(u,v;\boldsymbol{\xi}_*)\Big|, \tag{7.429}$$

evaluated at a reference $\boldsymbol{\xi}_* \in \mathcal{X}_{\text{adm}}$. Acceptance requires $\sup_{\mathfrak{P}} \mathcal{S}_r \le \varepsilon_{\text{gauge}}$ for all r. Discrete estimates use centred differences on a small gauge stencil:

$$\partial_{\xi_r} O_{\text{phys}}(u,v;\boldsymbol{\xi}_*) \;\approx\; \frac{O_{\text{phys}}(u,v;\boldsymbol{\xi}_* + \delta\xi_r\,\mathbf{e}_r) - O_{\text{phys}}(u,v;\boldsymbol{\xi}_* - \delta\xi_r\,\mathbf{e}_r)}{2\,\delta\xi_r}, \tag{7.430}$$

with $\delta\xi_r$ chosen so that $\boldsymbol{\xi}_* \pm \delta\xi_r\,\mathbf{e}_r \in \mathcal{X}_{\text{adm}}$.

Finite-set scan (uniform envelope). Given a finite admissible set $\{\boldsymbol{\xi}^{(k)}\}_{k=1}^{K} \subset \mathcal{X}_{\text{adm}}$, form the uniform gauge envelope

$$\Delta_{\text{gauge}}[O_{\text{phys}}] := \max_{k,k'} \sup_{(u,v)\in\mathfrak{P}} \Big| O_{\text{phys}}(u,v;\boldsymbol{\xi}^{(k)}) - O_{\text{phys}}(u,v;\boldsymbol{\xi}^{(k')}) \Big| \;\le\; \varepsilon_{\text{gauge}}. \tag{7.431}$$

By eq. (7.428), Δ_{gauge} must be of order $\varepsilon_{\text{gauge}}$; larger values signal off-shell contamination or an unstable plateau.

Commutation with band scans (mixed derivatives). Gauge slopes must commute (within tolerance) with UV/IR scans on $\mathfrak{P}$:

$$\Big|\partial_u\partial_{\xi_r} O_{\text{phys}} - \partial_{\xi_r}\partial_u O_{\text{phys}}\Big| \le \varepsilon_{\text{comm}}, \qquad \Big|\partial_v\partial_{\xi_r} O_{\text{phys}} - \partial_{\xi_r}\partial_v O_{\text{phys}}\Big| \le \varepsilon_{\text{comm}}, \tag{7.432}$$

tested via mixed increments (cf. eq. (7.425)). Violations point to window tightness issues or regulator misplacement.

ST closure residual (auxiliary guardrail). Let $\mathcal{R}_{\text{ST}}(u,v;\boldsymbol{\xi})$ denote a scalar residual of the Slavnov–Taylor identities evaluated on the reduced kernel (e.g. a norm of the linearised ST functional at two-point level). Require

$$\sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\text{ST}}(u,v;\boldsymbol{\xi}) \;\le\; \varepsilon_{\text{ST}}, \tag{7.433}$$

with $\varepsilon_{\text{ST}} \lesssim \varepsilon_{\text{gauge}}$. Nonzero ST residuals often coincide with apparent Nielsen drift.

Integrated outputs inherit Nielsen stability. For any admissible weight w supported in $\mathfrak{P}$ (cf. eq. (7.409)), integrated observables obey

$$\partial_{\xi_r}\overline{O}_{\text{phys}} = \int w\,\partial_{\xi_r} O_{\text{phys}} = \mathcal{O}(\varepsilon_{\text{gauge}}), \tag{7.434}$$

matching the inheritance principle of eq. (7.419).

Algorithm (run-sheet).

1. Choose $\boldsymbol{\xi}_*$ and a gauge stencil $\{\boldsymbol{\xi}^{(k)}\} \subset \mathcal{X}_{\mathrm{adm}}$.
2. On $\mathfrak{P}$, build slope maps $\mathcal{S}_r$ via eq. (7.430) and enforce $\sup_{\mathfrak{P}} \mathcal{S}_r \le \varepsilon_{\mathrm{gauge}}$.
3. Compute $\Delta_{\mathrm{gauge}}[O_{\mathrm{phys}}]$ via eq. (7.431).
4. Check mixed-derivative commutation eq. (7.432) and ST residual bound eq. (7.433).
5. Repeat for integrated outputs; compare with pointwise values (discrepancy within $\mathcal{O}(\varepsilon_{\mathrm{gauge}})$).

Failure modes and remedies. A nonzero Nielsen slope (or large Δ_{gauge}) indicates: (i) off-shell evaluation, (ii) lack of a certified plateau, or (iii) missing counterterms/an ST mismatch. Remedy by re-enforcing the projection to $\mathcal{H}_{\mathrm{phys}}$, tightening $\mathfrak{P}$ (§5.1–5.2), and restoring ST/Nielsen closures (Section 7.5 and eq. (7.339)); if needed, adjust the admissible regulator family per §5.4.

5.6 Kato continuity and spectral tracking

Set–up (physical kernel and poles). On the joint plateau $\mathfrak{P}$ (eq. (7.403)), consider the band–reduced physical inverse two–point kernel

$$\mathbb{H}_{\mathrm{phys}}(p;u,v)\,, \qquad (u,v) = (\ln \lambda_{\mathrm{UV}}, \ln \ell), \tag{7.435}$$

obtained in Section 7.7.3 (cf. eq. (7.336)). For fixed $(u,v) \in \mathfrak{P}$, *simple* physical poles $\{p_i^2(u,v)\}$ are those for which there exists an eigenvalue branch $\lambda_i(p^2;u,v)$ of $\mathbb{H}_{\mathrm{phys}}$ such that

$$\lambda_i\Big(p_i^2(u,v);u,v\Big) = 0, \qquad \partial_{p^2}\lambda_i\Big(p_i^2(u,v);u,v\Big) \neq 0, \tag{7.436}$$

(the transversality condition; simple zero). The associated (matrix) residue is defined by the Riesz–projector representation (restriction to the physical subspace):

$$\begin{aligned} Z_i(u,v) \;&:=\; \lim_{p^2 \to p_i^2(u,v)} \Big(p^2 - p_i^2(u,v)\Big)\, \mathbb{G}_{\mathrm{phys}}(p;u,v) \\ &= P_i(u,v)\, \Big[\partial_{p^2}\mathbb{H}_{\mathrm{phys}}\Big(p_i^2(u,v);u,v\Big)\Big]^{-1} P_i(u,v), \end{aligned} \tag{7.437}$$

where $\mathbb{G}_{\mathrm{phys}} = \mathbb{H}_{\mathrm{phys}}^{-1}$ and

$$P_i(u,v) \;:=\; \frac{1}{2\pi i}\oint_{\gamma_i} \Big(\mathbb{H}_{\mathrm{phys}}(p;u,v)\Big)^{-1}\, dp^2 \tag{7.438}$$

is the Riesz projector around a small contour γ_i enclosing only the simple pole at p_i^2. (Nielsen/ST and quartet decoupling guarantee that only physical blocks contribute, cf. eqs. (7.336) and (7.339).)

Pathwise Kato continuity (implicit–function control). Assume $\mathbb{H}_{\text{phys}}(p;u,v)$ is C^1 in (u,v) on $\mathfrak{P}$ and analytic in p^2 near each simple pole (Kato family of type (A) in p^2 with C^1 parameters). Then by the implicit function theorem applied to λ_i at eq. (7.436), each $p_i^2(u,v)$ is C^1 on any simply–connected component of $\mathfrak{P}$ where the pole remains simple. In particular, there exists a Lipschitz constant L_i such that for all $(u,v),(u',v')$ in that component,

$$\frac{\left|p_i^2(u,v)-p_i^2(u',v')\right|}{\|(u,v)-(u',v')\|} \;\le\; L_i, \tag{7.439}$$

and similarly for any scalar summary of Z_i (e.g. Z_i contracted with physical polarisations). Plateau smoothness bounds imply $L_i=\mathcal{O}(\varepsilon_{\text{grad}})$.

Discrete Lipschitz tests (mesh implementation). On the grid $\mathcal{G}$ (eq. (7.394)), track branches $p_i^2(u_i,v_j)$ consistently between neighbours and enforce

$$\mathcal{L}_i \;:=\; \max_{\langle(i,j)\sim(i',j')\rangle} \frac{\left|p_i^2(u_i,v_j)-p_i^2(u_{i'},v_{j'})\right|}{\sqrt{(u_i-u_{i'})^2+(v_j-v_{j'})^2}} \;\le\; \varepsilon_{\text{Kato}}, \tag{7.440}$$

and likewise $\mathcal{L}_i[Z] := \max_{\text{nbrs}} \|Z_i(u_i,v_j)-Z_i(u_{i'},v_{j'})\|/\|\Delta(u,v)\| \le \varepsilon_{\text{Kato}}$. Here "$\langle\cdot\sim\cdot\rangle$" denotes nearest–neighbour pairs. Report both $\mathcal{L}_i$ and pathwise totals along geodesics inside $\mathfrak{P}$.

Gap and multiplet handling (crossings vs. symmetry). Define the spectral gap between simple poles

$$\gamma_i(u,v) \;:=\; \min_{j\neq i}\left|p_j^2(u,v)-p_i^2(u,v)\right|. \tag{7.441}$$

Simple–branch regime: if $\inf_{\mathfrak{P}}\gamma_i \ge \gamma_{\min}>0$, branches are uniquely trackable and eq. (7.440) suffices.

Multiplet regime: if symmetry enforces degeneracy or γ_i dips below a threshold $\gamma_\times$, promote $\{p_i^2\}$ to a cluster $\mathcal{C}$ with projector

$$P_{\mathcal{C}}(u,v) \;:=\; \frac{1}{2\pi i}\oint_{\Gamma}\Big(\mathbb{H}_{\text{phys}}(p;u,v)\Big)^{-1}\,dp^2, \tag{7.442}$$

where Γ encloses the whole cluster. Track the subspace via canonical angles; enforce Grassmann–distance Lipschitzness:

$$\frac{\left\|P_{\mathcal{C}}(u_i,v_j)-P_{\mathcal{C}}(u_{i'},v_{j'})\right\|}{\|\Delta(u,v)\|} \;\le\; \varepsilon_{\text{Kato}}\,, \tag{7.443}$$

and replace $\{Z_i\}$ by the cluster residue $Z_{\mathcal{C}} := P_{\mathcal{C}}\,[\partial_{p^2}\mathbb{H}_{\text{phys}}]^{-1}P_{\mathcal{C}}$ (well–defined on the range). Physics claims must then be phrased at the multiplet level.

Matching and branch continuation (practical tracking). Between neighbouring nodes, assign branches by minimising a compound cost

$$\mathsf{C}(i \to j) \;=\; \alpha \left| p_i^2(u,v) - p_j^2(u',v') \right| \;+\; \beta\, \Theta_{\mathrm{can}}\Big(\mathrm{Ran} P_i, \mathrm{Ran} P_j\Big), \qquad \alpha,\beta > 0, \tag{7.444}$$

where Θ_{can} is a sum of principal angles between the one–dimensional ranges (or between cluster subspaces). Solve the local assignment (Hungarian algorithm) to propagate labels; reject assignments that violate eq. (7.440) or $\gamma_i \geq \gamma_\times$.

Residue stability and normalisation. For simple poles, eq. (7.437) implies

$$\| Z_i(u_i,v_j) - Z_i(u_{i'},v_{j'}) \| \;\leq\; C_i \, \| \Delta(u,v) \| \qquad \text{on } \mathfrak{P}, \tag{7.445}$$

with $C_i = \mathcal{O}(\varepsilon_{\mathrm{grad}})$ controlled by the plateau derivatives of $\partial_{p^2}\mathbb{H}_{\mathrm{phys}}$. When reporting scalar residues (e.g. spectral weights), fix a physical normalisation (polarisation or channel) once and for all and keep it constant across $\mathfrak{P}$.

Acceptance tests (spectral level). For each tracked branch (or cluster) on $\mathfrak{P}$, require:

$$\mathcal{L}_i \leq \varepsilon_{\mathrm{Kato}}, \quad \inf_{\mathfrak{P}} \gamma_i \geq \gamma_{\min} \;\; \text{(or multiplet handling via eq. (7.443))}, \quad \mathcal{L}_i[Z] \leq \varepsilon_{\mathrm{Kato}}, \tag{7.446}$$

together with regulator robustness Δ_{reg} (§5.4) and Nielsen stability (§5.5) for the extracted p_i^2, Z_i. Crossing or bifurcation events ($\gamma_i < \gamma_\times$) inside $\mathfrak{P}$ must be either (i) explained by symmetry and treated as clusters, or (ii) excluded from certification (shrink $\mathfrak{P}$).

Algorithm (run-sheet).

1. **Local solve:** at each $(u_i, v_j) \in \mathcal{G} \cap \mathfrak{P}$, find simple poles by solving $\lambda_k(p^2; u_i, v_j) = 0$ near reference values; compute P_i, Z_i via eq. (7.438)–eq. (7.437).
2. **Neighbour matching:** propagate labels using the cost eq. (7.444); flag any $\gamma_i < \gamma_\times$ and switch to cluster tracking eq. (7.442).
3. **Lipschitz checks:** evaluate $\mathcal{L}_i$, $\mathcal{L}_i[Z]$ via eq. (7.440) and record min gaps γ_i on $\mathfrak{P}$.
4. **Stability:** verify regulator envelope (§5.4) and gauge independence (§5.5) for $\{p_i^2, Z_i\}$.
5. **Report:** list $\varepsilon_{\mathrm{Kato}}$, $\gamma_{\min}$, $\gamma_\times$, violation flags, and any regions removed from $\mathfrak{P}$.

Failure modes and remedies. Excessive $\mathcal{L}_i$ or $\mathcal{L}_i[Z]$ typically indicates: (i) non–simple poles ($\partial_{p^2}\lambda_i \approx 0$), (ii) unresolved crossings (small γ_i), or (iii) off–plateau drift of $\mathbb{H}_{\mathrm{phys}}$. Remedy by (a) promoting to a cluster projector and reporting multiplet observables, (b) tightening $\mathfrak{P}$, or (c) re–establishing plateau/Nielsen/ST bounds (Section 7.3 and eq. (7.339)).

5.7 Channel-aware acceptance and reporting

Scope. For each certified connected component of the joint plateau $\mathfrak{P}$ (cf. §5.2), assemble a *channel-aware* packet covering (i) law coherence, (ii) state suppression and phase–twist susceptibilities, (iii) spectral health (poles/residues), and (iv) robustness under admissible regulators and gauge choices.

Bounds summary (achieved vs. targets). Report the achieved thresholds

$$(\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{osc}}, \varepsilon_{\mathrm{curv}}, \varepsilon_{\mathrm{reg}}, \varepsilon_{\mathrm{comm}}, \varepsilon_{\mathrm{gauge}}, \varepsilon_{\mathrm{Kato}})$$

measured on $\mathfrak{P}$, alongside the targets from eqs. (7.67) and (7.137) (and the budgets set in §5.4–5.6). Indicate the *bounding box* of $\mathfrak{P}$ in (u, v) and the admissible families $\{(P^{(i)}, K^{(i)})\}$ and $\{\boldsymbol{\xi}^{(k)}\}$ used.

Law unity (statistics on $\mathfrak{P}$). Define the summary statistics for the law–channel deficit:

$$\mu_{\mathrm{law}} := \langle 1 - \Lambda_{\mathrm{law}} \rangle_{\mathfrak{P}}\,, \quad \mu_{\mathrm{law}}^{\max} := \sup_{(u,v)\in\mathfrak{P}} \big(1 - \Lambda_{\mathrm{law}}(u,v)\big), \quad \mathrm{CI}_{\mathrm{law}} : \text{ bootstrap or jackknife on } \mathfrak{P}. \tag{7.447}$$

Acceptance: $\mu_{\mathrm{law}}^{\max} \le \varepsilon_{\mathrm{plat}}$ and the CI centred at $\mu_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}})$ (cf. eq. (7.259)); failures trigger rollback to Section 7.7.1.

State suppression (finite-size scaling at fixed plateau). At fixed $(u, v) \in \mathfrak{P}$, fit the finite-size dependence with an EFT-motivated family (stretched-exponential/exponential, optionally plus subleading corrections):

$$|\Lambda_{\mathrm{state}}(V)| \approx \exp\Big[- \kappa(\ell)\, V^{\nu} \Big] \times \begin{cases} 1, & \text{global SSB (NG)} \\ \exp[-\alpha_\partial\, |\partial\Omega|], & \text{gauged/BEH with boundary dressing} \end{cases} \tag{7.448}$$

with $\nu \ge 1$ in the global case and a boundary factor for the BEH case (cf. §4.6). Report best-fit parameters $\hat{\kappa}, \hat{\nu}$ (and $\hat{\alpha}_\partial$ when gauged) and goodness-of-fit:

$$\chi^2/\mathrm{dof} \;\le\; \chi^2_\star, \qquad \text{residual runs test within 5\%–95\% quantiles.} \tag{7.449}$$

Also quote the small-ϕ susceptibility $\chi_a = -\partial_\phi^2 \ln \Lambda_{\mathrm{state}}|_{\phi=0}$ and its scaling χ_a/V (global) or boundary scaling (gauged), cf. §§4.4–4.6.

Spectral health (mass/hyperbolicity and stability). Verify compliance with eqs. (7.13) and (7.15) and summarise via

$$m_{\min} \;:=\; \inf_{(u,v)\in\mathfrak{P}} \lambda_{\min}\Big(\mathsf{M}_{\mathrm{phys}}(u,v)\Big) \;\ge 0, \qquad \mathcal{H}_{\mathrm{hyp}} \;:=\; \inf_{(u,v)\in\mathfrak{P}} \inf_{\|n\|=1} \lambda_{\min}\Big(\mathrm{Re}\,\sigma_{\mathrm{prin}}(n)\Big) \;> 0, \tag{7.450}$$

together with Kato metrics from §5.6 (e.g. $\mathcal{L}[p_i^2]$, $\mathcal{L}[Z_i]$, $\gamma_{\min}$). If boundaries of $\mathfrak{P}$ are set by impending violations (e.g. $m_{\min} \downarrow 0$), annotate them.

Regulator and gauge robustness (overlays). Provide multi-(P, K) and multi-$\boldsymbol{\xi}$ overlays and their envelopes on $\mathfrak{P}$:

$$\Delta_{\mathrm{reg}}[\Lambda_\alpha] \;\le\; \varepsilon_{\mathrm{reg}}, \qquad \Delta_{\mathrm{gauge}}[O_{\mathrm{phys}}] \;\le\; \varepsilon_{\mathrm{gauge}}, \tag{7.451}$$

with definitions as in eqs. (7.420) and (7.431); include ordering-defect Δ_{ord} (cf. eq. (7.422)) and mixed-derivative commutation checks (eqs. (7.424), (7.425) and (7.432)).

Deliverables (per component of $\mathfrak{P}$). (i) Plateau mask and bounding box; (ii) heatmaps of local gradients/curvatures and slope maps in $\boldsymbol{\xi}$; (iii) law-unity statistics (7.447); (iv) V-scans with fits (7.309)–(7.449); (v) spectral dashboard; (vi) robustness overlays (7.451); (vii) raw seeds/configs sufficient for reproduction.

5.8 Failure modes and remedies

- *Fragmented plateaus (thin filaments, isolated pixels).* Symptoms: $\mathcal{M}_\alpha$ from §5.1 yields disjoint slivers; integrated readouts disagree with pointwise values beyond tolerance. Remedy: increase the stencil for the oscillation proxy; apply mild morphological closing; tighten admissible (P, K) to improve commutators; recheck commutation of limits (eqs. (7.424) and (7.425)) and shrink to the largest well-conditioned component.

- *Gauge drift persists (nonzero Nielsen slope).* Symptoms: $\mathcal{S}_r(u, v) = |\partial_{\xi_r} O_{\text{phys}}|$ exceeds $\varepsilon_{\text{gauge}}$ on $\mathfrak{P}$, or large Δ_{gauge} in eq. (7.431). Remedy: enforce ST/Nielsen ledger (Section 7.5 and eq. (7.339)), recompute the reduced kernel with the BRST-exact sector properly projected (cf. eq. (7.336)), and tighten $\mathfrak{P}$ (§5.1–5.2).

- *Regulator sensitivity (excess Δ_{reg}).* Symptoms: spreads across admissible (P, K) exceed ε_{reg}. Remedy: restrict to BRST-closer windows (where projector commutators obey eq. (7.265)); use the ordering-invariance test eq. (7.422); adjust UV/IR overlap to increase the certified commuting domain (Section 7.3).

- *Spectral crossings / bifurcations.* Symptoms: small spectral gaps $\gamma_i < \gamma_\times$, erratic branch labels, inflated Kato moduli. Remedy: switch to cluster tracking (Riesz projector $P_{\mathcal{C}}$, eq. (7.442)), enforce Grassmann Lipschitzness eq. (7.443), and phrase physics at the multiplet level; otherwise exclude the neighbourhood from $\mathfrak{P}$ and postpone identifications.

- *Finite-size anomalies (no V-decay in global case).* Symptoms: poor fits to (7.309), $\nu < 1$, or χ_a/V not stabilising. Remedy: re-check seed limits and ordering (cf. Section 7.7.2); verify Ward identities and the presence of an NG pole (§4.4–4.5); ensure measurements are taken strictly on $\mathfrak{P}$.

- *Numerical artefacts (underflow/phase noise).* Symptoms: $|\Lambda_\alpha|$ saturates numerical floor or exhibits phase jitter. Remedy: work with $-\ln|\Lambda_\alpha|$ and unwrap phases; increase sampling and use variance-reduced estimators; cross-validate with integrated readouts (§5.3).

Outcome. Step 5 furnishes a certified domain $\mathfrak{P}$ where all Quadrant II signatures are simultaneously stable: (i) $|\Lambda_{\text{law}}| \simeq 1$ within eq. (7.137); (ii) $|\Lambda_{\text{state}}|$ exhibits finite-size suppression at fixed plateau with accepted fits (7.309)–(7.449); (iii) physical poles/residues satisfy mass/hyperbolicity and remain Nielsen/ST stable. Any phenomenological labels ("Higgs-like", "graviton-like", "apeiron/chrono–kymon") remain *provisional* pending cross-quadrant checks, per Section 7.4.

7.7.6 Identity Ledger: Slavnov–Taylor, Ward, Nielsen, and Callan–Symanzik (On-band, Sectorwise)

Aim. To guarantee that all Quadrant II claims rest on symmetry-controlled, regulator-stable statements, we enforce the full *identity ledger* on the band: the Slavnov–Taylor (ST) master identity and its linearisation, global Ward identities (broken/unbroken), the Nielsen identity for gauge-parameter flows, and the Callan–Symanzik (CS) renormalisation-group equation. All checks are performed after the BRST projection to $\mathcal{H}_{\rm phys}$ and within certified plateaus of $(\ln \lambda_{\rm UV}, \ln \ell)$ (Sections 7.2, 7.3, 7.5, 7.7.3 and 7.7.4; [117, 442, 91, 82, 243, 114]).

6.1 Slavnov–Taylor master identity on the band

Set-up (Zinn–Justin sources; d-dimensional band). Let $\Gamma \equiv \Gamma[\Phi, K; \boldsymbol{\xi}; P_x, K^{(\ell)}_{\rm IR}]$ be the (band) 1PI effective action in d dimensions, with fields Φ^A and Zinn–Justin sources K_A coupled to the BRST variations $s\Phi^A$. All kernels/vertices are *implicitly composed* with the UV projector $P_x(\lambda_{\rm UV})$ and the IR window $K^{(\ell)}_{\rm IR}$ (cf. §5; the commutators eq. (7.244) ensure BRST compatibility on the band).

Master identity and linearisation. The Slavnov functional and the band ST master identity are

$$\begin{aligned} \mathcal{S}(\Gamma) &:= \int d^d x \sum_A \frac{\delta\Gamma}{\delta\Phi^A(x)} \frac{\delta\Gamma}{\delta K_A(x)} + (\text{ghost/gauge-fixing sector}), \\ \mathcal{S}(\Gamma) &= 0 \quad \text{on the band.} \end{aligned} \tag{7.452}$$

Linearising at Γ defines the nilpotent operator (the ST differential)

$$\mathcal{B}_\Gamma X \;:=\; \int d^d x \sum_A \left(\frac{\delta\Gamma}{\delta\Phi^A} \frac{\delta X}{\delta K_A} + \frac{\delta X}{\delta\Phi^A} \frac{\delta\Gamma}{\delta K_A} \right) \;+\; (\text{ghost/gauge-fixing terms})\,, \tag{7.453}$$

obeying

$$\mathcal{S}(\Gamma) = 0 \;\Longrightarrow\; \mathcal{B}_\Gamma^2 = 0\,. \tag{7.454}$$

Quadratic level (constraints on the Hessian). Let $\mathcal{H}_{\rm band}$ be the (band) Hessian at the background φ (eq. (7.311)). The linearised identity imposes

$$\mathcal{B}_\Gamma\, \mathcal{H}_{\rm band} \;=\; 0 \qquad (\text{as an operator identity on the band})\,, \tag{7.455}$$

which encodes, in particular: (i) transversality relations tying longitudinal gauge blocks to the ghost/Nakanishi–Lautrup sector; (ii) compatibility of mixing terms with BRST doublets; and (iii) the cohomological exactness used in §3 to derive eqs. (7.335) and (7.336). Together with the Nielsen identity (eq. (7.339)) this ensures that pole locations and residues extracted from $\mathbb{H}_{\rm phys}$ are gauge-parameter independent on shell.

Residuals and acceptance. Define band residuals (operator norms restricted to $\mathcal{H}_{\rm phys}$)

$$\mathcal{R}_{\rm ST}(u,v) \;:=\; \big\|\mathcal{S}(\Gamma)\big\|_{\rm phys}\,, \qquad \mathcal{R}_{\rm lin}(u,v) \;:=\; \big\|\mathcal{B}_\Gamma\,\mathcal{H}_{\rm band}\big\|_{\rm phys}\,, \tag{7.456}$$

evaluated on the joint plateau component $\mathfrak{P}$ (see §5.2). The acceptance criteria are

$$\sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\rm ST}(u,v) \;\le\; \varepsilon_{\rm ST}\,, \qquad \sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\rm lin}(u,v) \;\le\; \varepsilon_{\rm ST}\,, \tag{7.457}$$

with $\varepsilon_{\rm ST}$ chosen at or below the plateau budgets in eq. (7.137). Violations disqualify the candidate plateau or trigger a rebuild of gauge-fixing/renormalisation ([117, 243]).

Remarks. (i) All functional derivatives in eqs. (7.452) and (7.453) are taken at fixed band operators, which commute with the BRST charge by eq. (7.244). (ii) In BV notation, $\mathcal{B}_\Gamma$ is the linearisation of the antibracket $(\Gamma,\cdot)$; nilpotency eq. (7.454) is the Jacobi identity at $\mathcal{S}(\Gamma)=0$. (iii) The projections used in §3 imply that the ST constraints reduce to the physical blocks after quartet decoupling.

6.2 Global Ward identities (unbroken and broken)

Local Ward identities on the band (general d). Let R_α be unbroken generators and T_a broken generators of a global symmetry G, with conserved currents J^μ_α, J^μ_a. For any BRST-closed, gauge-invariant $\mathcal{O}$, the band-projected Ward–Takahashi identities read

$$\begin{aligned}
\partial_\mu \Big\langle J^\mu_\alpha(x)\,\mathcal{O}(y)\Big\rangle_{\rm band} &= i\,\Big\langle \delta_\alpha\mathcal{O}(y)\Big\rangle_{\rm band}\,\delta^{(d)}(x-y),\\
\partial_\mu \Big\langle J^\mu_a(x)\,\mathcal{O}(y)\Big\rangle_{\rm band} &= i\,\Big\langle \delta_a\mathcal{O}(y)\Big\rangle_{\rm band}\,\delta^{(d)}(x-y).
\end{aligned} \tag{7.458}$$

with all insertions composed with $P_x, K^{(\ell)}_{\rm IR}$ as in §4.4–§4.5. In momentum space, for amputated vertices this yields the standard constraints (e.g. current conservation and transversality).

Unbroken sector (conservation and transversality). For unbroken R_α, eq. (7.458) implies that current insertions are conserved and for vector correlators the transverse projector saturates the physical contribution:

$$\begin{aligned}
&k_\mu\,\Gamma^{\mu\nu}_{\alpha\beta}(k;u,v)=0,\\
&\Gamma^{\rm phys}_{\alpha\beta}(k;u,v) \coloneqq \Pi^{\mu\nu}_{\rm T}(k)\,\Gamma_{\alpha\beta;\nu\rho}(k;u,v)\,\Pi^{\rho\sigma}_{\rm T}(k).
\end{aligned} \tag{7.459}$$

Here $\Gamma^{\rm phys}$ determines the physical pole structure on the band.

This forbids mass terms for unbroken global currents and, in a gauged realisation with unbroken subgroup, enforces massless transverse vectors (photon-like) in the physical spectrum.

Broken sector (NG vs. BEH). For broken T_a, eq. (7.458) implies (global case) a Nambu–Goldstone pole in the current–current correlator's spectral density; schematically (EFT regime, small k),

$$\Big\langle J^\mu_a J^\nu_b\Big\rangle(k) \;\sim\; \frac{\rho_{ab}\,k^\mu k^\nu}{k^2} \;+\; \cdots\,, \qquad k^2\to 0, \tag{7.460}$$

with stiffness matrix ρ_{ab} (cf. §4.5). In a gauged realisation (BEH), the would-be NG modes are reorganised into longitudinal polarisations of massive vectors; the physical TT correlator shows no massless pole and obeys ST-consistent relations with the gauge-fixing/ghost sector, as guaranteed by eqs. (7.452) and (7.455).

Band and plateau implementation. All Ward identities above are enforced and tested *on the certified plateau* (cf. §5): band projections commute with symmetry/BRST generators by eq. (7.244), and gauge-parameter independence of *physical* outputs follows from the Nielsen identity (eq. (7.339)). Acceptance requires:

$$\begin{aligned}&\text{(i) Unbroken:} \quad \sup_{(u,v)\in\mathfrak{P}} \left\| k_\mu \Gamma^{\mu\nu}_{\alpha\beta}(k;u,v) \right\| \;\le\; \varepsilon_{\mathrm{Ward}},\\ &\text{(ii) Broken global:}\quad \text{presence of an NG pole consistent with eq. (7.460) and §4.5„}\\ &\quad\text{with stiffness proxies from phase–twist susceptibilities matching within plateau}\\ &\quad\text{tolerances}\\ &\text{(iii) Gauged (BEH):}\quad \text{absence of massless poles in the TT current block; massive-}\\ &\quad\text{vector spectrum and residues ST/Nielsen-stable.}\end{aligned} \tag{7.461}$$

Failures indicate either off-shell evaluation, explicit breaking, or a breakdown of the gauge-fixing/renormalisation sector; remedy per §3–§5 and Section 7.5.

6.3 Nielsen identity (gauge-parameter flows)

Band Nielsen identity (general d). Let $\boldsymbol{\xi}$ denote an admissible set of gauge parameters and ξ any one of its components. On the band, the Nielsen identity states that the ξ-derivative of the 1PI effective action is BRST-exact with respect to the linearised ST operator $\mathcal{B}_\Gamma$ (cf. eqs. (7.453) and (7.454)):

$$\frac{\partial \Gamma}{\partial \xi} \;=\; \mathcal{B}_\Gamma \mathcal{N}_\xi \qquad \text{(all insertions composed with } P_x, K^{(\ell)}_{\mathrm{IR}}\text{)}\,, \tag{7.462}$$

for some band operator $\mathcal{N}_\xi$ of ghost number -1. Differentiating twice w.r.t. fields and evaluating at the broken background φ gives a band identity for the quadratic kernel:

$$\begin{aligned}\partial_\xi \mathcal{H}_{\mathrm{band}} &= \mathcal{B}_\Gamma \mathcal{N}^{(2)}_\xi,\\ \mathcal{N}^{(2)}_\xi &:= \left.\frac{\delta^2 \mathcal{N}_\xi}{\delta\Phi\,\delta\Phi}\right|_{\Phi=\varphi}.\end{aligned} \tag{7.463}$$

After BRST projection to the physical subspace and use of the doublet/quartet structure (cf. §3), this reduces to the on-shell statement already used in eq. (7.339):

$$\begin{aligned}&\partial_\xi \mathbb{H}^{(\lambda_{\mathrm{UV}},\ell)}_{\mathrm{phys}}(p) = \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}^{(\lambda_{\mathrm{UV}},\ell)}_\xi(p)\},\\ \Rightarrow\quad &\partial_\xi\,[\text{physical poles/residues}] = 0 \quad \text{on shell.}\end{aligned} \tag{7.464}$$

Consequences for readouts. For any BRST-closed, ghost-number 0 insertion $\mathcal{O}$, graded cyclicity on $\mathcal{H}_{\mathrm{phys}}$ (eq. (7.331)) yields:

$$\partial_\xi \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell) = 0 \quad \text{on the certified plateau,} \tag{7.465}$$

and for phase–twist susceptibilities ($\chi_a = -\partial_\phi^2 \ln \Lambda_{\mathrm{state}}|_{\phi=0}$)

$$\partial_\xi \chi_a = \partial_\xi \operatorname{Var}_{\mathrm{band}}\big[Q_a[F]\big] = \operatorname{Tr}_{\mathcal{H}_{\mathrm{phys}}}\Big(\mathcal{O}_a \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}_\xi\}\Big) = 0 \quad \text{(on shell, on the plateau),} \tag{7.466}$$

with $\mathcal{O}_a$ the BRST-closed quadratic form defining the variance (§4.4).

Acceptance (numerical Nielsen tests). Define the bandwise Nielsen residual for any physical observable O_{phys}:

$$\mathcal{R}_{\mathrm{Niel}}[O_{\mathrm{phys}}](u, v; \xi) := \big|\partial_\xi O_{\mathrm{phys}}(u, v; \xi)\big| . \tag{7.467}$$

On the joint plateau $\mathfrak{P}$ we require

$$\sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\mathrm{Niel}}[O_{\mathrm{phys}}](u, v; \xi) \;\le\; \varepsilon_{\mathrm{gauge}} \quad \text{for all tested } \xi,$$

with $\varepsilon_{\mathrm{gauge}}$ chosen no larger than the plateau budgets of eq. (7.137) (cf. §5.5). Persistent nonzero slopes indicate off-shell evaluation, a broken ST ledger, or an uncertified plateau; rebuild per §3–§5 and [117, 114, 243].

6.4 Callan–Symanzik equation (RG on the band)

CS flow for band-projected functionals. Let μ be the renormalisation scale for couplings $\{g^i\}$, with beta functions β^i and field anomalous dimensions γ_Φ. The Callan–Symanzik (CS) operator acting on the band 1PI functional in d dimensions reads

$$\Big(\mu\partial_\mu + \beta^i \partial_{g^i} + \gamma_\Phi \mathcal{N}_\Phi + \sum_r \gamma_{J_r} \mathcal{N}_{J_r}\Big)\, \Gamma \;=\; 0, \tag{7.468}$$

where $\mathcal{N}_\Phi$ counts fields and $\mathcal{N}_{J_r}$ counts renormalised sources/insertions. By construction all objects are composed with the same $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$.

Interplay with regulator scans (plateau consistency). Small variations of the *regulator* scales $(\lambda_{\mathrm{UV}}, \ell)$ inside a certified plateau affect band-projected Green functions only within the tolerance budgets (eqs. (7.67) and (7.137)). RG-improved predictions must therefore satisfy:

$$\Big(\mu\partial_\mu + \beta^i \partial_{g^i} + \gamma \cdot \mathcal{N}\Big)\, O_{\mathrm{phys}}(u, v; \mu, \{g\}) \;=\; 0 \quad \text{on } \mathfrak{P}, \tag{7.469}$$

and be *stable* against admissible regulator changes:

$$\sup_{(u,v)\in\mathfrak{P}} \Big| \delta_{(P,K)} O_{\mathrm{phys}} - \Big(\mu\partial_\mu + \beta^i \partial_{g^i} + \gamma \cdot \mathcal{N}\Big) O_{\mathrm{phys}}\, \delta \ln \mu \Big| \;\le\; \varepsilon_{\mathrm{reg}} , \tag{7.470}$$

where $\delta_{(P,K)}$ denotes the observed spread across the admissible family $\{(P^{(i)}, K^{(i)})\}$ (cf. eq. (7.67)) and $\delta \ln \mu$ is the corresponding RG step.

Acceptance (RG robustness). For a chosen set of physical outputs O_{phys} (pole masses p_i^2, residues Z_i, phase–twist susceptibilities χ_a, etc.), enforce on $\mathfrak{P}$:

$$\sup_{(u,v)\in\mathfrak{P}} \left|\Big(\mu\partial_\mu + \beta^i\partial_{g^i} + \gamma\cdot\mathcal{N}\Big)O_{\mathrm{phys}}\right| \;\le\; \varepsilon_{\mathrm{RG}}\,, \qquad \Delta_{\mathrm{reg}}[O_{\mathrm{phys}}] \;\le\; \varepsilon_{\mathrm{reg}}, \tag{7.471}$$

with $\varepsilon_{\mathrm{RG}}$ comparable to (or tighter than) the plateau budgets, and with Kato/Lipschitz continuity in (u,v) as in §5.6 to exclude false "plateaus" driven by unresolved spectral rearrangements.

Remarks. (i) The CS flow commutes with BRST reduction: applying $\mathsf{P}_{\mathrm{phys}}$ to eq. (7.468) preserves the form of eq. (7.469) for physical blocks. (ii) Off the plateau, residual regulator dependence can fake RG flow; eq. (7.470) guards against that by comparing band spreads to the CS prediction. (iii) In practice, using RG-invariant combinations (e.g. ratios p_i/μ or stiffness proxies normalised by appropriate powers) sharpens the test in eq. (7.471).

6.5 Anomaly filters (algebraic renormalisation)

Wess–Zumino consistency on the band. Possible breakings Δ of the identity ledger (ST/Ward/Nielsen) are constrained by the linearised ST operator $\mathcal{B}_\Gamma$ (cf. eqs. (7.453) and (7.454)). On the band, with all objects composed with $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$, the Wess–Zumino (WZ) condition reads

$$\mathcal{B}_\Gamma\,\Delta \;=\; 0\,, \qquad \mathrm{gh}(\Delta)=1, \quad \deg(\Delta)=d\,, \tag{7.472}$$

so that Δ defines a cohomology class $[\Delta]\in H^1(\mathcal{B}_\Gamma)$. Local, integrated functionals are understood modulo total derivatives.

Trivial vs. nontrivial breakings. A breaking is *cohomologically trivial* if

$$\Delta \;=\; \mathcal{B}_\Gamma\,\widehat{\Delta} + \partial_\mu R^\mu \qquad\Rightarrow\qquad \text{removable by counterterms/field redefinitions on the band.} \tag{7.473}$$

Nontrivial representatives (e.g. gauge, mixed, or gravitational anomalies) live in $H^{1,d}(s\,|\,d)$ in the BRST bicomplex and are *forbidden* in an admissible plateau.

Band residuals and operational test. Define identity residuals on the joint plateau $\mathfrak{P}$:

$$\mathcal{R}_{\mathrm{WZ}}(u,v) \;:=\; \big\|\mathcal{B}_\Gamma\,\Delta\big\|_{\mathrm{phys}}, \qquad \mathcal{R}_{\mathrm{coh}}(u,v) \;:=\; \inf_{\widehat{\Delta},R}\big\|\Delta - \mathcal{B}_\Gamma\widehat{\Delta} - \partial_\mu R^\mu\big\|_{\mathrm{phys}}, \tag{7.474}$$

where norms are taken on $\mathcal{H}_{\mathrm{phys}}$ and the infimum ranges over local counterterm candidates $\widehat{\Delta}$ and currents R^μ. For concrete gauge groups/representations we also track the coefficients of known anomaly bases (descent of characteristic classes), collecting them into a vector $\mathbf{a}(u,v)$ (e.g. cubic/gauge, mixed, gravitational).

Acceptance (anomaly filters). On $\mathfrak{P}$ we require

$$\sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\mathrm{WZ}} \le \varepsilon_{\mathrm{ST}}, \qquad \sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\mathrm{coh}} \le \varepsilon_{\mathrm{anom}}, \qquad \sup_{(u,v)\in\mathfrak{P}} \|\mathbf{a}(u,v)\| \le \varepsilon_{\mathrm{anom}}, \tag{7.475}$$

with $\varepsilon_{\mathrm{anom}}$ chosen $\le$ the plateau budgets of eq. (7.137). Thus: (i) no nontrivial class in $H^1(\mathcal{B}_\Gamma)$ is present in the inspected sector; (ii) any residual breaking is $\mathcal{B}_\Gamma$-exact (up to a divergence) and numerically small; (iii) global-chiral, gauge, mixed, and gravitational anomalies are absent for the realised representation content (cf. [117, 243]).

Remarks. (1) Band commutators eq. (7.244) ensure that projecting with $P_x, K_{\mathrm{IR}}^{(\ell)}$ does not alter the WZ consistency analysis in cohomology. (2) In even d the anomaly scan is efficiently implemented via descent equations for the relevant characteristic classes and checked directly on $\mathfrak{P}$.

6.6 Sectorwise enforcement and interface with Steps 3–5

Checklist and cross-links. We enforce the identity ledger *per step* and feed its residuals into plateau certification:

1. **Quadratic kernel (Step 3).** Verify the linearised ST constraint on the band, $\mathcal{B}_\Gamma \mathcal{H}_{\mathrm{band}} = 0$ (eq. (7.455)), and after BRST projection use quartet decoupling to obtain the physical blocks (eq. (7.336)). Confirm hyperbolicity and mass positivity (eqs. (7.13) and (7.15)); failures trigger a rebuild of the gauge-fixing/renormalisation sector.

2. **Visibilities and soft structure (Step 4).** Check law-channel Nielsen stability $\partial_\xi \Lambda_{\mathrm{law}} = 0$ on the plateau (eq. (7.465)); extract phase–twist cumulants and verify Ward/Nielsen protection (eqs. (7.460) and (7.466)). In the gauged (BEH) case, confirm the absence of massless TT poles and ST-consistent massive-vector structure (§4.6, eq. (7.452)).

3. **Plateaus and robustness (Step 5).** Extend the acceptance mask $\mathcal{M}_\alpha$ (cf. §5.1) by *identity residual coordinates*:

$$\mathcal{M}_\alpha^+(u,v) = \mathcal{M}_\alpha(u,v) \wedge \left\{ \begin{array}{ll} \mathcal{R}_{\mathrm{ST}} \le \varepsilon_{\mathrm{ST}}, & \mathcal{R}_{\mathrm{lin}} \le \varepsilon_{\mathrm{ST}}, \\ \mathcal{R}_{\mathrm{Niel}} \le \varepsilon_{\mathrm{gauge}}, & \mathcal{R}_{\mathrm{WZ}} \le \varepsilon_{\mathrm{ST}}, \\ \mathcal{R}_{\mathrm{coh}} \le \varepsilon_{\mathrm{anom}} & \end{array} \right\}. \tag{7.476}$$

   and use this strengthened mask to define the joint plateau $\mathfrak{P}$ (§5.2). Regulator robustness and commutation of limits remain enforced via eq. (7.67) and §5.4.

Outcome. With eqs. (7.475) and (7.476) satisfied, the Step 3–5 artefacts (reduced physical kernel, visibilities, soft factors, and spectral data) are jointly consistent: ST/Ward/Nielsen identities hold on the band; anomalies are filtered out cohomologically; and all claims remain stable on the certified plateau $\mathfrak{P}$.

6.7 Practical run-sheet (auditable checks)

Sampling grid and on-shell locus. Fix a rectangular mesh in $(u, v) \equiv (\ln \lambda_{\mathrm{UV}}, \ln \ell)$ and a discrete set of admissible gauges $\{\xi_k\}$. At each mesh point, restrict to the on-shell locus as in Section 7.2 (vanishing band equations of motion and BRST closure), and use the same background φ and band operators $P_x, K_{\mathrm{IR}}^{(\ell)}$ across all tests.

1. **Source-extended action.** Build the Zinn–Justin sector and evaluate the ST ledger on the band: $\mathcal{S}(\Gamma)$ and $\mathcal{B}_\Gamma$ from eqs. (7.452) and (7.453), with the band commutators of eq. (7.244) enforced for the chosen (P_x, K_{IR}).

2. **ST residuals (on shell).** Compute the operator norms restricted to $\mathcal{H}_{\mathrm{phys}}$ $\mathcal{R}_{\mathrm{ST}}, \mathcal{R}_{\mathrm{lin}}$ defined in eq. (7.456) over the (u, v) mesh; persist them as audit layers and inject into the plateau mask per eq. (7.476).

3. **Ward suite (un/broken).** From $\mathcal{H}_{\mathrm{phys}}$ (§3) extract two-/three-point functions and test: (i) unbroken transversality eq. (7.459); (ii) broken-sector NG/BEH expectations eq. (7.460). For auditing, record the Ward residual

$$\mathcal{R}_{\mathrm{Ward}}(k; u, v) \;:=\; \Big\| k_\mu \, \Gamma^{\mu\nu}(k; u, v) \Big\|_{\mathrm{phys}} , \tag{7.477}$$

   and its sup over tested momenta in the IR window.

4. **Nielsen slopes (finite differences).** For any physical output O_{phys} (pole mass/residue, Λ_{law}, phase–twist susceptibility χ_a), estimate

$$\widehat{\partial_\xi O_{\mathrm{phys}}}(u, v; \xi_k) := \frac{O_{\mathrm{phys}}(u, v; \xi_{k+1}) - O_{\mathrm{phys}}(u, v; \xi_{k-1})}{\xi_{k+1} - \xi_{k-1}} , \tag{7.478}$$

   and store $\mathcal{R}_{\mathrm{Niel}} := |\widehat{\partial_\xi O_{\mathrm{phys}}}|$ for the acceptance bound in eq. (7.467) and §5.5.

5. **CS consistency (RG vs. regulator scans).** Track RG flows using eqs. (7.468) and (7.469) and compare with small changes of (P_x, K_{IR}) inside the admissible family via the discrepancy

$$\mathcal{D}_{\mathrm{CS}}[O_{\mathrm{phys}}] := \Big| \delta_{(P,K)} O_{\mathrm{phys}} - \big(\mu \partial_\mu + \beta^i \partial_{g^i} + \gamma \cdot \mathcal{N}\big) O_{\mathrm{phys}} \, \delta \ln \mu \Big| , \tag{7.479}$$

   to be bounded by eqs. (7.470) and (7.471).

6. **Cohomology filter (algebraic renormalisation).** If a breaking Δ is detected, evaluate the WZ residuals $\mathcal{R}_{\mathrm{WZ}}, \mathcal{R}_{\mathrm{coh}}$ in eq. (7.474) and the anomaly coefficient vector $\mathbf{a}$; accept only $\mathcal{B}_\Gamma$-exact (up to divergences) pieces below the tolerances in eq. (7.475), otherwise exclude the region or revise renormalisation conditions.

Auditable artefacts.

(i) Heatmaps over (u, v) for residuals $\mathcal{R}_{\mathrm{ST}}$, $\mathcal{R}_{\mathrm{lin}}$, $\mathcal{R}_{\mathrm{Niel}}$, $\mathcal{R}_{\mathrm{WZ}}$, $\mathcal{R}_{\mathrm{coh}}$, $\mathcal{R}_{\mathrm{Ward}}$, $\mathcal{D}_{\mathrm{CS}}$.

(ii) Kato–continuity trackers for poles/residues (§5.6).

(iii) Regulator overlays showing spreads vs. eq. (7.67).

6.8 Acceptance tests (ledger-complete)

Aggregated ledger. On the joint plateau $\mathfrak{P}$ (cf. §5.2) we require the following sup-norm bounds:

$$\sup_{(u,v)\in\mathfrak{P}} \left\{ \mathcal{R}_{\mathrm{ST}}(u,v),\ \mathcal{R}_{\mathrm{lin}}(u,v) \right\} \ \le\ \varepsilon_{\mathrm{plat}}, \tag{7.480}$$

$$\sup_{(u,v)\in\mathfrak{P}} \sup_{k\in \mathrm{IR\,win}} \mathcal{R}_{\mathrm{Ward}}(k;u,v) \le \varepsilon_{\mathrm{Ward}}$$

NG/BEH-consistent soft structure per eq. (7.460). (7.481)

$$\sup_{(u,v)\in\mathfrak{P}} \mathcal{R}_{\mathrm{Niel}}[O_{\mathrm{phys}}](u,v;\xi_k) \ \le\ \varepsilon_{\mathrm{gauge}} \quad \text{for all tested } O_{\mathrm{phys}} \text{ (cf. eq. (7.467))}, \tag{7.482}$$

$$\sup_{(u,v)\in\mathfrak{P}} \mathcal{D}_{\mathrm{CS}}[O_{\mathrm{phys}}](u,v) \ \le\ \varepsilon_{\mathrm{reg}} \quad \text{and} \quad \Delta_{\mathrm{reg}}[O_{\mathrm{phys}}] \ \le\ \varepsilon_{\mathrm{reg}} \ \text{(cf. eqs. (7.67) and (7.471))}, \tag{7.483}$$

$$\sup_{(u,v)\in\mathfrak{P}} \left\{ \mathcal{R}_{\mathrm{WZ}}(u,v),\ \mathcal{R}_{\mathrm{coh}}(u,v),\ \|\mathbf{a}(u,v)\| \right\} \le \varepsilon_{\mathrm{anom}}. \tag{7.484}$$

(no nontrivial $H^1(\mathcal{B}_\Gamma)$ representatives; cf. eq. (7.475))

Outcome. With eqs. (7.480) to (7.484) satisfied, the Quadrant II analysis is symmetry- and RG-controlled on certified plateaus: (i) the reduced physical kernel of Section 7.7.3 satisfies ST/Nielsen; (ii) the interferometric readouts of Section 7.7.4 obey Ward/Nielsen protection and exhibit the law/state signatures required; (iii) RG stability holds in the sense of Section 7.3. Any phenomenological mode labels ("Higgs-like", "graviton-like", "apeiron/chrono–kymon") remain *provisional* pending the cross-quadrant programme.

7.7.7 Physicality Tests: Nonnegative Spectrum, Hyperbolicity, and Spectral Positivity on $\mathcal{H}_{\mathrm{phys}}$

Aim. On the certified plateau $\mathfrak{P}$ (Section 7.7.5) and after BRST projection (Section 7.7.3), we must demonstrate *physicality* of dynamics and correlators: (i) the *physical mass operator* on $\mathcal{H}_{\mathrm{phys}}$ is nonnegative (cf. eq. (7.13)); (ii) the *principal symbol* of the physical kinetic operator is *hyperbolic* with causal cone matching the chronogeometric background (cf. eq. (7.15)); and (iii) band-projected two-point functions admit a Källén–Lehmann representation with *nonnegative* spectral densities and no negative-norm contributions (BRST quartets decoupled). All statements are enforced *on shell*, Nielsen/Slavnov–Taylor stable (Section 7.5), and regulator-robust (Section 7.3; [442, 117, 91, 82, 243]).

7.1 Physical mass operator on $\mathcal{H}_{\mathrm{phys}}$

Definition and extraction. From the reduced quadratic kernel $\mathcal{H}_{\mathrm{phys}}$ constructed in Section 7.7.3, define the physical mass operator $\mathbb{M}^2_{\mathrm{phys}}$ via the pole condition (cf. eq. (7.13)) for each physical block $X \in \{A^T, h, \pi\}$:

$$\det\left[\mathcal{H}^{XX}_{\mathrm{phys}}(k)\right]\Big|_{k^2=m_X^2} = 0, \qquad m_X^2 \ge 0, \qquad \mathbb{M}^2_{\mathrm{phys}}\,|X\rangle = m_X^2\,|X\rangle \ \text{ on } \mathcal{H}_{\mathrm{phys}}. \tag{7.485}$$

For an isolated simple pole, the residue matrix is

$$Z_X \;=\; \lim_{k^2\to m_X^2} (k^2 - m_X^2)\left[\mathcal{H}^{XX}_{\mathrm{phys}}(k)\right]^{-1}, \tag{7.486}$$

and determines one-particle normalisation and spectral weight (Källén–Lehmann).

Mixing and projectors. When fields mix inside X (e.g. (h,π)), let $v_{X,\alpha}(k)$ be right null-vectors of $\mathcal{H}^{XX}_{\mathrm{phys}}(k)$ at $k^2 = m^2_{X,\alpha}$. Define the spectral projector onto the pole subspace

$$\mathsf{P}_{X,\alpha} \;=\; Z_{X,\alpha}\, v_{X,\alpha}\, w^\dagger_{X,\alpha}, \qquad w^\dagger_{X,\alpha}\,\partial_{k^2}\mathcal{H}^{XX}_{\mathrm{phys}}\, v_{X,\alpha} = 1, \tag{7.487}$$

where $w_{X,\alpha}$ are left null-vectors and $Z_{X,\alpha}$ the scalar residues fixed by the normalisation condition. The block residue is $Z_X = \sum_\alpha \mathsf{P}_{X,\alpha}$.

Positivity tests (no ghosts). On $\mathcal{H}_{\mathrm{phys}}$ we require positivity of spectral weights:

$$\forall\, u \in \mathcal{H}_{\mathrm{phys}}: \quad u^\dagger Z_X\, u \;\geq 0 \qquad \text{and} \qquad Z_X \succeq 0 \;\; \text{(Loewner order)}. \tag{7.488}$$

Violations indicate ghost leakage or an incomplete BRST reduction; rollback to §3 and the identity ledger of §6.

Algorithm (auditable).

1. *Pole localisation.* On the joint plateau $\mathfrak{P}$ (§5.2), solve $\det \mathcal{H}^{XX}_{\mathrm{phys}}(k) = 0$ for $k^2 = m_X^2$; in practice, fit the inverse kernel to a rational form near the pole and cross-check with dispersion fits $\omega_X(|\mathbf{k}|)$.
2. *Residues.* Compute Z_X via eq. (7.486) or, with mixing, eq. (7.487); verify eq. (7.488).
3. *Acceptance.* Enforce $m_X^2 \geq 0$ and $Z_X \succeq 0$; store error bars from the plateau budgets (eq. (7.137)) and regulator spreads (eq. (7.67)).
4. *Kato continuity.* Check Lipschitz continuity of m_X^2, Z_X across $\mathfrak{P}$ as in §5.6; flag/resolve crossings and near-degeneracies.
5. *Nielsen stability.* Verify $\partial_\xi m_X^2 = \partial_\xi Z_X = 0$ within tolerance (cf. eqs. (7.464) and (7.467)).

Remarks. (i) NG modes (global G) correspond to $m_\pi^2 = 0$ at $|\mathbf{k}| \to 0$ with stiffness extracted from the small-k slope of the pole (cf. §4.5); (ii) in the gauged (BEH) case, only the transverse block contributes, with $m_{A^T} > 0$ and no massless TT pole (§4.6).

7.2 Principal symbol and hyperbolicity

Symbol and cone. Write the kinetic operator in each physical sector as a local differential operator $\mathcal{K}^{XX}_{\mathrm{phys}}(\partial)$ (quadratic order). Its principal symbol $\sigma_{\mathrm{prin}}(\mathcal{K}^{XX}_{\mathrm{phys}})(x,k)$ is the homogeneous highest-order part in k_μ. With respect to the chronogeometric cone (gaiamiti background metric), the hyperbolicity criteria recalled in eq. (7.15) are imposed on $\mathfrak{P}$.

Operational hyperbolicity tests (band, d dimensions).

1. **Real characteristics.** For each sector X, the characteristic polynomial
$$C_X(x,k) \;:=\; \det \sigma_{\mathrm{prin}}\Big(\mathcal{K}^{XX}_{\mathrm{phys}}\Big)(x,k) \tag{7.489}$$
has only real roots in k_0 for all spatial $\mathbf{k}$ sampled on $\mathfrak{P}$.

2. **Symmetrisers and energy estimates.** There exists a positive-definite symmetriser $S_X(x)$ such that $S_X\,\sigma_{\mathrm{prin}}(\mathcal{K}^{XX}_{\mathrm{phys}})$ is symmetric in k and yields an energy estimate uniform on $\mathfrak{P}$:
$$\frac{d}{dt}\,E_X(t) \;\le\; C_X\,E_X(t)\,, \qquad E_X(t) \;\sim\; \langle \Psi_X,\, S_X\,\Psi_X\rangle_{\mathrm{phys}}\,, \tag{7.490}$$
ensuring well-posed Cauchy evolution and finite propagation speed (domain of dependence within the background light cone).

3. **Causal dispersion.** From the pole condition $\det \mathcal{H}^{XX}_{\mathrm{phys}}(\omega,\mathbf{k}) = 0$ extract $\omega_X(\mathbf{k})$ and verify the group-velocity bound
$$\sup_{(u,v)\in\mathfrak{P}}\;\sup_{\mathbf{k}\in \mathrm{IR\,win}} \Big|\nabla_{\mathbf{k}}\,\omega_X(\mathbf{k})\Big| \;\le\; 1 \;+\; \varepsilon_{\mathrm{vel}}\,, \tag{7.491}$$
with uncertainties governed by eq. (7.137) (units $c = 1$).

Acceptance and reporting. Report: (i) verification of real characteristics eq. (7.489); (ii) symmetriser constants and energy-estimate bounds eq. (7.490); (iii) dispersion fits and the group-velocity metric eq. (7.491). All metrics obey the tolerance and robustness criteria of Section 7.7.5 (including Kato continuity, regulator spreads, and Nielsen stability). Failures (tachyonic roots, lack of symmetriser, superluminal drift beyond tolerance) trigger rollback to Steps 3–6 and exclusion from the joint plateau $\mathfrak{P}$.

7.3 Spectral positivity (Källén–Lehmann on the band)

Representation on the band. For each BRST–physical field/operator X (scalar or the transverse part of a vector), the band–projected Wightman two–point function admits a Källén–Lehmann representation compatible with the UV/IR pipeline (Section 7.3):
$$\langle X(x)\,X(0)\rangle_{\mathrm{band}} = \int_0^\infty d\mu^2\;\rho_X(\mu^2)\;\Delta_+^{(d)}(x;\mu^2)\,, \qquad \rho_X(\mu^2)\ge 0\,, \tag{7.492}$$
where $\Delta_+^{(d)}$ is the free positive–frequency kernel in d spacetime dimensions. In momentum space (with the implicit composition by $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$),
$$G_X(p) \equiv \big[\mathcal{H}^{XX}_{\mathrm{phys}}(p)\big]^{-1} = \int_0^\infty d\mu^2\;\frac{\rho_X(\mu^2)}{p^2-\mu^2+i0} \quad \text{on } \mathcal{H}_{\mathrm{phys}}\,. \tag{7.493}$$
For a spin–1 field, ρ_X refers to the transverse sector and the correlator carries the projector Π_{T} (cf. eqs. (7.320) and (7.336)).

Extraction and positivity. The band spectral density is obtained from the discontinuity of the physical Green function:

$$\rho_X(\mu^2) = \frac{1}{\pi} \lim_{\epsilon\to 0^+} \operatorname{Im} G_X\Big(p^2 = \mu^2 + i\epsilon\Big) \qquad \text{(on the certified band)}\,. \tag{7.494}$$

BRST cohomology (Section 7.2) guarantees that only cohomology representatives contribute: longitudinal/ghost/Nakanishi–Lautrup quartets cancel, so no negative–norm states enter ([442, 117]).

Discrete poles and continuum. Decompose ρ_X into pole and continuum parts,

$$\rho_X(\mu^2) = \sum_n Z_{X,n}\,\delta(\mu^2 - m_{X,n}^2) \;+\; \rho_X^{\text{cont}}(\mu^2)\,, \qquad Z_{X,n} \ge 0, \quad \rho_X^{\text{cont}}(\mu^2) \ge 0\,, \tag{7.495}$$

with $Z_{X,n}$ the (nonnegative) residues defined in eqs. (7.486) and (7.487). Unbroken/broken Ward and ST identities constrain sum rules among $\{Z_{X,n}\}$ and moments of ρ_X^{cont} (Section 7.5).

Acceptance suite. On the joint plateau $\mathfrak{P}$ (cf. §5.2) we require:

$$\rho_X(\mu^2) \ge 0 \quad \text{for a.e. } \mu^2 \text{ in the fitted support}, \qquad Z_{X,n} \ge 0 \quad \text{(all isolated poles)}\,, \tag{7.496}$$

together with regulator robustness and gauge independence within the established budgets:

$$\Delta_{\text{reg}}[\rho_X] \le \varepsilon_{\text{reg}}, \qquad \partial_\xi \rho_X = 0 \;\text{ within } \varepsilon_{\text{gauge}} \quad \text{(Nielsen on shell; cf. §5.5)}. \tag{7.497}$$

Violations (negative dips, gauge drift beyond tolerance) indicate leakage from nonphysical sectors or off–plateau evaluation and trigger a rollback to Steps 3–6.

Reporting. Report the pole list $\{m_{X,n}^2, Z_{X,n}\}$ with Kato–continuity trackers (cf. §5.6), the fitted ρ_X^{cont} with confidence bands, and Ward/ST–compatible sum rules used as cross–checks.

7.4 Microcausality and locality

Pauli–Jordan commutator on the band. Define the Pauli–Jordan function

$$\Delta_X(x) \;:=\; \langle [\,X(x), X(0)\,] \rangle_{\text{band}} = \int_0^\infty d\mu^2\; \rho_X(\mu^2)\; \Delta_{\text{PJ}}^{(d)}(x;\mu^2)\,, \tag{7.498}$$

where $\Delta_{\text{PJ}}^{(d)}$ is the standard Pauli–Jordan kernel in d dimensions. Local hyperbolic dynamics implies $\operatorname{supp}\Delta_{\text{PJ}}^{(d)} \subseteq \overline{\mathcal{C}}$ (the closed light cone), hence microcausality $\Delta_X(x) = 0$ for spacelike separations $x^2 < 0$.

Band effects and test. Finite UV/IR windows induce a controlled nonlocality (Gibbs tails for hard cutoffs, exponential or power–law for smooth windows). On a certified plateau ($\mathfrak{P}$) we require spacelike suppression bounded by a causal budget $\varepsilon_{\text{causal}}$ determined by the window shapes:

$$\sup_{x^2 \le -\sigma^2} \big|\Delta_X(x)\big| \;\le\; \varepsilon_{\text{causal}}(\lambda_{\text{UV}}, \ell; \sigma), \qquad \varepsilon_{\text{causal}} \xrightarrow[\lambda_{\text{UV}}\to\infty,\; \ell\to\infty]{} 0\,. \tag{7.499}$$

Operationally:

1. Reconstruct ρ_X from $\mathcal{H}_{\rm phys}^{-1}$ (cf. eq. (7.494)) and synthesise Δ_X via eq. (7.498).
2. Independently Fourier–transform the retarded/advanced propagators built from $\mathcal{H}_{\rm phys}$ on the band; confirm consistency of the spacelike suppression.
3. Verify that the measured $\varepsilon_{\rm causal}$ respects eq. (7.499) on $\mathfrak{P}$ and is robust across admissible $(P_x, K_{\rm IR})$ (cf. eq. (7.67)).

Acceptance and remedies. Persistent spacelike leakage (beyond $\varepsilon_{\rm causal}$) or gauge–parameter drift in Δ_X indicates either (i) failure of hyperbolicity (rollback to eq. (7.15)), (ii) off–shell evaluation (enforce the identity ledger of §6), or (iii) unsuitable windowing (adjust $(\lambda_{\rm UV}, \ell)$ or choose smoother $(P_x, K_{\rm IR})$). For gauge fields, microcausality is enforced for BRST–physical (transverse) observables; any apparent violation confined to gauge–variant sectors is dismissed by cohomological projection (Section 7.2).

7.5 Optical–theorem and unitarity proxies (on band)

Forward unitarity on the band. For BRST–physical channels, the optical theorem relates the imaginary part of the *forward* amplitude to a sum of positive transition probabilities. With amputated, band–projected, BRST–consistent external legs and vertices (ST/Nielsen enforced; cf. §6), the forward amplitude $\mathcal{M}_{i\to i}(s)$ satisfies

$$2\,\mathrm{Im}\,\mathcal{M}_{i\to i}(s) \;=\; \sum_{n\in\mathcal{H}_{\rm phys}} \int d\Pi_n^{(\rm band)} \left|\mathcal{M}_{i\to n}(s)\right|^2 \;\geq\; 0\,, \tag{7.500}$$

where $d\Pi_n^{(\rm band)}$ is the n–body phase space consistent with the IR window $K_{\rm IR}^{(\ell)}$ and UV projector $P_x(\lambda_{\rm UV})$ (cf. Section 7.3). Gauge–parameter independence of $\mathrm{Im}\,\mathcal{M}$ on shell follows from the Nielsen identity (cf. §6.3).

Cutkosky cuts with band windows. Let $\mathcal{H}_{\rm phys}$ generate the physical propagators and vertices. For any physical polarisation configuration, compute the cut discontinuity

$$\mathrm{Disc}\,\mathcal{M} \;=\; 2i\,\mathrm{Im}\,\mathcal{M} \;=\; \sum_{\rm cuts} \int d\Pi_{\rm cut}^{(\rm band)} \prod_{\text{cut lines}} \big(2\pi\big)\,\delta^{(+)}(k^2 - m^2)\,, \tag{7.501}$$

with all internal lines taken from the BRST–physical spectrum and the measure restricted by $(P_x, K_{\rm IR})$. *Acceptance:*

$$\mathrm{Im}\,\mathcal{M} \;\geq\; -\,\varepsilon_{\rm unit} \qquad \text{for all tested channels on } \mathfrak{P}, \tag{7.502}$$

with $\varepsilon_{\rm unit}$ chosen at or below the plateau budgets of eq. (7.137). Any systematic violation indicates either nonphysical leakage (incomplete BRST reduction) or off–plateau evaluation.

Partial waves in d dimensions. In the centre–of–mass frame, expand elastic $2\to2$ amplitudes in hyperspherical harmonics on S^{d-2}. Denote the partial–wave coefficients by $a_\ell(s)$

(with normalisation fixed so that the elastic unitarity circle applies). On the band and for BRST–physical external states,

$$|a_\ell(s)| \;\le\; 1, \qquad \operatorname{Im} a_\ell(s) \;\ge\; |a_\ell(s)|^2 \qquad \text{(elastic sector; inelasticity } \eta_\ell \le 1\text{)}, \tag{7.503}$$

within numerical tolerances dictated by $\mathfrak{P}$. We diagnose with the unitarity–circle distance

$$\delta_\ell(s) \;:=\; \Big| a_\ell(s) - \tfrac{i}{2} \Big| - \tfrac{1}{2} \;\le\; \varepsilon_{\mathrm{pw}}\,, \tag{7.504}$$

and the inequality defect

$$\Delta_\ell^{(\mathrm{inel})}(s) \;:=\; |a_\ell(s)|^2 - \operatorname{Im} a_\ell(s) \;\le\; \varepsilon_{\mathrm{pw}}\,. \tag{7.505}$$

Nielsen/ST stability. On $\mathfrak{P}$, the gauge–parameter derivatives of all proxies vanish within tolerance:

$$\partial_\xi \operatorname{Im} \mathcal{M} = 0, \quad \partial_\xi\, a_\ell(s) = 0 \qquad \text{(within } \varepsilon_{\mathrm{gauge}}\text{; cf. §5.5, §6.3)}. \tag{7.506}$$

Failure points to off–shell evaluation or identity–ledger violations (rollback to §6).

Reporting. We report, for each tested channel: (i) forward $\operatorname{Im}\mathcal{M}$ with band cuts and $\varepsilon_{\mathrm{unit}}$; (ii) $\{\delta_\ell, \Delta_\ell^{(\mathrm{inel})}\}$ vs. s; (iii) regulator and gauge spreads (see below). All quantities are quoted with plateau and robustness confidence intervals (cf. §5).

7.6 Regulator & gauge robustness of physicality

Spreads for the physical vector. Collect the physical outputs in $\mathbf{P} = \{\, m_X^2,\; Z_X,\; \rho_X(\mu^2),$ hyperbolicity metrics, $\operatorname{Im}\mathcal{M},\; a_\ell \,\}$.

Across an admissible family $\{(P^{(i)}, K^{(i)})\}$ and gauge parameters $\{\xi_k\}$ (cf. §5.4–§5.5), define

$$\Delta_{\mathrm{phys}}^{(\mathrm{reg})} := \max_{i,j} \sup_{(u,v)\in\mathfrak{P}} \big\| \mathbf{P}^{(i)}(u,v) - \mathbf{P}^{(j)}(u,v) \big\|, \qquad \Delta_{\mathrm{phys}}^{(\mathrm{gauge})} := \max_{k,k'} \sup_{(u,v)\in\mathfrak{P}} \big\| \mathbf{P}(\xi_k) - \mathbf{P}(\xi_{k'}) \big\|. \tag{7.507}$$

Here $\|\cdot\|$ denotes a channel–aware norm (block–diagonal over entries; spectral norm for matrices; L^∞ over μ^2 for ρ_X; sup over s for $\operatorname{Im}\mathcal{M}$ and a_ℓ).

Acceptance. We require

$$\Delta_{\mathrm{phys}}^{(\mathrm{reg})} \;\le\; \varepsilon_{\mathrm{reg}}\,, \qquad \Delta_{\mathrm{phys}}^{(\mathrm{gauge})} \;\le\; \varepsilon_{\mathrm{gauge}}\,, \tag{7.508}$$

with $\varepsilon_{\mathrm{reg}}$ controlled by eq. (7.67) and $\varepsilon_{\mathrm{gauge}}$ not exceeding the plateau tolerances of eq. (7.137). Any excess spread excludes the corresponding region from the joint plateau $\mathfrak{P}$ and triggers a rollback: rebuild $\mathcal{H}_{\mathrm{band}}$ (Step 3), revalidate the ledger (Step 6), and tighten the window family (Step 5).

Outcome. With eqs. (7.500), (7.503) and (7.508) satisfied on $\mathfrak{P}$, the physical content inferred from $\mathcal{H}_{\mathrm{phys}}$ is simultaneously unitary (to band accuracy), BRST/identity–consistent, and robust against admissible regulator and gauge variations.

7.7 Practical run-sheet (auditable tests)

1. **Pole extraction (mass & residues).** From $\mathcal{H}_{\mathrm{phys}}$ (cf. Section 7.7.3), locate poles of $\mathcal{H}_{\mathrm{phys}}^{-1}$ on the joint plateau $\mathfrak{P}$ (cf. §5):
   (a) Solve $\det \mathcal{H}_{\mathrm{phys}}^{XX}(p) = 0$ for each physical block $X \in \{A^T, h, \pi\}$ to obtain $m_X^2 \geq 0$ (cf. eq. (7.13)).
   (b) Compute residue matrices $Z_X = \lim_{p^2 \to m_X^2} (p^2 - m_X^2) \left[\mathcal{H}_{\mathrm{phys}}^{XX}(p)\right]^{-1}$ and enforce $Z_X \succcurlyeq 0$ (Källén–Lehmann consistency, eqs. (7.493) to (7.495)).
   (c) Track (m_X^2, Z_X) across $\mathfrak{P}$ and verify Kato–type continuity (Section 7.7.5).
2. **Hyperbolicity and causality.** Build the principal symbols $\sigma_{\mathrm{prin}}(\mathcal{K}_{\mathrm{phys}}^{XX})$ and check:
   (a) Real characteristics in k_0 for all spatial $\mathbf{k}$ (eq. (7.15)).
   (b) Uniform energy estimates (well-posed Cauchy problem) on $\mathfrak{P}$.
   (c) Group velocities at poles satisfy $v_g = \left|\partial\omega/\partial|\mathbf{k}|\right| \leq 1$ within the plateau tolerances of eq. (7.137).
3. **Spectral positivity (KL).** Reconstruct $\rho_X(\mu^2)$ from discontinuities of $\mathcal{H}_{\mathrm{phys}}^{-1}$ (cf. eq. (7.494)) and verify:
   (a) $\rho_X(\mu^2) \geq 0$ almost everywhere and $Z_{X,n} \geq 0$ for discrete poles (eqs. (7.492), (7.495) and (7.496)).
   (b) Ward/ST-compatible sum rules on pole/continuum weights (Section 7.5).
4. **Microcausality.** Form the Pauli–Jordan commutator $\Delta_X(x)$ from ρ_X (cf. eq. (7.498)) and confirm spacelike suppression consistent with band windowing (eq. (7.499)); cross-check with retarded/advanced reconstructions.
5. **Unitarity proxies.**
   (a) Compute band Cutkosky cuts and verify $\mathrm{Im}\,\mathcal{M} \geq -\varepsilon_{\mathrm{unit}}$ for physical polarisations (eqs. (7.501) and (7.502)).
   (b) For elastic $2 \to 2$ sub-blocks, evaluate partial waves and enforce $|a_\ell(s)| \leq 1$ and $\mathrm{Im}\, a_\ell(s) \geq |a_\ell(s)|^2$ within $\varepsilon_{\mathrm{pw}}$ (eqs. (7.503) to (7.505)).
6. **Robustness and gauge independence.** Repeat the suite across admissible (P_x, K_{IR}) and gauges ξ; certify spreads $\Delta_{\mathrm{phys}}^{(\mathrm{reg})}, \Delta_{\mathrm{phys}}^{(\mathrm{gauge})}$ within $\varepsilon_{\mathrm{reg}}, \varepsilon_{\mathrm{gauge}}$ (cf. eqs. (7.67), (7.137), (7.507) and (7.508)) and Nielsen/ST stability (§6).

7.8 Failure modes and remedies

- *Tachyons* ($m_X^2 < 0$). Indicates an unstable background φ or wrong order of limits. **Remedy:** revisit the seed protocol and ordered limits (Section 7.7.2); rebuild $\mathcal{H}_{\text{band}}$ (eq. (7.311)) and re-test hyperbolicity (eq. (7.15)) on $\mathfrak{P}$.

- *Ghost leakage / negative residues.* Non-positive Z_X or negative spectral weight signals incomplete BRST reduction. **Remedy:** enforce quartet decoupling (eqs. (7.328) and (7.332)) and on-shell simplifications (eq. (7.336)); re-validate the ST/Nielsen ledger (Section 7.7.6).

- *Hyperbolicity loss / superluminality.* Violations of eq. (7.15) or $v_g > 1$. **Remedy:** tighten $(\lambda_{\text{UV}}, \ell)$ windows (Section 7.3), prefer smoother regulators, and exclude offending regions from $\mathfrak{P}$ (cf. §5.4–§5.6).

- *Spectral negativity.* Negative dips in ρ_X or inconsistent sum rules. **Remedy:** re-check BRST projection and Ward/ST constraints (Section 7.5); apply anomaly filters (Section 7.7.6, §6.5) and recompute discontinuities (eq. (7.494)).

- *Microcausality violation.* Spacelike leakage beyond $\varepsilon_{\text{causal}}$. **Remedy:** reduce IR support or soften UV edges (adjust $K_{\text{IR}}^{(\ell)}$, P_x); verify commutation of limits and regulator robustness on $\mathfrak{P}$ (cf. §5.4, eq. (7.499)).

- *Unitarity-proxy failure.* Systematic $\operatorname{Im}\mathcal{M} < 0$ or partial-wave defects beyond ε_{pw}. **Remedy:** ensure amplitudes are built from $\mathcal{H}_{\text{phys}}$ with BRST-physical external states; re-impose ST/Nielsen constraints (Section 7.7.6) and refine the band cuts (eq. (7.501)).

- *Regulator/gauge sensitivity.* Excess spreads $\Delta_{\text{phys}}^{(\text{reg})}$ or $\Delta_{\text{phys}}^{(\text{gauge})}$. **Remedy:** restrict to BRST-closer windows, narrow the admissible (P_x, K_{IR}) family, and rebuild the joint plateau per §5.2–§5.5; re-certify ledger closure (§6).

Outcome. On a certified joint plateau $\mathfrak{P}$, the broken-state dynamics on $\mathcal{H}_{\text{phys}}$ passes the auditable health checks: non-tachyonic spectra, causal hyperbolic propagation, positive spectral weights, and band-accurate unitarity proxies—robust under admissible regulator and gauge variations. Any emergent phenomenological labels ("Higgs-like", "graviton-like", "apeiron/chrono–kymon") remain *provisional* pending the cross-quadrant and stability criteria already mandated (cf. Section 7.4).

7.7.8 Readout Consolidation and Cross–Quadrant Comparison

Aim. To conclude the Quadrant II run, we (i) *consolidate* all visibilities and spectral diagnostics into plateau–certified summaries; (ii) produce *reporting artifacts* (tables/figures) whose content is regulator– and gauge–stable per Sections 7.7.5 and 7.7.6; and (iii) execute a *cross–quadrant comparison* to distinguish QII (SSB) from QI/QIII/QIV based on law/state visibilities, Ward/Nielsen structure, and spectral health (Sections 7.7.3, 7.7.4 and 7.7.7; [91, 82, 442, 117, 243, 114]).

8.1 Plateau–certified aggregation of visibilities

Let $(u, v) = (\ln \lambda_{\mathrm{UV}}, \ln \ell)$ and let $\mathfrak{P}$ be the joint plateau from Section 7.7.5. For each readout $R_\alpha \in \{\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}\}$ define the plateau aggregates

$$\overline{R}_\alpha \equiv \mathrm{Avg}_{(u,v)\in\mathfrak{P}}[R_\alpha], \qquad \Delta_\alpha^{\max} \equiv \sup_{(u,v)\in\mathfrak{P}} \left|R_\alpha - \overline{R}_\alpha\right|, \qquad \mathcal{G}_\alpha^{\max} \equiv \sup_{(u,v)\in\mathfrak{P}} \sqrt{\left|\partial_u R_\alpha\right|^2 + \left|\partial_v R_\alpha\right|^2}. \tag{7.509}$$

Acceptance (law channel). We require

$$\left|1 - \overline{\Lambda}_{\mathrm{law}}\right| \;\le\; \varepsilon_{\mathrm{plat}}, \qquad \max\left\{\Delta_{\mathrm{law}}^{\max},\; \mathcal{G}_{\mathrm{law}}^{\max}\right\} \;\le\; \text{bounds in } \textit{eq.}\ (7.137), \tag{7.510}$$

which implements presentation invariance on certified windows (cf. eq. (7.259)).

Finite–size signature (state channel). At fixed $(u, v) \in \mathfrak{P}$ and fixed phase–twist protocol, the visibility exhibits volume suppression as in Section 7.7.4:

$$\lim_{V\to\infty} |\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; V)| = 0. \tag{7.511}$$

with fitted rate/exponent reported alongside the plateau diagnostics.

Integrated (marginal) visibilities. For any admissible weight w supported on a connected component of $\mathfrak{P}$,

$$\overline{R}_\alpha^{[u]}(v) = \int_{u_1}^{u_2} w(u; v)\, R_\alpha(u, v)\, du, \quad \overline{R}_\alpha^{[v]}(u) = \int_{v_1}^{v_2} w(v; u)\, R_\alpha(u, v)\, dv, \qquad \int w = 1, \tag{7.512}$$

inherit the same bounds as eq. (7.137) (Jensen/mean–value control; cf. Section 7.4.5). Discrepancies between pointwise and integrated aggregates beyond tolerance flag hidden micro–oscillations or insufficient windowing and trigger a revisit of the plateau mask.

Report. We quote $\overline{\Lambda}_{\mathrm{law}}, \overline{\Lambda}_{\mathrm{state}}$ with $\Delta^{\max}$ and $\mathcal{G}^{\max}$, plus integrated counterparts (7.512), all confined to $\mathfrak{P}$ and accompanied by regulator/gauge spreads per eqs. (7.67) and (7.137).

8.2 Spectral and identity–ledger overlays

From the block reduction in Section 7.7.3 and the physicality checks of §7, collect (for each physical channel) the pole masses $\{m_i^2\}$, residues $\{Z_i\}$, and hyperbolicity metrics, and overlay them with the identity–ledger residuals of Section 7.7.6. For any scalar observable $O \in \{m_i^2, Z_i, \text{hyperbolicity figures}\}$ define the plateau spread and the Nielsen slope:

$$\mathrm{Spread}_{\mathfrak{P}}(O) \equiv \sup_{(u,v)\in\mathfrak{P}} O(u, v) - \inf_{(u,v)\in\mathfrak{P}} O(u, v), \qquad \mathrm{NielsenSlope}(O) \equiv \sup_{(u,v)\in\mathfrak{P}} \left|\partial_\xi O(u, v)\right|. \tag{7.513}$$

Acceptance.

$$\begin{aligned} \mathrm{Spread}_{\mathfrak{P}}(O) &\le \text{bounds in eq. (7.137)}, \\ \mathrm{NielsenSlope}(O) &\le \varepsilon_{\mathrm{gauge}}. \end{aligned} \tag{7.514}$$

(gauge–parameter independence on shell; cf. §6.3.) When O is matrix–valued (e.g. residue matrices), $\mathrm{Spread}_{\mathfrak{P}}$ is taken in the operator norm and NielsenSlope in the induced matrix norm. All overlays are reported together with the ST master–identity residuals (sup–norm on $\mathfrak{P}$) to document that spectral stability coincides with ledger closure (cf. §6.1–§6.2).

Breaking pattern and particle–like census (formal summary). Let $G \to H$ be the spontaneous breaking pattern realised by a vacuum v. On Lie algebras,

$$\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}, \qquad r \equiv \dim \mathfrak{m} = \dim G - \dim H,$$

where $\mathfrak{m}$ is spanned by the broken generators. Let $\mathfrak{g}_{\text{gauge}} \subseteq \mathfrak{g}$ denote the gauged subalgebra and $\mathfrak{h}_{\text{gauge}} = \mathfrak{g}_{\text{gauge}} \cap \mathfrak{h}$ its unbroken part. Define the broken/gauged counts

$$r_{\text{g}} \equiv \dim \mathfrak{g}_{\text{gauge}} - \dim \mathfrak{h}_{\text{gauge}}, \qquad r_{\text{gl}} \equiv r - r_{\text{g}}, \tag{7.515}$$

and let N_s be the number of real scalar directions active near v (so $N_s \geq r$). All statements below refer to the BRST cohomology $\mathcal{H}_{\text{phys}}$ and are to be evaluated on certified plateaus (cf. Section 7.7.5).

(a) Chronogeometric sector. Massless spin-2 tensor (*provisional,* "graviton-like") with 2 helicities; unaffected by internal SSB in this setup (cf. Sections 7.4 and 7.7.7).

(b) Unbroken gauged generators $\mathfrak{h}_{\text{gauge}}$. $\dim \mathfrak{h}_{\text{gauge}}$ massless vectors (spin-1; physical polarisations only after BRST projection), persisting from the unbroken gauge symmetry (cf. Section 7.7.3).

(c) Broken generators $\mathfrak{m}$: global vs. gauged.

- *Global broken* (r_{gl}): r_{gl} Nambu–Goldstone scalars (spin-0, gapless in the $V \to \infty$ limit) in the relativistic/Lorentz-invariant case; see the caveat on type-B modes below.
- *Gauged broken* (r_{g}): r_{g} massive vectors (spin-1) via BEH reorganisation; the corresponding would-be NG modes are eaten and are not counted separately (cf. Sections 7.7.2 and 7.7.4).

(d) Radial/Higgs-like scalars. $(N_s - r)$ massive spin-0 excitations along directions orthogonal to the vacuum manifold; one physical DoF each. These pass the physicality tests on $\mathcal{H}_{\text{phys}}$ (cf. eqs. (7.13) and (7.15) and Section 7.7.7).

Dimensional DoF counts. In d spatial dimensions, a massless (massive) spin-1 field carries $d-1$ (d) physical polarisations after BRST projection. Thus the bosonic DoF ledger reads

$$\underbrace{(d-1)\,\dim \mathfrak{g}_{\text{gauge}} + N_s}_{\text{before breaking}} = \underbrace{(d-1)\,\dim \mathfrak{h}_{\text{gauge}}}_{\text{unbroken gauge}} + \underbrace{d\, r_{\text{g}}}_{\text{BEH massive vectors}} + \underbrace{r_{\text{gl}}}_{\text{NG scalars}} + \underbrace{(N_s - r)}_{\text{radial/Higgs-like}}, \tag{7.516}$$

using $r = r_{\text{g}} + r_{\text{gl}}$. Specialising to d=3 (3+1D) reproduces the familiar numbers (massless vector: 2 helicities; massive vector: 3 polarisations).

Closed-form counts (3+1D DoF).

Massless vectors:	$2\,\dim \mathfrak{h}_{\text{gauge}}$,	
Massive vectors (BEH):	$3\,r_{\text{g}}$,	(massless spin-2 carries 2 helicities;
NG scalars (in spectrum):	r_{gl},	*provisional* identification).
Radial/Higgs-like scalars:	$N_s - r$,	

DoF bookkeeping (consistency check). Before breaking: $(d-1)\dim\mathfrak{g}_{\text{gauge}}+N_s$ bosonic DoF (gauge vectors + scalars). After breaking, the RHS of eq. (7.516) equals the same quantity; hence bosonic DoF are conserved and each eaten NG supplies the longitudinal polarisation of a BEH massive vector (cf. Sections 7.7.3 and 7.7.6).

Remarks (scope and caveats).

- *Type-B NG at finite densities.* In non-Lorentz-invariant settings (e.g. nonzero charge densities), NG counting can reduce: $N_{\text{NG}}=r_{\text{gl}}-\frac{1}{2}\operatorname{rank}\mathcal{C}$ with $\mathcal{C}_{ab}\propto\lim_{V\to\infty}V^{-1}\langle[Q_a,Q_b]\rangle$ (type-B pairs with quadratic dispersion). Our default census assumes the relativistic/Lorentz-invariant regime used in the band reduction; deviations must be reported with the same plateau certification and identity-ledger checks.
- *Dimensional quirks/topological terms.* In lower d or in the presence of topological masses (e.g. Chern–Simons in 2+1D), vector DoF and dispersion change; any such cases must be flagged explicitly and recast in the d-dimensional ledger eq. (7.516).
- *BRST cohomology.* All counts are made on $\mathcal{H}_{\text{phys}}$; ghost/longitudinal quartets cancel and do not contribute (cf. Section 7.7.3).

Particle-like modes in Quadrant II (SSB) on $\mathcal{H}_{\text{phys}}$. Law is held symmetric (Section 7.7.1); the broken state is prepared and analysed on certified plateaus with BRST/Slavnov–Taylor/Nielsen protection (Sections 7.7.2 to 7.7.7). Tags marked "provisional'' require cross-quadrant confirmation (Section 7.4). Counts below are quoted for 3+1D; the general d-dimensional ledger appears in eq. (7.516).

(1) Gaiamiti $\hat{\Phi}$ (chronogeometric). *Mode:* tensor (graviton-like; *provisional*); *Spin:* 2; *Gap:* massless; *DoF (3+1D):* 2 (helicities ±2). Rationale: retains the unbroken QI character on the band; identification is provisional pending cross-quadrant checks (Sections 7.4 and 7.7.7).

(2) Tantrakyma $\hat{\Theta}$ (unbroken H). *Mode:* gauge vector(s) (unbroken); *Spin:* 1; *Gap:* massless; *DoF (3+1D):* 2 (helicities ±1). Verified via BRST projection and spectral positivity on plateaus (Sections 7.7.3 and 7.7.7).

(3) Global SSB (broken global G). *Mode:* Nambu–Goldstone boson(s) π^a; *Spin:* 0; *Gap:* gapless (massless as $V\to\infty$); *DoF:* 1 per broken generator (count $=\dim G-\dim H$ in the Lorentz-invariant regime). Diagnosed by phase–twist interferometry and Ward/Nielsen-protected soft structure (Sections 7.5 and 7.7.4). *Caveat:* in non-Lorentz-invariant settings (finite densities) type-B pairing can reduce the count; deviations must be noted explicitly (cf. discussion around eq. (7.516)).

(4) Gauged SSB (BEH reorganisation). (a) *Massive gauge vector(s)*; *Spin:* 1; *Gap:* $m_V^2>0$; *DoF (3+1D):* 3 (helicities ±1 plus longitudinal); *Count:* $\dim G_{\text{gauge}}-\dim H_{\text{gauge}}$. (b) *Would-be NG modes:* eaten (not counted separately). Verified by pole/residue extraction and Nielsen-stable masses on $\mathfrak{P}$ (Sections 7.7.3 and 7.7.7).

(5) Scalar sector in $\hat{\Phi},\hat{\Theta}$ (radial). *Mode:* radial / Higgs-like excitations; *Spin:* 0; *Gap:* gapped ($m_h^2>0$); *DoF:* 1 per independent radial direction (model-dependent). Certified by nonnegative mass operator, hyperbolicity, and spectral positivity (eqs. (7.13) and (7.15) and Section 7.7.7).

Notes. (i) Items separate *global* from *gauged* breaking: NG bosons appear only for global G, while in gauged phases they reorganise via BEH into longitudinal vector polarisation (Sections 7.7.2 and 7.7.4). (ii) All statements are evaluated *on certified plateaus* and are gauge/regulator-robust within the bounds of eqs. (7.67) and (7.137). (iii) Chronogeometric identifications ("graviton-like"), as well as any "apeiron/chrono–kymon" tags, remain *provisional* until confirmed by the cross-quadrant programme (Section 7.4).

Quadrant II in one view. The SSB analysis freezes the *law* while varying only the *state*. Concretely, we keep the symmetric kinetic baseline H_0 fixed on both law branches and verify unity of the law visibility by interferometric calibration (Sections 7.4 and 7.7.1). All measurements are performed *on the band* with UV/IR controls (Section 7.3), and quantitative statements are made *at plateau* where gradients/oscillations/curvature obey eq. (7.137). On shell, the Slavnov–Taylor, Ward, and Nielsen identities protect both readouts and spectra, rendering them gauge–parameter independent and anomaly–filtered within the certified window (Section 7.5; [117, 442, 243]).

Preparing and diagnosing the broken state. An infinitesimal seed selects a vacuum on $\mathcal{M}_{\rm vac}\cong G/H$ without altering H_0 (Section 7.7.2). Around the chosen background, the band Hessian is assembled, split into transverse/longitudinal sectors, and projected to BRST cohomology so that unphysical quartets decouple (Sections 7.2 and 7.7.3; [442, 117]). The holosymmetric probe then reads *visibilities*: $|\Lambda_{\rm law}|=1+\mathcal{O}(\varepsilon_{\rm plat})$ by construction, while the *state* visibility exhibits finite–size suppression at fixed plateau—the operational hallmark of spontaneous selection (Section 7.7.4 and eq. (7.139)). Phase–twist interferometry ties this suppression to current fluctuations and, via Ward/Nielsen protection, to NG soft structure for global G or to BEH reorganisation for gauged G (Sections 7.5 and 7.7.4; [91, 82]).

Certified stability of the claims. Plateau certification provides joint masks where law/state visibilities, physical poles/residues, and identity–ledger residuals are simultaneously stable (Section 7.7.5). On these domains we verify (i) nonnegativity of the physical mass operator and (ii) hyperbolicity of the principal symbol—hence causal propagation with no tachyons—together with (iii) Källén–Lehmann positivity for band–projected correlators (cf. eqs. (7.13) and (7.15); Section 7.7.7; [91, 82]). Gauge and regulator robustness are enforced by Nielsen stability and regularisation bounds (Section 7.7.6 and eq. (7.67)), so the final readouts and figures are reproducible within certified tolerances (Section 7.7.8).

"Particle–like" content and mode taxonomy. On $\mathcal{H}_{\rm phys}$ the broken–state spectrum organises as follows (Sections 7.7.3 and 7.7.7). *Global G:* massless Nambu–Goldstone scalars π^a (one per broken generator in the Lorentz–invariant regime) carry the soft pole dictated by the broken Ward identities; massive h–type scalars populate radial directions; spectator vectors in unbroken subgroups remain in their QI pattern ([91]). *Gauged G (BEH):* would–be NG modes are absorbed; transverse gauge bosons acquire masses and appear as physical spin–1 poles with positive residues, while longitudinal artefacts remain BRST–exact and do not contribute; scalar excitations in radial directions manifest as "Higgs–like" modes with plateau–stable masses and residues (Sections 7.7.4 and 7.7.7; [82, 117]). The chronogeometric (gaiamiti)

sector's massless spin–2, when present, retains its unbroken QI character on the band; any "graviton–like'' or "apeiron/chrono–kymon'' tags are *provisional* pending cross–quadrant checks (Section 7.4).

Outcome and discrimination. Taken together, QII is singled out by (i) *unity of the law* within eq. (7.137), (ii) *volume decay* of $|\Lambda_{\text{state}}|$ at fixed plateau, and (iii) a mode census consistent with NG/BEH expectations and the physicality tests cited above (Sections 7.7.4 and 7.7.7). The consolidated artefacts (maps, scaling plots, spectral overlays) are regulator/-gauge–stable and support a clean separation from QI (symmetric), QIII (emergent symmetry under coarse graining), and QIV (explicit breaking) (Section 7.7.8). Any phenomenological labels—"Higgs–like", "graviton–like", "apeiron/chrono–kymon''—are highlighted but explicitly flagged as *provisional* until validated by the multi–quadrant programme (Section 7.4; [243, 114]).

7.8 Quadrant III: Explicit (But Small) Law Breakings

Aim and posture. In QIII we deliberately introduce *explicit* symmetry-breaking terms in the *law* channel while insisting on a *symmetric/coherent* state. Operationally, we reuse the band-limited instrumentation ($P_x(\lambda_{\text{UV}})$, $K_{\text{IR}}^{(\ell)}$) and readouts defined earlier—coherence amplitudes $\mathcal{C}_\alpha$ and visibilities Λ_α in eqs. (7.115), (7.116), (7.122) and (7.129)—together with the acceptance/plateau pipeline of Sections 6.12.4 and 7.3.9. BRST/Slavnov–Taylor (ST) consistency is maintained on shell throughout, as in eq. (7.16) ([104, 445, 105, 106, 442, 117, 243]).

7.8.1 Data, Regime, and Physical Reading

Definition 7.346 (Quadrant III data and small-breaking regime)**.** Work on the band and within the IR window (UV projector $P_x(\lambda_{\text{UV}})$, IR kernel $K_{\text{IR}}^{(\ell)}$; cf. Section 6.12.4 and Definition 6.282). Keep the *state channel symmetric* (backgrounds from Section 7.1.5), and introduce *explicit but small* law breakings in the Lagrangian,

$$\mathcal{L} \;=\; \mathcal{L}_0 \;+\; \sum_k \epsilon_k\, \mathcal{O}_k \;+\; \zeta\Psi,$$

where $\zeta(\,\cdot\,) := \{\hat{Q}_{\text{BRST}}, \cdot\,\}$, $\delta_a\mathcal{L}_0 = \nabla_\mu K_a^\mu$, $\delta_a\mathcal{O}_k = \mathcal{S}_{k,a}$ (all band/IR–tagged), and $\{\epsilon_k\}$ are scale–small couplings. Let Δ_k be the RG scaling dimensions of the symmetry–breaking operators and set $\Delta := \min_k \Delta_k$. All statements are evaluated on $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ with BRST–closed tags and channel projectors (cf. Section 7.1.3).

Proposition 7.347 (Scale–tagged Ward source and physical reduction)**.** *The adjoint–covariant, scale–tagged Ward identity is*

$$\nabla_\mu^{(\text{ad})} J_a^{(\lambda_{\text{UV}},\ell)\mu} = \Delta_a^{(\lambda_{\text{UV}},\ell)}, \qquad \nabla_\mu^{(\text{ad})} J^\mu := \nabla_\mu J^\mu + i[\mathcal{A}_\mu, J^\mu],$$

with (cf. Definition 6.295)

$$\Delta_a^{(\lambda_{\text{UV}},\ell)} = \sum_k \epsilon_k(\ell)\left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})}\right\rangle_{\boldsymbol{\Psi}} \;+\; \left\langle \zeta\,\eta_a^{(\lambda_{\text{UV}},\ell)}\right\rangle_{\boldsymbol{\Psi}} \;+\; \mathcal{A}_a^{(\lambda_{\text{UV}},\ell)}.$$

On $\mathcal{H}_{\mathrm{phys}}$ and with anomaly-free BRST the last two terms vanish, so

$$\nabla^{(\mathrm{ad})}_{\mu}\,\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_{k} \epsilon_k(\ell)\,\left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\mathbf{\Psi}},$$

in agreement with eq. (6.377) and eq. (6.336) (see also Lemma 6.233). References: *[117, 82, 230].*

Proof. Start from the scale–tagged, gauge–fixed Lagrangian decomposition (UV then IR; tags suppressed for readability)

$$\mathcal{L} = \mathcal{L}_0 + \sum_k \epsilon_k\,\mathcal{O}_k + \zeta\Psi,$$

and let δ_a be a (possibly local/relational) variation with $\delta_a\mathcal{L}_0 = \nabla_\mu K^\mu_a$ and $\delta_a\mathcal{O}_k = \mathcal{S}_{k,a}$. By the relational Ward lemma Lemma 6.233 (Noether–Belinfante improvement absorbing $\nabla_\mu K^\mu_a$), there exists a local functional η_a generated by $\delta_a\Psi$ such that the *off–shell* identity holds

$$\nabla_\mu J^\mu_{a,\mathrm{imp}} = \sum_k \epsilon_k\,\mathcal{S}_{k,a} + \zeta\,\eta_a + \mathcal{A}_a. \tag{7.517}$$

Adjoint covariantization. If G is gauged, promote the divergence to the adjoint–covariant one, $\nabla^{(\mathrm{ad})}_\mu J^\mu := \nabla_\mu J^\mu + i[\mathcal{A}_\mu, J^\mu]$, obtaining

$$\nabla^{(\mathrm{ad})}_\mu J^\mu_{a,\mathrm{imp}} = \sum_k \epsilon_k\,\mathcal{S}_{k,a} + \zeta\,\eta_a + \mathcal{A}_a, \tag{7.518}$$

as in Definition 6.295 and standard derivations [117, 82, 230].

Scale tagging. Apply the band/IR tagging functor (UV projector $P_x(\lambda_{\mathrm{UV}})$ and IR window $K^{(\ell)}_{\mathrm{IR}}$; cf. Definition 6.282 and Section 6.12.4). By the assumptions used in Section 6.12.4 and Section 7.1.3, $[\nabla_\mu, P_x(\lambda_{\mathrm{UV}})] = 0$ and the scalar smearing $K^{(\ell)}_{\mathrm{IR}}$ commutes with covariant differentiation and with the channel projectors; moreover, both tags are BRST–closed (ghost number 0). Therefore (7.518) lifts directly to the scale–tagged form

$$\nabla^{(\mathrm{ad})}_\mu J^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_k \epsilon_k(\ell)\,\mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} + \zeta\,\eta^{(\lambda_{\mathrm{UV}},\ell)}_a + \mathcal{A}^{(\lambda_{\mathrm{UV}},\ell)}_a,$$

where the notation matches Definition 6.295 and collects the tagged sources into $\Delta^{(\lambda_{\mathrm{UV}},\ell)}_a := \sum_k \epsilon_k(\ell)\,\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a}\rangle_{\mathbf{\Psi}} + \langle \zeta\,\eta^{(\lambda_{\mathrm{UV}},\ell)}_a\rangle_{\mathbf{\Psi}} + \mathcal{A}^{(\lambda_{\mathrm{UV}},\ell)}_a$.

Physical reduction. Taking expectation values in a homogeneous state $|\mathbf{\Psi}\rangle$ and projecting with $\mathsf{P}_{\mathrm{phys}}$ to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ yields

$$\nabla^{(\mathrm{ad})}_\mu \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_k \epsilon_k(\ell)\,\left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\mathbf{\Psi}} + \left\langle \zeta\,\eta^{(\lambda_{\mathrm{UV}},\ell)}_a \right\rangle_{\mathbf{\Psi}} + \mathcal{A}^{(\lambda_{\mathrm{UV}},\ell)}_a.$$

On the anomaly–free Stage I, the last term vanishes; and in BRST cohomology at ghost number 0, ζ–exact insertions vanish (Nielsen–type independence; cf. Section 7.1.3). Hence

$$\nabla^{(\mathrm{ad})}_\mu \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_k \epsilon_k(\ell)\,\left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\mathbf{\Psi}},$$

which is exactly eq. (6.377) and agrees with eq. (6.336) (see also Lemma 6.233). This proves the proposition. □

Proposition 7.348 (Law deficit scaling and small-breaking control)**.** *Let $\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}$ be the (channel-resolved) law visibility (cf. Section 6.12.3) evaluated on $\mathcal{H}_{\mathrm{phys}}$ with BRST–closed tags. Assume the breakings are RG–irrelevant with minimal scaling dimension $\Delta > d + z$. Then for fixed UV band and large IR window,*

$$1 - |\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}| = \mathcal{O}\Big(\ell^{\,\Delta-(d+z)}\Big),$$

as stated in Proposition 6.277. Moreover, if $\mathcal{O}(\lambda_{\mathrm{UV}}, \ell)$ (a ghost–number–zero diagnostic of the same breaking) satisfies the plateau criterion Section 6.12.4 on a box $\mathcal{B}$, its extraction is regulator–stable within $\mathcal{B}$. Idea of proof. *Combine the physical Ward identity above with clustering under $K_{\mathrm{IR}}^{(\ell)}$ and the scaling of the integrated insertions $\mathcal{S}_{k,a}$; use Proposition 6.298 to pass to plateau-stable readouts.*

Proof. Work on the BRST–closed physical sector $\mathcal{H}_{\mathrm{phys}}$ with UV/IR tags (gh$= 0$) and use the adjoint–covariant, scale–tagged Ward identity of Proposition 7.347:

$$\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = \sum_k \epsilon_k(\ell) \left\langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} \quad \text{(anomaly–free BRST)}. \tag{7.519}$$

Step 1: From Ward source to a bound on the visibility deficit. Let W_ℓ be the (spatio–temporal) IR window with characteristic scale ℓ (product of the spatial kernel $K_{\mathrm{IR}}^{(\ell)}$ and a time window of width $\asymp \ell^z$; cf. Section 6.12.4). Integrate (7.519) against W_ℓ and use Stokes' theorem in adjoint form to relate the flux imbalance to the windowed source:

$$\left| \int d^{d+1}x\, W_\ell(x)\, \nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{\mu}(x) \right| = \left| \int d^{d+1}x\, W_\ell(x) \sum_k \epsilon_k(\ell)\, \langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})}(x) \rangle_{\mathbf{\Psi}} \right|.$$

The law visibility $\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}$ (cf. Section 6.12.3 and eq. (7.122)) compares the two law branches through this flux; by standard Cauchy–Schwarz/triangle estimates (as in Proposition 7.357's Dyson bound together with the branch equivalence Proposition 7.365) one obtains

$$1 - |\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}| \;\le\; C_0 \int d^{d+1}x\, |W_\ell(x)| \sum_k |\epsilon_k(\ell)| \left| \langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})}(x) \rangle_{\mathbf{\Psi}} \right| \;+\; \mathcal{O}(\varepsilon_{\mathrm{soft}}^2), \tag{7.520}$$

with C_0 independent of $(\lambda_{\mathrm{UV}}, \ell)$ on a plateau window (cf. Proposition 7.359).

Step 2: Scaling of the windowed source. Assume the breakings are RG–irrelevant with minimal scaling dimension $\Delta > d + z$ (definition used in Section 6.12.3). Denote $S_k := \mathcal{S}_{k,a}$ for brevity. Under the anisotropic scaling $(t, \mathbf{x}) \mapsto (b^z t, b\mathbf{x})$, a correlator of a local density S_k scales as $b^{-\Delta_k}$ of its argument; the normalised window scales as $W_\ell(x) = \ell^{-(d+z)} W_1\Big(t/\ell^z, \mathbf{x}/\ell\Big)$. Hence

$$\int d^{d+1}x\, |W_\ell(x)| \left| \langle S_k^{(\lambda_{\mathrm{UV}})}(x) \rangle_{\mathbf{\Psi}} \right| = \ell^{-(d+z)} \int d^{d+1}y\, |W_1(y)| \left| \langle S_k^{(\lambda_{\mathrm{UV}})}(\ell^z y_0, \ell \mathbf{y}) \rangle_{\mathbf{\Psi}} \right|.$$

By RG–irrelevance, the windowed one–point scales as $\left| \langle S_k(\ell^z y_0, \ell \mathbf{y}) \rangle \right| \le C_k\, \ell^{\Delta_k}$ uniformly for y in the support of W_1 (after factoring the UV band $P_x(\lambda_{\mathrm{UV}})$, cf. Section 6.12.4), so

$$\int d^{d+1}x\, |W_\ell(x)| \left| \langle S_k^{(\lambda_{\mathrm{UV}})}(x) \rangle_{\mathbf{\Psi}} \right| \;\le\; C_k'\, \ell^{\,\Delta_k - (d+z)}. \tag{7.521}$$

Let $\Delta := \min_k \Delta_k$; then $\sum_k C'_k\, \ell^{\Delta_k-(d+z)} \le C'\, \ell^{\Delta-(d+z)}$.

Step 3: Conclusion for the deficit and plateau stability. Insert (7.521) into (7.520) and absorb the (slow) running of $\epsilon_k(\ell)$ inside the plateau window into the constant (by Proposition 7.359):

$$1 - |\Lambda_{\text{law}}^{(\lambda_{\text{UV}},\ell)}| \;\le\; C\,\ell^{\,\Delta-(d+z)} \;+\; \mathcal{O}(\varepsilon_{\text{soft}}^2),$$

which gives the stated scaling Proposition 6.277.

For the second claim, let $\mathcal{O}(\lambda_{\text{UV}}, \ell)$ be any ghost–number–zero diagnostic obeying the plateau criterion Section 6.12.4 on a box $\mathcal{B}$; by Proposition 7.359 its variations under $(\lambda_{\text{UV}}, \ell) \mapsto (\tilde{\lambda}_{\text{UV}}, \tilde{\ell}) \in \mathcal{B}$ are bounded by the logarithmic tolerances, so its extraction is regulator–stable within $\mathcal{B}$.

This completes the proof. □

Proposition 7.349 (Symmetric state, shifted law)**.** *Keep the symmetric backgrounds from Section 7.1.5 and expand the law EOM eqs. (6.333) and (6.334) to first order in ϵ_k. Then expectation values of G–odd order parameters remain zero up to $\mathcal{O}(\epsilon_k)$ (no state SSB), while the Hessian blocks receive $\mathcal{O}(\epsilon_k)$ shifts determined by the breaking operators' second variations. Physical poles/residues of the band–tagged propagators shift analytically in ϵ_k and remain gauge–parameter independent by cohomological identities (cf. Section 7.2.2).*

Proof. Work on the BRST–closed physical sector $\mathcal{H}_{\text{phys}}$ with the UV/IR tags $P_x(\lambda_{\text{UV}})$, $K_{\text{IR}}^{(\ell)}$ (ghost number 0; commuting with channel projectors; cf. Section 7.1.3). Let the band–tagged, gauge–fixed Lagrangian be

$$\mathcal{L}^{(\lambda_{\text{UV}},\ell)} = \mathcal{L}_0^{(\lambda_{\text{UV}},\ell)} + \sum_k \epsilon_k\, \mathcal{O}_k^{(\lambda_{\text{UV}})} + \zeta \Psi^{(\lambda_{\text{UV}},\ell)},$$

and recall the law EOM $\mathcal{E}_{\mathbf{\Phi}}^{(\lambda_{\text{UV}},\ell)} = 0$, $\mathcal{E}_{\mathbf{\Theta}}^{(\lambda_{\text{UV}},\ell)} = 0$ (no new labels; cf. eqs. (6.333) and (6.334)). Keep the symmetric backgrounds from Section 7.1.5, so at $\epsilon_k = 0$ one has $\mathcal{E}_{\mathbf{\Phi}}[\bar{\Phi}] = 0$, $\mathcal{E}_{\mathbf{\Theta}}[\bar{\Theta}] = 0$.

(i) G–odd order parameters remain zero up to $\mathcal{O}(\epsilon_k)$. Prepare a G–invariant, BRST–physical initial state (identity state branch; cf. Definition 7.369), so for any G–odd operator $\hat{\mathcal{O}}_{\text{odd}}$ one has $\langle \hat{\mathcal{O}}_{\text{odd}} \rangle_0 = 0$. Let the law micro–Hamiltonian be $\hat{H}_{\text{micro}} = \hat{H}_0 + \sum_k \epsilon_k \hat{\mathcal{O}}_k^{(\lambda_{\text{UV}},\ell)}$ (cf. Definition 7.350). Evolve to time T and expand by Dyson/Duhamel:

$$\big\langle \hat{\mathcal{O}}_{\text{odd}}(T) \big\rangle_{\text{micro}} = \langle \hat{\mathcal{O}}_{\text{odd}}(T) \rangle_0 + i \sum_k \epsilon_k \int_0^T ds\, \Big\langle \big[\hat{\mathcal{O}}_{\text{odd}}^{H_0}(T),\, \hat{\mathcal{O}}_k^{(\lambda_{\text{UV}},\ell),H_0}(s) \big] \Big\rangle_0 + \mathcal{O}(\epsilon^2).$$

The first term vanishes by G–invariance; the integral is bounded by $\sum_k |\epsilon_k|\, C_k\, T$ with C_k finite on a plateau window (boundedness in the $\mathcal{K}$–seminorm; cf. Definition 7.355 and Proposition 7.359). Hence $\langle \hat{\mathcal{O}}_{\text{odd}}(T) \rangle_{\text{micro}} = \mathcal{O}(\epsilon_k)$ (uniformly at fixed T and within the plateau), which excludes state SSB (an $\mathcal{O}(1)$ effect) under the QIII posture.

(ii) Hessian shifts are $\mathcal{O}(\epsilon_k)$ from second variations. Expand the law EOM functionals to first order in ϵ around $(\bar{\Phi}, \bar{\Theta})$:

$$0 = \mathcal{E}_{\mathbf{\Phi}}[\bar{\Phi}] + \sum_k \epsilon_k \left. \frac{\delta}{\delta \hat{\mathbf{\Phi}}} \int \mathcal{O}_k^{(\lambda_{\text{UV}})} \right|_{\bar{\Phi},\bar{\Theta}} + \text{ terms linear in fluctuations},$$

$$0 = \mathcal{E}_{\mathbf{\Theta}}[\bar{\Theta}] + \sum_k \epsilon_k \left. \frac{\delta}{\delta \hat{\mathbf{\Theta}}} \int \mathcal{O}_k^{(\lambda_{\text{UV}})} \right|_{\bar{\Phi},\bar{\Theta}} + \text{ terms linear in fluctuations}.$$

Since $\mathcal{E}_\bullet[\bar\bullet] = 0$, the *linearised* operators (quadratic kernel/Hessian acting on fluctuations $(\delta\hat{\mathbf{\Phi}}, \delta\hat{\mathbf{\Theta}})$) receive additive $\mathcal{O}(\epsilon_k)$ contributions from the *second* functional variations of the breaking insertions:

$$\mathbb{H}^{(\lambda_{\mathrm{UV}},\ell)}(\epsilon) = \mathbb{H}^{(\lambda_{\mathrm{UV}},\ell)}(0) + \sum_k \epsilon_k \begin{pmatrix} \dfrac{\delta^2 \mathcal{O}_k^{(\lambda_{\mathrm{UV}})}}{\delta\hat{\mathbf{\Phi}}\,\delta\hat{\mathbf{\Phi}}} & \dfrac{\delta^2 \mathcal{O}_k^{(\lambda_{\mathrm{UV}})}}{\delta\hat{\mathbf{\Phi}}\,\delta\hat{\mathbf{\Theta}}} \\ \dfrac{\delta^2 \mathcal{O}_k^{(\lambda_{\mathrm{UV}})}}{\delta\hat{\mathbf{\Theta}}\,\delta\hat{\mathbf{\Phi}}} & \dfrac{\delta^2 \mathcal{O}_k^{(\lambda_{\mathrm{UV}})}}{\delta\hat{\mathbf{\Theta}}\,\delta\hat{\mathbf{\Theta}}} \end{pmatrix}_{(\bar\Phi,\bar\Theta)}$$

(cf. Section 7.2.5).

Thus each kinetic/mass/mixing block shifts by $\mathcal{O}(\epsilon_k)$ determined by the breaking operators' second variations evaluated on the symmetric background.

(iii) Analytic, gauge–independent shifts of physical poles/residues. Restrict to $\mathcal{H}_{\mathrm{phys}}$ (quartet decoupling; cf. Section 7.2.1) and denote the physical quadratic kernel by $\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\epsilon)$. By admissibility (form smallness) and Proposition 7.357, the family $\epsilon \mapsto \mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\epsilon)$ is a self–adjoint, analytic (type–A) perturbation of $\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(0)$. Rellich–Kato theory then gives analytic dependence of isolated spectral data; in particular, the poles/residues of the band–tagged propagators $\mathcal{D}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\epsilon) = \big(\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\epsilon)\big)^{-1}$ shift analytically in $\{\epsilon_k\}$. Gauge–parameter independence follows from BRST/Slavnov–Taylor consistency on the band (Proposition 7.358) and the cohomological/Nielsen identities used in Section 7.2.2 (physical, ghost–number–zero poles/residues are invariant under ζ–exact changes of the gauge fermion).

Combining (i)–(iii) proves the proposition. □

Quadrant III logic. We hold the *state* symmetric while allowing small, explicit deformations of the law. The scale–tagged Ward identity quantifies the resulting nonconservation by a controlled source proportional to the tiny couplings ϵ_k. Because tags are BRST–closed and all observables are taken in $\mathcal{H}_{\mathrm{phys}}$, ghosts and gauge artifacts do not pollute the readout; plateaus ensure UV/IR robustness of the inferred deficits and mass shifts. As ℓ grows, irrelevant breakings die off with the exponent $\Delta - (d+z)$, matching Proposition 6.277 and preserving Quadrant III membership.

Band-limited micro–Hamiltonian.

Definition 7.350 (QIII law-channel micro–Hamiltonian, band/IR tagged)**.** Let $\hat H_0(t;\lambda_{\mathrm{UV}},\ell)$ be the symmetric baseline Hamiltonian of eq. (7.241), obtained from the G–invariant quadratic kernel (cf. Proposition 7.2) and evaluated *on the band* with UV projector $P_x(\lambda_{\mathrm{UV}})$ and IR window $K_{\mathrm{IR}}^{(\ell)}$ (cf. Section 6.12.4 and Definition 6.282). Fix a family $\{\hat{\mathcal{O}}_B\}_B$ of local, Hermitian operators built from the field multiplet and covariant derivatives (cf. the band Hessian in eq. (7.10)). Their band/IR–tagged versions are

$$\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)} := K_{\mathrm{IR}}^{(\ell)}\, P_x(\lambda_{\mathrm{UV}})\, \hat{\mathcal{O}}_B\, P_x(\lambda_{\mathrm{UV}})\, K_{\mathrm{IR}}^{(\ell)}$$

("UV then IR" order; cf. *eq.* (6.353)*and Section* 6.12.4).

For small, real couplings ε_B the *QIII micro–Hamiltonian in the law channel* is

$$\boxed{\hat{H}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) = \hat{H}_0(t;\lambda_{\mathrm{UV}},\ell) + \sum_B \varepsilon_B\, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(t).} \tag{7.522}$$

Assumption 7.351 (Admissibility and symmetry posture)**.** *The breaking operators $\hat{\mathcal{O}}_B$ satisfy:*

(A1) BRST closure (on shell).
$\delta_{\mathrm{BRST}}\hat{\mathcal{O}}_B = \{\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{O}}_B\} = 0$ *and* $\mathrm{gh}(\hat{\mathcal{O}}_B) = 0$*, whereas they* break *the global symmetry G:* $\delta_G^{(\mathrm{global})}\hat{\mathcal{O}}_B \neq 0$*. This keeps Slavnov–Taylor identities exact while allowing global Ward sources (cf. eq. (7.16) and Section 6.12.2; [117, 243]).*

(A2) Locality and power counting.
$\hat{\mathcal{O}}_B$ *are local polynomials (or Wick polynomials) with canonical/anomalous dimensions compatible with the renormalisation scheme used (spurion tracking for G–charges as in [440]; see also Definition 7.346).*

(A3) Smallness (form bound).
$\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$ *is $\mathcal{K}$–form–bounded w.r.t. $\hat{H}_0$ with* small *relative bound measured by the seminorm of eq. (7.526), i.e.* $\varepsilon_B\, \|\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}\|_{\mathcal{K}} \leq \varepsilon_{\mathrm{soft}} \ll 1$.

(A4) Band/IR compatibility.
$P_x(\lambda_{\mathrm{UV}})$ *and* $K_{\mathrm{IR}}^{(\ell)}$ *are BRST–closed (ghost number 0) and commute with channel projectors Π_α (cf. Section 7.1.3); thus tagging preserves domains and cohomology.*

Proposition 7.352 (Self–adjointness, BRST invariance, and physical unitarity)**.** *Under Assumption 7.351, $\hat{H}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)$ is self–adjoint on the domain of $\hat{H}_0$ and generates a unitary evolution on the band–limited Hilbert space. Moreover,*

$$[\hat{Q}_{\mathrm{BRST}},\ \hat{H}_{\mathrm{micro}}] = 0,$$

so the evolution descends to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ and preserves BRST cohomology. Consequently, physical matrix elements and spectra are gauge–parameter independent (Nielsen identities).

Proof idea. Kato–Rellich theory gives self–adjointness from (A3) (small form bound) on the common domain of $\hat{H}_0$ [115]. BRST closure (A1) and nilpotency imply $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_0] = 0$ (since $[\hat{Q}_{\mathrm{BRST}}, \{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}] = 0$) and $[\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}] = 0$, hence the commutator vanishes. Gauge–parameter independence on $\mathcal{H}_{\mathrm{phys}}$ follows from cohomological/Nielsen identities [117, 82].

Proof. (i) Self–adjointness and unitary evolution. Write

$$\hat{H}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) = \hat{H}_0(t;\lambda_{\mathrm{UV}},\ell) + V(t), \qquad V(t) := \sum_B \varepsilon_B\, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(t),$$

with $\hat{H}_0$ the symmetric baseline of eq. (7.241). By admissibility (A3) in Definition 7.356, each tagged breaking $\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$ is $\mathcal{K}$–form–bounded relative to $\hat{H}_0$ with small relative bound:

$$\left\|\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}\right\|_{\mathcal{K}} \leq \beta_B, \qquad \sum_B |\varepsilon_B|\, \beta_B \leq \varepsilon_{\mathrm{soft}} \ll 1.$$

Therefore $V(t)$ is a symmetric form perturbation of $\hat{H}_0$ with arbitrarily small relative bound on the common form domain $\mathfrak{h} = \overline{\mathrm{Dom}\,\mathcal{K}^{1/2}}$ (cf. Definition 7.355). By the Kato–Rellich theorem (form version), for each fixed t the operator $\hat{H}_{\mathrm{micro}}(t)$ is self–adjoint on $\mathrm{Dom}\,\hat{H}_0$ and bounded below; moreover, the family is stable under small variations of $(\varepsilon_B, \lambda_{\mathrm{UV}}, \ell)$ (see also Proposition 7.357). Standard Kato theory for time–dependent self–adjoint Hamiltonians with a *time–independent* form domain then yields a unique unitary propagator $U_{\mathrm{micro}}(t, s; \lambda_{\mathrm{UV}}, \ell)$ (the $\mathcal{T}$–exponential) on the band–limited Hilbert space.[9] Hence $\hat{H}_{\mathrm{micro}}$ generates a unitary evolution.

(ii) BRST invariance. By construction in the symmetric baseline and Section 7.1.3, $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_0] = 0$ (the gauge–fixing piece is $\{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}$ and $[\hat{Q}_{\mathrm{BRST}}, \{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}] = 0$ by nilpotency and the graded Jacobi identity). For the explicit breakings, admissibility gives $\delta_{\mathrm{BRST}}\hat{\mathcal{O}}_B = 0$ and the tags are BRST–closed: $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = [\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}] = 0$ (cf. eq. (7.244)). Therefore

$$[\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}] = \left[\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)} P_x(\lambda_{\mathrm{UV}}) \hat{\mathcal{O}}_B P_x(\lambda_{\mathrm{UV}}) K_{\mathrm{IR}}^{(\ell)}\right] = 0,$$

and by linearity $[\hat{Q}_{\mathrm{BRST}}, V(t)] = 0$. Consequently $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_{\mathrm{micro}}] = 0$.

(iii) Descent to the physical sector and gauge parameter independence. Since $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_{\mathrm{micro}}] = 0$, the propagator intertwines with $\hat{Q}_{\mathrm{BRST}}$: $\hat{Q}_{\mathrm{BRST}}\, U_{\mathrm{micro}}(t, s) = U_{\mathrm{micro}}(t, s)\, \hat{Q}_{\mathrm{BRST}}$. Thus U_{micro} maps $\ker \hat{Q}_{\mathrm{BRST}}$ into itself and $\mathrm{im}\,\hat{Q}_{\mathrm{BRST}}$ into itself; it descends to a unitary evolution on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$. Variations of gauge parameters change the gauge fermion by $\Psi_\zeta \to \Psi_\zeta + \delta\Psi$ and induce a BRST-exact deformation $\delta\hat{H} = \{\hat{Q}_{\mathrm{BRST}}, \delta\Psi\}$; by the same argument as above, the induced variation of any ghost-number-zero physical matrix element is a BRST coboundary and therefore vanishes on $\mathcal{H}_{\mathrm{phys}}$ (Nielsen-type identities; cf. Section 7.1.3). Hence physical spectra and matrix elements are gauge-parameter independent. □

Proposition 7.353 (Ward structure with explicit breakings (scale–tagged, physical sector))**.** *Let δ_a be a (possibly local/relational) symmetry variation with $\delta_a\mathcal{L}_0 = \nabla_\mu K_a^\mu$ and $\delta_a\hat{\mathcal{O}}_B = \mathcal{S}_{B,a}$ (band–tagged). Then the adjoint–covariant, scale–tagged Ward identity reads*

$$\nabla_\mu^{(\mathrm{ad})} J_a^{(\lambda_{\mathrm{UV}},\ell)\mu} = \sum_B \varepsilon_B \left\langle \mathcal{S}_{B,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\boldsymbol{\Psi}} + \left\langle \zeta\, \eta_a^{(\lambda_{\mathrm{UV}},\ell)} \right\rangle_{\boldsymbol{\Psi}} + \mathcal{A}_a^{(\lambda_{\mathrm{UV}},\ell)},$$

as in Definition 6.295. On the physical sector and with anomaly-free BRST, ζ–exact and anomalous terms drop, yielding

$$\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = \sum_B \varepsilon_B \left\langle \mathcal{S}_{B,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\boldsymbol{\Psi}},$$

in agreement with eq. (6.377) and the relational Ward lemma Lemma 6.233 (cf. [117, 230]).

Proof. Work with the scale–tagged Lagrangian $\mathcal{L} = \mathcal{L}_0 + \sum_B \varepsilon_B \mathcal{O}_B + \zeta\Psi$ (UV/IR tags suppressed; cf. Definition 6.295). Let δ_a be the (possibly local/relational) variation with

[9] We use that $t \mapsto V(t)$ is strongly measurable and locally bounded as a quadratic form, which holds for local Wick polynomials with band/IR tags; cf. the assumptions preceding Definition 7.356.

$\delta_a \mathcal{L}_0 = \nabla_\mu K_a^\mu$ and $\delta_a \mathcal{O}_B = \mathcal{S}_{B,a}$. By the relational Ward lemma Lemma 6.233 (applied to the present decomposition), there exists a local functional η_a from $\delta_a \Psi$ such that, after the usual Noether–Belinfante improvement absorbing $\nabla_\mu K_a^\mu$, the (improved) current obeys the local off–shell identity

$$\nabla_\mu J^\mu_{a,\mathrm{imp}} = \sum_B \varepsilon_B \, \mathcal{S}_{B,a} \; + \; \zeta \, \eta_a \; + \; \mathcal{A}_a, \tag{7.523}$$

with a possible anomaly $\mathcal{A}_a$ (vanishing in the anomaly–free case), cf. Definition 6.295 and [117, 230].

Adjoint covariantization. If G is gauged, replace ∇_μ by the adjoint–covariant divergence $\nabla^{(\mathrm{ad})}_\mu J^\mu := \nabla_\mu J^\mu + i[\mathcal{A}_\mu, J^\mu]$; this yields exactly the definition in Definition 6.295:

$$\nabla^{(\mathrm{ad})}_\mu J^\mu_{a,\mathrm{imp}} = \sum_B \varepsilon_B \, \mathcal{S}_{B,a} \; + \; \zeta \, \eta_a \; + \; \mathcal{A}_a. \tag{7.524}$$

Scale tagging. Apply the band/IR tagging functor (UV then IR; cf. Definition 6.282 and Section 6.12.4). Using $[\nabla_\mu, P_x(\lambda_{\mathrm{UV}})] = 0$ (assumption in Section 6.12.4) and the fact that $P_x(\lambda_{\mathrm{UV}})$, $K^{(\ell)}_{\mathrm{IR}}$ are BRST–closed of ghost number 0 and commute with channel projectors (cf. Section 7.1.3 and eq. (7.244)), we obtain the scale–tagged identity

$$\nabla^{(\mathrm{ad})}_\mu J^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_B \varepsilon_B \, \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{B,a} \; + \; \zeta \, \eta^{(\lambda_{\mathrm{UV}},\ell)}_a \; + \; \mathcal{A}^{(\lambda_{\mathrm{UV}},\ell)}_a, \tag{7.525}$$

which is precisely the statement in the first display of the proposition (compare with Definition 6.295 and eq. (6.376)).

Physical reduction. Taking expectation values in a homogeneous state $|\mathbf{\Psi}\rangle$ and projecting to the physical sector with $\mathsf{P}_{\mathrm{phys}}$ gives

$$\nabla^{(\mathrm{ad})}_\mu \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_B \varepsilon_B \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{B,a} \right\rangle_{\mathbf{\Psi}} \; + \; \left\langle \zeta \, \eta^{(\lambda_{\mathrm{UV}},\ell)}_a \right\rangle_{\mathbf{\Psi}} \; + \; \mathcal{A}^{(\lambda_{\mathrm{UV}},\ell)}_a,$$

where $\bar{J} := \langle \hat{J} \rangle_{\mathbf{\Psi}}$ and we used that tags commute with $\mathsf{P}_{\mathrm{phys}}$ (cf. Section 7.1.3). On the anomaly–free Stage I and within BRST cohomology (ghost number 0), ζ–exact insertions vanish and the anomaly term is absent; hence

$$\nabla^{(\mathrm{ad})}_\mu \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_B \varepsilon_B \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{B,a} \right\rangle_{\mathbf{\Psi}},$$

which is eq. (6.377) and agrees with the relational Ward identity in Lemma 6.233. This completes the proof. □

Remark 7.354 (Law–channel purity and branch equality)**.** In Quadrant III we keep the *state* channel symmetric while allowing explicit law deformations. The branch generators use the *same* G–invariant baseline $\hat{H}_0$ and differ only by the small, tagged $\varepsilon_B \, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$ insertions as in (7.522). Any change of presentation by gauge–parameter scans or ζ–exact decorations is cohomologically trivial on $\mathcal{H}_{\mathrm{phys}}$ (cf. Section 7.1.3).

Smallness and admissibility.

Definition 7.355 ($\mathcal{K}$–weighted seminorm and form domain)**.** Let $\mathcal{K}$ be the positive, self–adjoint kinetic operator appearing in the symmetric baseline Hamiltonian of eq. (7.241); write $\mathfrak{h} := \overline{\mathrm{Dom}\,\mathcal{K}^{1/2}}$ for its form domain endowed with the graph norm $\|\Psi\|_{\mathcal{K}} := \|\mathcal{K}^{1/2}\Psi\|$. For any band/IR–tagged operator $\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}$ define the $\mathcal{K}$–weighted operator seminorm

$$\boxed{\left\|\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\right\|_{\mathcal{K}} := \sup_{\|\Psi\|_{\mathcal{K}}=1} \left|\left\langle \Psi \middle| \mathcal{K}^{-1/2}\,\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\,\mathcal{K}^{-1/2} \middle| \Psi \right\rangle\right|.} \tag{7.526}$$

We say that a tagged operator is *$\mathcal{K}$–form–bounded with (relative) bound β* if $\left\|\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\right\|_{\mathcal{K}} \leq \beta < \infty$.

Definition 7.356 (Admissible explicit breaking in QIII)**.** A family $\{\hat{\mathcal{O}}_B\}_B$ of symmetry–breaking operators is *admissible* if:

(A1) **BRST closure (on shell) and ghost number** 0**:** $\delta_{\mathrm{BRST}}\hat{\mathcal{O}}_B = \{\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{O}}_B\} = 0$ and $\mathrm{gh}(\hat{\mathcal{O}}_B) = 0$, but $\delta_G^{(\mathrm{global})}\hat{\mathcal{O}}_B \neq 0$ (so global G is explicitly broken in the law channel while Slavnov–Taylor remains exact on shell), cf. eq. (7.16) and [117, 442, 243].

(A2) **Locality and power counting:** $\hat{\mathcal{O}}_B$ is a local (Wick) polynomial in the band/IR-tagged fields and covariant derivatives, with canonical/anomalous dimensions tracked as in eq. (7.211); broken G-charges are monitored by a spurion S_B such that $\varepsilon_B S_B \hat{\mathcal{O}}_B$ is G-invariant [440].

(A3) **Small relative form bound:** for the tagged operator, defined as

$$\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)} := K_{\mathrm{IR}}^{(\ell)} P_x(\lambda_{\mathrm{UV}}) \hat{\mathcal{O}}_B P_x(\lambda_{\mathrm{UV}}) K_{\mathrm{IR}}^{(\ell)},$$

one has

$$\varepsilon_B \left\|\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}\right\|_{\mathcal{K}} \leq \varepsilon_{\mathrm{soft}} \ll 1 \quad \text{(smallness on the band and within the IR window).}$$

(A4) **Pipeline stability:** under the regularisation pipeline $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$ (cf. eq. (7.67)), the seminorm varies smoothly and obeys plateau–type bounds of Section 6.12.4.

(A5) **Band/IR compatibility:** $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ are BRST–closed (ghost number 0) and commute with the channel projectors Π_α, so tagging preserves domains, cohomology, and channel resolution (cf. Section 7.1.3).

Proposition 7.357 (Kato–Rellich stability and unitary dynamics)**.** *Let $\hat{H}_{\mathrm{micro}}$ be as in Definition 7.350 with admissible $\{\hat{\mathcal{O}}_B\}_B$. Then $\hat{H}_{\mathrm{micro}}(t; \lambda_{\mathrm{UV}}, \ell)$ is self–adjoint on the form domain of $\hat{H}_0(t; \lambda_{\mathrm{UV}}, \ell)$ and generates a unitary evolution on the band–limited Hilbert space. Moreover, for $t \geq 0$,*

$$\left\|U_{\mathrm{micro}}(t; \lambda_{\mathrm{UV}}, \ell) - U_0(t; \lambda_{\mathrm{UV}}, \ell)\right\| \leq C\,\varepsilon_{\mathrm{soft}}\,t + \mathcal{O}(\varepsilon_{\mathrm{soft}}^2\,t^2),$$

with a constant C depending on $\mathcal{K}$ but independent of $(\lambda_{\mathrm{UV}}, \ell)$ inside a plateau box. Sketch. *By (A3) each $\varepsilon_B \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$ is $\mathcal{K}$–form–small relative to $\hat{H}_0$, hence $\hat{H}_0 + \sum_B \varepsilon_B \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$ is self–adjoint and lower bounded (Kato–Rellich) and yields a unitary group; the difference bound follows from a first–order Dyson estimate [115].*

Proof. Write

$$\hat{H}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) = \hat{H}_0(t;\lambda_{\mathrm{UV}},\ell) + V(t), \qquad V(t) := \sum_B \varepsilon_B\, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(t),$$

with $\hat{H}_0$ the symmetric baseline of eq. (7.241). By admissibility (A3) in Definition 7.356 and the $\mathcal{K}$–seminorm of Definition 7.355–(7.526), each tagged breaking is $\mathcal{K}$–form–bounded relative to $\hat{H}_0$ with small bound:

$$\left\|\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(t)\right\|_{\mathcal{K}} \le \beta_B, \qquad \sum_B |\varepsilon_B|\,\beta_B \le \varepsilon_{\mathrm{soft}} \ll 1,$$

uniformly for $(\lambda_{\mathrm{UV}},\ell)$ inside a plateau window (cf. Proposition 7.359 and Section 6.12.4).

(i) Self–adjointness. For each fixed t, $V(t)$ is a symmetric form perturbation of $\hat{H}_0(t)$ with relative bound < 1 on the common form domain $\mathfrak{h} = \overline{\mathrm{Dom}\,\mathcal{K}^{1/2}}$. By the Kato–Rellich theorem (form version), $\hat{H}_{\mathrm{micro}}(t) = \hat{H}_0(t) + V(t)$ is self–adjoint on $\mathrm{Dom}\,\hat{H}_0(t)$ and bounded below [115].

(ii) Unitary dynamics. The quadratic forms $q_t[\Psi] := \langle \mathcal{K}^{1/2}\Psi, \mathcal{K}^{1/2}\Psi\rangle + \langle \Psi, V(t)\Psi\rangle$ are defined on the time–independent form domain $\mathfrak{h}$, are closed, and depend (locally) boundedly/measurably on t for local Wick polynomials with band/IR tags (same regularity as used in Definition 7.356). Kato's theory for time–dependent self–adjoint Hamiltonians with fixed form domain then yields a unique unitary propagator $U_{\mathrm{micro}}(t,s;\lambda_{\mathrm{UV}},\ell)$ solving $i\partial_t U_{\mathrm{micro}}(t,s) = \hat{H}_{\mathrm{micro}}(t) U_{\mathrm{micro}}(t,s)$ with $U_{\mathrm{micro}}(s,s) = \mathbf{1}$ [115].

(iii) Difference bound. Duhamel's formula gives

$$U_{\mathrm{micro}}(t) - U_0(t) = -i \int_0^t U_{\mathrm{micro}}(t,s)\, V(s)\, U_0(s)\, ds.$$

Taking operator norms and using unitarity,

$$\|U_{\mathrm{micro}}(t) - U_0(t)\| \;\le\; \int_0^t \|V(s)\|_{\mathrm{op}}\, ds.$$

By the $\mathcal{K}$–form bound and equivalence of the induced operator norms on $\mathfrak{h}$ (cf. Remark 7.361), there exists a constant $C = C(\mathcal{K})$ such that $\|V(s)\|_{\mathrm{op}} \le C \sum_B |\varepsilon_B| \left\|\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(s)\right\|_{\mathcal{K}} \le C\,\varepsilon_{\mathrm{soft}}$. Hence

$$\|U_{\mathrm{micro}}(t) - U_0(t)\| \le C\,\varepsilon_{\mathrm{soft}}\, t,$$

and the standard Dyson expansion yields the second–order remainder $\mathcal{O}(\varepsilon_{\mathrm{soft}}^2 t^2)$. Inside a plateau box, C can be chosen independent of $(\lambda_{\mathrm{UV}},\ell)$ by Proposition 7.359.

This proves self–adjointness, unitary evolution, and the stated bound. □

Proposition 7.358 (BRST/Slavnov–Taylor consistency on the band)**.** *Under (A1)–(A5),*

$$[\hat{Q}_{\mathrm{BRST}},\, \hat{H}_{\mathrm{micro}}] = 0 \quad \textit{and} \quad \mathcal{S}(\Gamma) = 0 \quad \textit{(ST identity)}$$

hold on the band and within the IR window; here $\mathcal{S}(\Gamma)$ denotes the Slavnov functional acting on the effective action. Consequently, physical matrix elements, spectra, and channel–resolved visibilities evaluated on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ are gauge–parameter independent (Nielsen identities) and unaffected by ζ–exact decorations, cf. Section 7.1.3. Justification. *BRST closure and ghost number 0 prevent cohomology obstructions; band/IR tags are BRST–closed and commute with Π_α, so the standard algebra carries through [117, 442, 243, 82].*

Proof. (i) Hamiltonian–level BRST invariance on the band. From Definition 7.350 write

$$\hat{H}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) = \hat{H}_0(t;\lambda_{\mathrm{UV}},\ell) + \sum_B \varepsilon_B\, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(t),$$
$$\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)} := K_{\mathrm{IR}}^{(\ell)} P_x(\lambda_{\mathrm{UV}})\, \hat{\mathcal{O}}_B\, P_x(\lambda_{\mathrm{UV}}) K_{\mathrm{IR}}^{(\ell)}.$$

By construction of the symmetric baseline and Section 7.1.3,

$$[\hat{Q}_{\mathrm{BRST}}, \hat{H}_0] = 0, \qquad [\hat{Q}_{\mathrm{BRST}}, \{\hat{Q}_{\mathrm{BRST}}, \Psi_\zeta\}] = 0$$

(the latter by nilpotency and graded Jacobi). By admissibility (A1)–(A5) of Definition 7.356 we have (on shell) $\delta_{\mathrm{BRST}}\hat{\mathcal{O}}_B = 0$ and the tags are BRST–closed of ghost number 0:

$$[\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{O}}_B] = 0, \qquad [\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})] = [\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}] = 0 \quad \text{(cf. eq. (7.244))}.$$

Therefore

$$[\hat{Q}_{\mathrm{BRST}}, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}] = \left[\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)} P_x\, \hat{\mathcal{O}}_B\, P_x K_{\mathrm{IR}}^{(\ell)}\right] = 0,$$

and by linearity $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_{\mathrm{micro}}] = 0$.

(ii) Slavnov–Taylor identity for the effective action on the band. Consider the scale–tagged gauge–fixed action $S^{(\lambda_{\mathrm{UV}},\ell)} = S_0^{(\lambda_{\mathrm{UV}},\ell)} + \sum_B \varepsilon_B \int \mathcal{O}_B^{(\lambda_{\mathrm{UV}})} + \int \zeta \Psi^{(\lambda_{\mathrm{UV}},\ell)}$, with antifield (Zinn–Justin) sources coupled to BRST variations in the usual way [117, 442, 243]. The functional measure is BRST invariant and the classical action is BRST invariant modulo ζ–exact terms; admissibility (A1) supplies $\delta_{\mathrm{BRST}}\mathcal{O}_B = 0$ and (A5) ensures that the linear tagging maps commute with BRST. Hence the standard derivation of the ST identity goes through *verbatim* for the generating functional $Z^{(\lambda_{\mathrm{UV}},\ell)}$, yielding the ST identity for the effective action $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$:

$$\mathcal{S}\big(\Gamma^{(\lambda_{\mathrm{UV}},\ell)}\big) = 0$$

in the anomaly–free case (Stage I), see e.g. [82, Ch. 16], [117, 442, 243]. The presence of $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ only composes the fields with BRST–closed linear operators and thus does not alter the cohomological content entering the ST operator.

(iii) Descent to $\mathcal{H}_{\mathrm{phys}}$ and Nielsen independence. From (i) the propagator U_{micro} intertwines with $\hat{Q}_{\mathrm{BRST}}$, so it preserves $\ker \hat{Q}_{\mathrm{BRST}}$ and $\mathrm{im}\, \hat{Q}_{\mathrm{BRST}}$ and descends to a unitary evolution on the ghost–number–zero cohomology $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$. Gauge–parameter variations amount to a deformation of the gauge fermion, $\Psi \mapsto \Psi + \delta\Psi$, and hence to a BRST–exact deformation of the action/Hamiltonian, $\delta S = \int \zeta\, \delta\Psi$, $\delta\hat{H} = \{\hat{Q}_{\mathrm{BRST}}, \delta\Psi\}$. The ST identity together with BRST triviality implies that the variation of any ghost–number–zero, BRST–closed observable reduces to a BRST coboundary; its expectation value vanishes upon projection to $\mathcal{H}_{\mathrm{phys}}$ (Nielsen identities), cf. Section 7.1.3 and [117, 82]. Because the tags commute with channel projectors Π_α (A5), the same conclusion holds for channel–resolved visibilities.

Combining (i)–(iii) proves $[\hat{Q}_{\mathrm{BRST}}, \hat{H}_{\mathrm{micro}}] = 0$, $\mathcal{S}(\Gamma) = 0$ on the band/within the IR window, and gauge–parameter independence of physical matrix elements, spectra, and channel–resolved visibilities. □

Proposition 7.359 (Pipeline/plateau robustness of the seminorm)**.** *If* $\mathcal{O}_B(\lambda_{\mathrm{UV}},\ell) := \big\|\hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}\big\|_{\mathcal{K}}$ *satisfies the plateau criterion Section 6.12.4 on* $[\lambda_{\mathrm{UV},1},\lambda_{\mathrm{UV},2}]\times[\ell_1,\ell_2]$*, then for any* $(\lambda_{\mathrm{UV}},\ell)$*,* $(\tilde\lambda_{\mathrm{UV}},\tilde\ell)$ *in this box,*

$$\big|\mathcal{O}_B(\tilde\lambda_{\mathrm{UV}},\tilde\ell)-\mathcal{O}_B(\lambda_{\mathrm{UV}},\ell)\big| \;\le\; \varepsilon_{\lambda_{\mathrm{UV}}}\Big|\ln\tfrac{\tilde\lambda_{\mathrm{UV}}}{\lambda_{\mathrm{UV}}}\Big| \;+\; \varepsilon_\ell\Big|\ln\tfrac{\tilde\ell}{\ell}\Big|.$$

Hence the smallness condition in (7.526) is stable under UV/IR scans within the plateau window.

Proof. Set

$$u:=\ln\lambda_{\mathrm{UV}},\qquad v:=\ln\ell,\qquad F(u,v):=\mathcal{O}_B\big(e^u,e^v\big)=\Big\|\hat{\mathcal{O}}_B^{(e^u,e^v)}\Big\|_{\mathcal{K}}.$$

By the plateau criterion Section 6.12.4 (cf. (6.380)), there exist constants $\varepsilon_{\lambda_{\mathrm{UV}}},\varepsilon_\ell$ such that, *uniformly* on the rectangle $[u_1,u_2]\times[v_1,v_2]=[\ln\lambda_{\mathrm{UV},1},\ln\lambda_{\mathrm{UV},2}]\times[\ln\ell_1,\ln\ell_2]$,

$$\big|\partial_u F(u,v)\big|\le\varepsilon_{\lambda_{\mathrm{UV}}},\qquad \big|\partial_v F(u,v)\big|\le\varepsilon_\ell.$$

Let (u,v) and $(\tilde u,\tilde v)$ be any two points in this rectangle (equivalently, $(\lambda_{\mathrm{UV}},\ell)$ and $(\tilde\lambda_{\mathrm{UV}},\tilde\ell)$ in the stated box). Apply the fundamental theorem of calculus along the piecewise C^1 path that first varies u at fixed v, then varies v at fixed $\tilde u$:

$$\begin{aligned}\big|F(\tilde u,\tilde v)-F(u,v)\big| &\le \Big|\int_u^{\tilde u}\partial_u F(s,v)\,ds\Big|+\Big|\int_v^{\tilde v}\partial_v F(\tilde u,t)\,dt\Big|\\ &\le \varepsilon_{\lambda_{\mathrm{UV}}}\,|\,\tilde u-u\,|+\varepsilon_\ell\,|\,\tilde v-v\,|.\end{aligned}$$

Returning to $(\lambda_{\mathrm{UV}},\ell)$ variables gives $|\,\tilde u-u\,|=|\ln\big(\tilde\lambda_{\mathrm{UV}}/\lambda_{\mathrm{UV}}\big)|$ and $|\,\tilde v-v\,|=|\ln\big(\tilde\ell/\ell\big)|$, hence

$$\big|\mathcal{O}_B(\tilde\lambda_{\mathrm{UV}},\tilde\ell)-\mathcal{O}_B(\lambda_{\mathrm{UV}},\ell)\big| \;\le\; \varepsilon_{\lambda_{\mathrm{UV}}}\Big|\ln\tfrac{\tilde\lambda_{\mathrm{UV}}}{\lambda_{\mathrm{UV}}}\Big| \;+\; \varepsilon_\ell\Big|\ln\tfrac{\tilde\ell}{\ell}\Big|.$$

This proves the displayed inequality. In particular, if the smallness condition $\varepsilon_B\,\mathcal{O}_B(\lambda_{\mathrm{UV}},\ell)\le\varepsilon_{\mathrm{soft}}$ holds at one point with a slack exceeding the right–hand side bound, then it holds throughout the plateau box; hence the smallness requirement in (7.526) is stable under UV/IR scans within that window. □

Corollary 7.360 (Controlled law deficit and spectral shifts)**.** *With admissible breakings and within a plateau window, the law–channel visibility deficit obeys*

$$1-|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}| = \mathcal{O}(\varepsilon_{\mathrm{soft}}) \;+\; \mathcal{O}\big(\ell^{\,\Delta-(d+z)}\big),$$

consistent with Proposition 6.277, and the physical pole locations/residues of the band–tagged propagators shift analytically in $\{\varepsilon_B\}$ *while remaining gauge–parameter independent (cf. Proposition 7.16).*

Proof. Law–visibility bound. Let Λ_{law} be defined as in eq. (7.122), with phases calibrated so that in the unbroken baseline ($\varepsilon_B = 0$) one has $\Lambda_{\mathrm{law}} = 1$ (cf. Proposition 7.367). Using Duhamel's formula with $\hat{H}_{\mathrm{micro}} = \hat{H}_0 + \sum_B \varepsilon_B \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$,

$$U_{\mathrm{micro}}(T) - U_0(T) = -i \int_0^T U_{\mathrm{micro}}(T,t) \left(\sum_B \varepsilon_B \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}(t) \right) U_0(t)\, dt,$$

and the unitarity of U_{micro}, U_0 together with the $\mathcal{K}$–form bound (A3), we obtain the operator–norm estimate

$$\| U_{\mathrm{micro}}(T) - U_0(T) \| \le C\, \varepsilon_{\mathrm{soft}}\, T + \mathcal{O}(\varepsilon_{\mathrm{soft}}^2 T^2) \quad \text{(cf. Proposition 7.357)}.$$

Since the law visibility is a normalised trace/overlap of the product of a branch unitary and its reference (cf. Definition 7.363 and Proposition 7.365), the above yields

$$1 - |\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}| \;=\; \mathcal{O}(\varepsilon_{\mathrm{soft}}) \;+\; R_{\mathrm{IR}}(\ell),$$

for some nonnegative remainder $R_{\mathrm{IR}}(\ell)$. By the scale–tagged Ward identity on the physical sector (with anomaly–free BRST),

$$\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = \sum_B \varepsilon_B \left\langle \mathcal{S}_{B,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\boldsymbol{\Psi}} \quad \text{(Proposition 7.353, eq. (6.377))},$$

and the locality/clustering hypotheses with IR windowing, the integrated source scales as $\ell^{\Delta-(d+z)}$ when the breakings are RG–irrelevant with minimal scaling dimension Δ; hence $R_{\mathrm{IR}}(\ell) = \mathcal{O}\big(\ell^{\Delta-(d+z)}\big)$, reproducing Proposition 6.277 (see Proposition 7.348). Together this gives the stated deficit bound.

Spectral (pole/residue) shifts and gauge independence. On $\mathcal{H}_{\mathrm{phys}}$ (ghost number 0) the band–tagged quadratic kernel reads

$$\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\varepsilon) = \mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(0) \;+\; \sum_B \varepsilon_B\, \mathbb{V}_{B,\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)},$$

where $\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(0)$ has positive kinetic blocks and $\mathbb{V}_{B,\mathrm{phys}}$ are bounded (by (A3) and Definition 7.355). For $\| \sum_B \varepsilon_B \mathbb{V}_{B,\mathrm{phys}} \|$ small (uniformly on a plateau window, cf. Proposition 7.359), the resolvent and hence the band–tagged propagator

$$\mathcal{D}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\varepsilon) = \Big(\mathbb{H}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}(\varepsilon) \Big)^{-1}$$

admit a convergent Neumann/Kato series in $\{\varepsilon_B\}$, implying analytic dependence of isolated poles and residues on $\{\varepsilon_B\}$ (Rellich/Kato analytic perturbation theory [115]). By Proposition 7.358 the BRST/ST identities hold on the band, so physical (ghost–number–zero, BRST–closed) poles/residues are gauge–parameter independent (Nielsen identities; cf. Section 7.1.3 and Proposition 7.16).

Combining these establishes the claimed visibility deficit and analytic, gauge–independent spectral shifts within the plateau window. □

Remark 7.361 (On the choice of $\mathcal{K}$ and equivalence of seminorms)**.** Let $\mathcal{K}_1, \mathcal{K}_2$ be positive, self–adjoint (elliptic) kinetic kernels with common form domain $\mathfrak{h} = \overline{\mathrm{Dom}\,\mathcal{K}_j^{1/2}}$ and suppose there exist $0 < m \le M < \infty$ such that, for all $\Psi \in \mathfrak{h}$,

$$m\,\langle \Psi, \mathcal{K}_1 \Psi\rangle \;\le\; \langle \Psi, \mathcal{K}_2 \Psi\rangle \;\le\; M\,\langle \Psi, \mathcal{K}_1 \Psi\rangle.$$

(Within a plateau box these bounds hold with m, M independent of $(\lambda_{\mathrm{UV}}, \ell)$.) Then the graph norms $\|\Psi\|_{\mathcal{K}_j} = \|\mathcal{K}_j^{1/2}\Psi\|$ are equivalent, and the $\mathcal{K}$–seminorms of (7.526) satisfy, for any tagged operator $\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}$,

$$m\,\big\|\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\big\|_{\mathcal{K}_2} \;\le\; \big\|\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\big\|_{\mathcal{K}_1} \;\le\; M\,\big\|\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\big\|_{\mathcal{K}_2}.$$

Hence the notion of "small" in (7.526) is insensitive to benign reparametrisations of the quadratic baseline (uniformly on the plateau). *Justification.* The quadratic–form bounds imply $m^{1/2}\|\cdot\|_{\mathcal{K}_1} \le \|\cdot\|_{\mathcal{K}_2} \le M^{1/2}\|\cdot\|_{\mathcal{K}_1}$ and yield a bounded, coercive intertwiner $R := \mathcal{K}_2^{1/2}\mathcal{K}_1^{-1/2}$ with $\|R\|^2 \le M$, $\|R^{-1}\|^2 \le 1/m$ (Kato's form theory). Then

$$\big\|\hat{\mathcal{O}}\big\|_{\mathcal{K}_2} = \big\|\mathcal{K}_2^{-1/2}\hat{\mathcal{O}}\mathcal{K}_2^{-1/2}\big\| = \big\|\mathcal{K}_1^{-1/2}R^{-1}\,\hat{\mathcal{O}}\,R^{-1}\mathcal{K}_1^{-1/2}\big\| \le \|R^{-1}\|^2\,\big\|\hat{\mathcal{O}}\big\|_{\mathcal{K}_1},$$

and symmetrically for the reverse inequality, giving the constants $1/m$ and M. (See, e.g., [115] for equivalence of closed forms and induced operator norms.)

Branch calibration (law channel).

Definition 7.362 (Presentation–equivalent micro–Hamiltonians)**.** Let $\hat{H}^{[j]}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)$, $j = 0, 1$, be two *law–channel* generators as in Definition 7.350, built from the same baseline $\hat{H}_0$ and the same set $\{\varepsilon_B, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}\}$, but differing by:

(P1) G**–preserving unitary field redefinitions:** $\hat{H}^{[1]}_{\mathrm{micro}} = \hat{U}_G^\dagger \hat{H}^{[0]}_{\mathrm{micro}} \hat{U}_G - i\,\hat{U}_G^\dagger \dot{\hat{U}}_G$, with $\hat{U}_G(t)$ unitary, $\mathrm{gh}(\hat{U}_G) = 0$, and $[\hat{U}_G,\, \hat{J}_a] = 0$ for all G–generators $\hat{J}_a$ (hence G–symmetric); and

(P2) **BRST–exact deformations:** $\hat{H}^{[1]}_{\mathrm{micro}} = \hat{H}^{[0]}_{\mathrm{micro}} + \{\hat{Q}_{\mathrm{BRST}},\, \delta\Psi(t)\}$, with $\mathrm{gh}(\delta\Psi) = -1$ and $\delta\Psi^\dagger = \delta\Psi$, so that $\{\hat{Q}_{\mathrm{BRST}}, \delta\Psi\}$ is Hermitian.

We write $\hat{H}^{[0]}_{\mathrm{micro}} \sim \hat{H}^{[1]}_{\mathrm{micro}}$ and say the two presentations are *presentation–equivalent*. *Note.* $\delta\Psi$ is a presentation fermion distinct from the fixed gauge–fixing fermion Ψ already used in $\{\hat{Q}_{\mathrm{BRST}}, \Psi\}$.

Definition 7.363 (Branch unitaries and calibration)**.** Given a presentation $\hat{H}^{[j]}_{\mathrm{micro}}$, define the law–channel time–evolution

$$\boxed{\begin{aligned} U_0^{(\mathrm{law;micro})}(T;\lambda_{\mathrm{UV}},\ell) &:= \mathcal{T}\,\exp\Big[-i\int_0^T \mathrm{d}t\,\hat{H}^{[0]}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)\Big],\\ U_1^{(\mathrm{law;micro})}(T;\lambda_{\mathrm{UV}},\ell) &:= \mathcal{T}\,\exp\Big[-i\int_0^T \mathrm{d}t\,\hat{H}^{[1]}_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)\Big]. \end{aligned}} \tag{7.527}$$

The *law visibility* is read as in eq. (7.122) (with the same BRST–closed tags and channel projectors), and its overall phase ϕ_{law} is *calibrated once* so that $\Lambda_{\mathrm{law}} = 1$ in the symmetric, unbroken limit (cf. Section 7.3.9).

Lemma 7.364 (Presentation coboundary)**.** *If $\hat{H}^{[1]}_{\mathrm{micro}} \sim \hat{H}^{[0]}_{\mathrm{micro}}$ in the sense of Definition 7.362, then*

$$U_1^{(\mathrm{law;micro})}(T) = \hat{U}_G^\dagger(T)\,\mathcal{T}\,\exp\Big(-i\int_0^T \mathrm{d}t\,\{\hat{Q}_{\mathrm{BRST}},\,\delta\Psi_H(t)\}\Big)\,U_0^{(\mathrm{law;micro})}(T)\,\hat{U}_G(0),$$

where $\delta\Psi_H(t)$ is $\delta\Psi(t)$ in the Heisenberg picture built with $\hat{H}^{[0]}_{\mathrm{micro}}$. Thus $U_1^{(\mathrm{law;micro})}(T)$ and $U_0^{(\mathrm{law;micro})}(T)$ differ by a G–symmetric unitary conjugation and a BRST–exact time–ordered exponential.

Proof. Set

$$W(t) := \mathcal{T}\,\exp\Big(-i\int_0^t \{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H(u)\}\,du\Big), \qquad X(t) := \hat{U}_G^\dagger(t)\,W(t)\,U_0^{(\mathrm{law;micro})}(t)\,\hat{U}_G(0).$$

Then $X(0)=\mathbf{1}$. Using

$$i\,\partial_t U_0^{(\mathrm{law;micro})}(t) = \hat{H}^{[0]}_{\mathrm{micro}}(t)\,U_0^{(\mathrm{law;micro})}(t), \quad i\,\partial_t W(t) = \{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H(t)\}\,W(t),$$

and $\partial_t \hat{U}_G^\dagger(t) = -\hat{U}_G^\dagger(t)\,\dot{\hat{U}}_G(t)\,\hat{U}_G^\dagger(t)$, a product-rule computation gives

$$i\,\partial_t X(t) = \Big(\hat{U}_G^\dagger \hat{H}^{[0]}_{\mathrm{micro}}\hat{U}_G - i\,\hat{U}_G^\dagger\dot{\hat{U}}_G + \hat{U}_G^\dagger\{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H(t)\}\hat{U}_G\Big)X(t).$$

Assuming $[\hat{U}_G,\hat{Q}_{\mathrm{BRST}}]=0$ and that $\delta\Psi$ is G–scalar (so $\hat{U}_G^\dagger\{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H\}\hat{U}_G = \{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H\}$), the bracket equals

$$\hat{H}^{[1]}_{\mathrm{micro}}(t) = \hat{U}_G^\dagger(t)\,\hat{H}^{[0]}_{\mathrm{micro}}(t)\,\hat{U}_G(t) - i\,\hat{U}_G^\dagger(t)\dot{\hat{U}}_G(t) + \{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H(t)\},$$

which is precisely the presentation relation of Definition 7.362. Hence $i\,\partial_t X(t) = \hat{H}^{[1]}_{\mathrm{micro}}(t)\,X(t)$ with $X(0)=\mathbf{1}$, so by uniqueness of time-ordered solutions, $X(T) = U_1^{(\mathrm{law;micro})}(T)$, i.e.

$$U_1^{(\mathrm{law;micro})}(T) = \hat{U}_G^\dagger(T)\,\mathcal{T}\,\exp\Big(-i\int_0^T \{\hat{Q}_{\mathrm{BRST}},\delta\Psi_H(t)\}\,dt\Big)\,U_0^{(\mathrm{law;micro})}(T)\,\hat{U}_G(0). \qquad \square$$

Proposition 7.365 (Physical equivalence of branch choices)**.** *Let $\mathsf{P}_{\mathrm{phys}}$ project onto $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$. Under the hypotheses above (BRST–closed tags; gh= 0 objects), for any ghost–number–zero density matrix ρ_0 supported on $\mathcal{H}_{\mathrm{phys}}$,*

$$\mathrm{Tr}\Big[U_1^{(\mathrm{law;micro})\dagger}(T)\,U_0^{(\mathrm{law;micro})}(T)\,\rho_0\Big] = \mathrm{Tr}\Big[U_{1'}^{(\mathrm{law;micro})\dagger}(T)\,U_{0'}^{(\mathrm{law;micro})}(T)\,\rho_0\Big]$$

for any other pair of presentations $([0'],[1'])$ equivalent to $([0],[1])$ in the sense of Definition 7.362, up to the single *overall calibration phase ϕ_{law}. Hence Λ_{law} is well defined on the* presentation class *and independent of gauge parameters (Nielsen identities; cf. Section 7.1.3).*

Idea. By Lemma 7.364, $U^{[1]}$ and $U^{[0]}$ differ by G–symmetric conjugations and a BRST–exact cocycle. Conjugations drop inside the trace with ρ_0 that commutes with G, and BRST–exact insertions vanish on $\mathcal{H}_{\mathrm{phys}}$ (cohomological triviality). Gauge–parameter changes produce ζ–exact deformations and are handled identically [117, 82]. $\square$

Proof. Fix two equivalent presentations $[0], [1]$ and $[0'], [1']$ in the sense of Definition 7.362. By Lemma 7.364 there exist (i) G-symmetric unitaries $W_a \in G$ (possibly scale-tagged but BRST-closed, cf. Section 7.1.3) and (ii) a finite family of BRST–exact coboundary insertions (i.e. ζ-exact) such that, for each branch $a \in \{0, 1\}$,

$$U_{a'}^{(\mathrm{law;micro})}(T) = e^{\,i\varphi_a}\, W_a\, U_a^{(\mathrm{law;micro})}(T)\, W_a^{-1} \;+\; \mathcal{B}_a, \tag{7.528}$$

where each term in $\mathcal{B}_a$ is a time-ordered insertion that is ζ-exact. (BRST-closed tags ensure cohomological well-posedness; cf. Section 7.1.3.)

Taking adjoints and forming the interference product,

$$\begin{aligned} U_{1'}^{(\mathrm{law;micro})\dagger}(T)\, U_{0'}^{(\mathrm{law;micro})}(T) = e^{\,i(\varphi_0-\varphi_1)} \Big[W_1\, U_1^{(\mathrm{law;micro})\dagger}(T)\, W_1^{-1} \Big] \\ \times \Big[W_0\, U_0^{(\mathrm{law;micro})}(T)\, W_0^{-1} \Big] \;+\; \mathcal{B}, \end{aligned} \tag{7.529}$$

with $\mathcal{B}$ a finite sum of time-ordered ζ-exact insertions (Duhamel expansion; closure under time ordering).

Let $\rho_0 = \mathsf{P}_{\mathrm{phys}} \rho_0 \mathsf{P}_{\mathrm{phys}}$ with $\mathrm{gh}(\rho_0) = 0$. By G-invariance of the physical sector, $[\,\rho_0, W_a\,] = 0$, hence by cyclicity

$$\mathrm{Tr}\Big(\big[W_1 U_1^\dagger W_1^{-1}\big] \big[W_0 U_0 W_0^{-1}\big] \rho_0 \Big) = \mathrm{Tr}\Big(U_1^\dagger\, U_0\, \rho_0 \Big). \tag{7.530}$$

Any ζ-exact insertion vanishes in the physical trace:

$$\mathrm{Tr}\Big(\zeta X\, \rho_0 \Big) = \mathrm{Tr}\Big(\{\hat{Q}_{\mathrm{BRST}}, X\}\, \rho_0 \Big) = \mathrm{Tr}\Big(\hat{Q}_{\mathrm{BRST}} X \rho_0 \Big) - \mathrm{Tr}\Big(X \hat{Q}_{\mathrm{BRST}} \rho_0 \Big) = 0, \tag{7.531}$$

using $\hat{Q}_{\mathrm{BRST}} \rho_0 = \rho_0 \hat{Q}_{\mathrm{BRST}} = 0$. Applying (7.530)–(7.531) to (7.529) gives

$$\mathrm{Tr}\Big[U_{1'}^\dagger(T)\, U_{0'}(T)\, \rho_0 \Big] = e^{\,i(\varphi_0-\varphi_1)}\; \mathrm{Tr}\Big[U_1^\dagger(T)\, U_0(T)\, \rho_0 \Big]. \tag{7.532}$$

Define the single calibration phase $\phi_{\mathrm{law}} := \varphi_0 - \varphi_1$. Fixing it at baseline sets $e^{i\phi_{\mathrm{law}}} = 1$, yielding the equality asserted in Proposition 7.365. Gauge–parameter variations obey the Nielsen identity (Section 7.1.3),

$$\partial_\xi \langle \mathcal{O} \rangle_{\mathrm{phys}} = \langle \zeta(\zeta_\xi)\, \mathcal{O} \rangle = \Big\langle \{\hat{Q}_{\mathrm{BRST}}, \zeta_\xi\}\, \mathcal{O} \Big\rangle,$$

which vanishes by (7.531), so Λ_{law} is presentation-class and gauge independent [117, 82]. □

Intuition. Equivalent presentations differ by harmless G-rotations and BRST coboundaries. Rotations disappear in a G-invariant trace, and coboundaries are invisible on $H^0(\hat{Q}_{\mathrm{BRST}})$. The only residue is a fixed global $U(1)$ calibration between branches, which we pin once (ϕ_{law}) and forget.

Lemma 7.366 (BRST/Nielsen decomposition of regulator derivatives)**.** *Let the tagged branch generators $\mathcal{L}_a(t; \lambda_{\mathrm{UV}}, \ell)$ be built with BRST–closed tags (gh= 0) that commute with the physical*

projector (cf. Section 7.1.3). For $\kappa \in \{\ln \lambda_{\mathrm{UV}}, \ln \ell\}$ *there exist operator families* $\mathcal{N}_{a,\kappa}(t)$ *with* $\mathrm{gh}(\mathcal{N}_{a,\kappa}) = -1$ *and* $\Delta_{a,\kappa}(t)$ *with* $\mathrm{gh}(\Delta_{a,\kappa}) = 0$ *such that*

$$\partial_\kappa \mathcal{L}_a(t) = \zeta\, \mathcal{N}_{a,\kappa}(t) \;+\; \Delta_{a,\kappa}(t), \tag{7.533}$$

and, within any plateau window (Section 6.12.4), the plateau-suppressed remainder $\Delta_{a,\kappa}$ *is uniformly bounded by the prescribed tolerances.*

Proof of Lemma 7.366. Fix $a \in \{0,1\}$ and $\kappa \in \{\ln \lambda_{\mathrm{UV}}, \ln \ell\}$. Write the tagged generator as

$$\mathcal{L}_a(t) = \mathcal{L}_a^{\mathrm{tag}}(t) + \zeta\, \Psi_a(t),$$

where the tag dependence is entirely in $\mathcal{L}_a^{\mathrm{tag}}$ (built from $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$) and Ψ_a is the gauge fermion ($\mathrm{gh}= -1$).

(i) Gauge-fixing sector. Since tags are BRST–closed ($\mathrm{gh}= 0$), $\partial_\kappa\big(\zeta \Psi_a\big) = \zeta\big(\partial_\kappa \Psi_a\big)$. Define

$$\mathcal{N}_{a,\kappa}^{(\mathrm{gf})}(t) := \partial_\kappa \Psi_a(t) \qquad (\mathrm{gh} = -1).$$

(ii) Tag-dependent sector via smooth projector calculus. On a certified plateau (Section 6.12.4), the band projectors vary smoothly with a spectral gap to the band edges. Hence there exists an anti-Hermitian generator $G_{a,\kappa}(t)$ ($\mathrm{gh}= 0$) such that, for each tagged operator block,

$$\partial_\kappa \mathcal{O}_B^{(\lambda_{\mathrm{UV}},\ell)}(t) = \Big[G_{a,\kappa}(t),\, \mathcal{O}_B^{(\lambda_{\mathrm{UV}},\ell)}(t)\Big] \;+\; R_{B,a,\kappa}(t),$$

with a remainder bounded uniformly by the plateau tolerances. Summing the blocks,

$$\partial_\kappa \mathcal{L}_a^{\mathrm{tag}}(t) = \Big[G_{a,\kappa}(t),\, \mathcal{L}_a^{\mathrm{tag}}(t)\Big] \;+\; R_{a,\kappa}(t), \qquad \|R_{a,\kappa}\| = \mathcal{O}(\text{tolerance}).$$

(iii) Cohomological triviality of presentation variations. Within the BRST–consistent reading (Section 7.1.3) and anomaly-free sector, presentation changes generated by $G_{a,\kappa}$ act trivially on $H^0(\hat{Q}_{\mathrm{BRST}})$; therefore the commutator $\Big[G_{a,\kappa}, \mathcal{L}_a^{\mathrm{tag}}\Big]$ is BRST–exact. Thus there exists $\widetilde{\mathcal{N}}_{a,\kappa}(t)$ with $\mathrm{gh}(\widetilde{\mathcal{N}}_{a,\kappa}) = -1$ such that

$$\Big[G_{a,\kappa}(t),\, \mathcal{L}_a^{\mathrm{tag}}(t)\Big] = \zeta\, \widetilde{\mathcal{N}}_{a,\kappa}(t).$$

(Equivalently, apply the BRST doublet/quartet mechanism, cf. Lemma 6.211 and eq. (6.279).)

(iv) Assemble $\mathcal{N}_{a,\kappa}$ *and* $\Delta_{a,\kappa}$. Define

$$\mathcal{N}_{a,\kappa}(t) := \mathcal{N}_{a,\kappa}^{(\mathrm{gf})}(t) + \widetilde{\mathcal{N}}_{a,\kappa}(t), \qquad \Delta_{a,\kappa}(t) := R_{a,\kappa}(t).$$

Then $\mathrm{gh}(\mathcal{N}_{a,\kappa}) = -1$, $\mathrm{gh}(\Delta_{a,\kappa}) = 0$, and combining (i)–(iii) yields

$$\partial_\kappa \mathcal{L}_a(t) = \zeta\, \mathcal{N}_{a,\kappa}(t) \;+\; \Delta_{a,\kappa}(t),$$

with $\Delta_{a,\kappa}$ uniformly bounded on the plateau as required. □

Proposition 7.367 (Calibration and stability on plateaus)**.** *Choose ϕ_{law} so that $\Lambda_{\mathrm{law}} = 1$ in the unbroken baseline ($\varepsilon_B = 0$). Then, within any plateau window for the tags (cf. Section 6.12.4),*

$$\partial_{\ln \lambda_{\mathrm{UV}}} \Lambda_{\mathrm{law}} = 0, \qquad \partial_{\ln \ell} \Lambda_{\mathrm{law}} = 0,$$

up to the prescribed tolerances, and the value of Λ_{law} is independent of presentation choices and gauge parameters. Reason. *Tags are BRST–closed ($gh = 0$) and commute with projectors; presentation changes are G–unitary or ζ–exact; plateaus remove residual regulator dependence.*

Proof of Proposition 7.367. Let

$$\Lambda_{\mathrm{law}}(T; \lambda_{\mathrm{UV}}, \ell) := \mathrm{Tr}\Big[U_1^{(\mathrm{law;micro})\dagger}(T)\, U_0^{(\mathrm{law;micro})}(T)\, \rho_0 \Big], \qquad \rho_0 = \mathsf{P}_{\mathrm{phys}} \rho_0 \mathsf{P}_{\mathrm{phys}},\ \mathrm{gh}(\rho_0) = 0,$$

with tags BRST–closed and commuting with projectors (cf. Section 7.1.3). Fix ϕ_{law} so that at $\varepsilon_B = 0$ one has $\Lambda_{\mathrm{law}} = 1$.

Step 1: Regulator derivatives reduce to ζ–exact insertions. For $\kappa \in \{\ln \lambda_{\mathrm{UV}}, \ln \ell\}$ the Duhamel formula gives

$$\partial_\kappa U_a(T) = \int_0^T dt\; U_a(T,t)\, \partial_\kappa \mathcal{L}_a(t)\, U_a(t,0),$$

hence

$$\begin{aligned} \partial_\kappa \Lambda_{\mathrm{law}} &= \mathrm{Tr}\Big[\big(\partial_\kappa U_1^\dagger\big) U_0\, \rho_0 \Big] + \mathrm{Tr}\Big[U_1^\dagger \big(\partial_\kappa U_0\big)\, \rho_0 \Big] \\ &= \sum_{a=0,1} \sigma_a \int_0^T dt\ \ \mathrm{Tr}\Big[U_1^\dagger(T)\, \mathcal{T}\{\partial_\kappa \mathcal{L}_a(t)\}\, U_0(T)\, \rho_0 \Big], \end{aligned} \tag{7.534}$$

with $\sigma_1 = -1$, $\sigma_0 = +1$. Apply Lemma 7.366: $\partial_\kappa \mathcal{L}_a = \zeta\, \mathcal{N}_{a,\kappa} + \Delta_{a,\kappa}$.

Step 2: ζ–exact pieces vanish on $\mathcal{H}_{\mathrm{phys}}$; G–conjugations drop. Inserting (7.533) into (7.534), all terms with $\zeta\, \mathcal{N}_{a,\kappa}$ vanish under the trace with ρ_0 by the standard cohomological argument (cf. the step around (7.531) in Proposition 7.365):

$$\mathrm{Tr}(\zeta X\, \rho_0) = \mathrm{Tr}\big(\{\hat{Q}_{\mathrm{BRST}}, X\} \rho_0 \big) = 0, \qquad \mathrm{gh}(X) \text{ definite},$$

using $\hat{Q}_{\mathrm{BRST}} \rho_0 = \rho_0 \hat{Q}_{\mathrm{BRST}} = 0$ and $\mathrm{gh}(\rho_0) = 0$. Any G–symmetric conjugations from presentation changes cancel inside the trace with ρ_0 (cyclicity and $[\,\rho_0, G\,] = 0$; cf. Proposition 7.365).

Step 3: Plateau suppression yields regulator stability. Only the $\Delta_{a,\kappa}$ pieces remain. By Section 6.12.4, their contribution is bounded by the plateau tolerances, hence

$$\partial_{\ln \lambda_{\mathrm{UV}}} \Lambda_{\mathrm{law}} = \mathcal{O}(\text{tolerance}), \qquad \partial_{\ln \ell} \Lambda_{\mathrm{law}} = \mathcal{O}(\text{tolerance}),$$

vanishing in the ideal plateau limit.

Step 4: Presentation/gauge independence. Presentation changes within an equivalence class act by G–unitaries and ζ–coboundaries; by Proposition 7.365 they affect Λ_{law} only by the single global calibration phase. With ϕ_{law} fixed at baseline ($\varepsilon_B = 0$), Λ_{law} is presentation–independent on plateaus. Gauge–parameter variations obey Nielsen identities,

$$\partial_\xi \langle \mathcal{O} \rangle_{\mathrm{phys}} = \big\langle \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}_\xi\}\, \mathcal{O} \big\rangle,$$

which vanish on $\mathcal{H}_{\mathrm{phys}}$ by the same BRST argument, giving gauge–parameter independence [117, 82]. □

Remark 7.368 (Calibration intuition and two-branch diagnostic)**.** Calibrated in the symmetric baseline ($\varepsilon_B = 0$) so that $\Lambda_{\text{law}} = 1$, the branch interferometer only "feels" BRST–exact coboundaries generated by Nielsen kernels and G–unitary presentation changes; both are invisible on $\mathcal{H}_{\text{phys}}$ (cf. Lemma 7.366 and Proposition 7.365). On certified plateaus (Section 6.12.4), regulator variations contribute only the plateau–suppressed remainders $\Delta_{a,\kappa}$, hence $\partial_{\ln \lambda_{\text{UV}}} \Lambda_{\text{law}} = \partial_{\ln \ell} \Lambda_{\text{law}} = 0$ up to tolerances and gauge–parameter independence holds by the Nielsen identities (see Proposition 7.367).

Operationally, keeping two law–channel branches with the same baseline $\hat{H}_0$ but different presentations remains useful: any contrast that survives the BRST/G–unitary and gauge/-plateau filtering diagnoses genuine G–breaking encoded in the scale–tagged Ward source (cf. Proposition 7.353), not a presentation or regulator artifact.

State posture and calibration (identity branch).

Definition 7.369 (State channel: identity branches and phase calibration)**.** Reuse the *identity* state branches of eq. (7.125), namely

$$U_0^{(\text{state})} = U_1^{(\text{state})} = U_0,$$

by setting the W–operator in eq. (7.124) to the identity (no SSB kick). Fix the state–visibility phase ϕ_{state} once and for all as in eq. (7.129) so that, in the symmetric/unbroken limit, the state visibility is calibrated to unit modulus. All objects are evaluated *on the band* with the BRST–closed tags $P_x(\lambda_{\text{UV}})$ and $K_{\text{IR}}^{(\ell)}$ (commuting with channel projectors), and on the physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ (cf. Section 7.1.3).

Proposition 7.370 (Channel separation under identity state branches)**.** *Under Definition 7.369 and with the law channel generated by Definition 7.350, the state visibility measured as in eq.* (7.129) *satisfies*

$$\Lambda_{\text{state}}(\lambda_{\text{UV}}, \ell; T) = 1$$

in the symmetric/unbroken limit, independently of presentation choices and gauge parameters; any deviation from unit modulus in the QIII setting is thus attributable to the law *channel.*
Reason. *Identity branches imply* $U_0^{(\text{state})} = U_1^{(\text{state})}$*, so the overlap/trace defining* Λ_{state} *reduces to a normed inner product; BRST–closed tags (gh= 0) and Nielsen identities ensure gauge–parameter independence on* $\mathcal{H}_{\text{phys}}$ *(cf. Section 7.1.3).*

Proof. Let $\rho_0 = \mathsf{P}_{\text{phys}} \rho_0 \mathsf{P}_{\text{phys}}$ be a unit–trace, ghost–number–zero density matrix on $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$. By Definition 7.369, the identity–state condition gives $U_0^{(\text{state})}(T) = U_1^{(\text{state})}(T) =: U^{(\text{state})}(T)$. Thus, using eq. (7.129),

$$\Lambda_{\text{state}}(\lambda_{\text{UV}}, \ell; T) = \operatorname{Tr}\Big[U^{(\text{state})\dagger}(T)\, U^{(\text{state})}(T)\, \rho_0\Big] = \operatorname{Tr}(\rho_0) = 1,$$

since $U^{(\text{state})}$ is unitary and $\operatorname{Tr} \rho_0 = 1$.

Presentation independence. Any presentation change within the equivalence class acts by a G–unitary and BRST–exact coboundaries that are *identical* on both identity branches. Writing $U^{(\text{state})} \mapsto U'^{(\text{state})} = e^{i\varphi}\, W\, U^{(\text{state})} W^{-1}$ with $W \in G$, cyclicity and $[\,\rho_0, W\,] = 0$ give

$$\operatorname{Tr}\Big[U'^{(\text{state})\dagger} U'^{(\text{state})} \rho_0\Big] = \operatorname{Tr}\Big[U^{(\text{state})\dagger} U^{(\text{state})} \rho_0\Big].$$

BRST–exact insertions induced at the generator level vanish on $\mathcal{H}_{\mathrm{phys}}$:

$$\mathrm{Tr}\Big(\{\hat{Q}_{\mathrm{BRST}}, X\}\,\rho_0\Big) = 0 \quad \text{for any } X \text{ of definite ghost number},$$

cf. the argument around (7.531) in Proposition 7.365.

Gauge–parameter independence. Either directly,

$$\partial_\xi \Lambda_{\mathrm{state}} = \mathrm{Tr}\Big[\partial_\xi(U^\dagger U)\,\rho_0\Big] = \mathrm{Tr}\Big[0\cdot\rho_0\Big] = 0 \quad (\text{unitarity } U^\dagger U = \mathbf{1}),$$

or via the Nielsen identity (cf. Section 7.1.3),

$$\partial_\xi \langle \mathcal{O}\rangle_{\mathrm{phys}} = \Big\langle \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}_\xi\}\,\mathcal{O}\Big\rangle,$$

and with $\mathcal{O} = U^{(\mathrm{state})\dagger}U^{(\mathrm{state})} = \mathbf{1}$ on $\mathcal{H}_{\mathrm{phys}}$ one again finds $\partial_\xi \Lambda_{\mathrm{state}} = 0$, since BRST–exact insertions drop out and the tags are BRST–closed (gh$= 0$).

Therefore, in the symmetric/unbroken limit, $\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; T) = 1$ independently of presentation and gauge. Any deviation from unit modulus observed in QIII must originate in the *law* channel. □

Intuition. Identity branches make the state-channel interferometer a norm check: $U^\dagger U = \mathbf{1}$ inside a G-invariant, BRST-closed trace, so it pins to one; only the law-channel dynamics can move it off unit modulus.

Initial readouts and records.

Definition 7.371 (Initial law deficit and state–coherence check)**.** Choose a minimal coarse–graining scale $\ell_{\min}$ consistent with the reciprocal–resolution constraints used around Section 6.12.4 (cf. Proposition 4.436). For a fixed readout time $T^\star$ (the interferometric normalisation of eq. (7.116)), define the *initial law deficit* and confirm state coherence via

$$\boxed{E^{(\mathrm{init})}_{\mathrm{law}}(\ell_{\min}) := 1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell_{\min}; T^\star) > 0, \qquad \Big|1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell_{\min}; T^\star)\Big| \le \varepsilon_{\mathrm{init}}.} \tag{7.535}$$

The tolerance $\varepsilon_{\mathrm{init}}$ is chosen below the plateau thresholds of Section 6.12.4 so that the statement "$\Lambda_{\mathrm{state}} \approx 1$" is meaningful uniformly in the volume V.

Proposition 7.372 (Gauge/presentation independence and plateau robustness)**.** *With the calibrations of Definition 7.369 and BRST–closed tags, the quantities in eq. (7.535) are independent of gauge–parameter choices and of presentation–equivalent changes in the law channel (cf. Definition 7.362 and Proposition 7.365). If, furthermore,* $(\lambda_{\mathrm{UV}}, \ell)$ *is varied* within *a plateau window of Section 6.12.4, then*

$$\partial_{\ln \lambda_{\mathrm{UV}}} E^{(\mathrm{init})}_{\mathrm{law}} = 0, \qquad \partial_{\ln \ell} E^{(\mathrm{init})}_{\mathrm{law}} = 0,$$

and Λ_{state} *remains within* $\varepsilon_{\mathrm{init}}$ *of unity, up to the prescribed plateau tolerances.* Reason. *BRST–closed tags (gh$= 0$) commute with projectors and preserve cohomology; Nielsen identities render physical readouts gauge independent; plateau bounds control UV/IR sensitivity (cf. Sections 6.12.4 and 7.1.3).*

Proof. Let the initial deficits be defined as in eq. (7.535), built from the ghost–number–zero physical state $\rho_0 = \mathsf{P}_{\mathrm{phys}}\rho_0\mathsf{P}_{\mathrm{phys}}$ and the QIII evolutions. Assume the state–channel calibration of Definition 7.369 (identity branches in the state channel) and BRST–closed tags that commute with projectors (cf. Section 7.1.3).

(i) Gauge–parameter and presentation independence. Each ingredient entering eq. (7.535) is a physical, gh= 0 trace on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$. Gauge–parameter variations insert BRST–exact Nielsen terms,

$$\partial_\xi \langle \mathcal{O} \rangle_{\mathrm{phys}} = \Big\langle \{\hat{Q}_{\mathrm{BRST}}, \mathcal{N}_\xi\}\, \mathcal{O} \Big\rangle,$$

which vanish on $\mathcal{H}_{\mathrm{phys}}$ by the cohomological null property $\mathrm{Tr}\Big(\{\hat{Q}_{\mathrm{BRST}}, X\}\rho_0\Big) = 0$ (see the step around (7.531)) [117, 82]. Presentation–equivalent changes in the *law* channel act by G–unitary conjugations and BRST coboundaries; these drop in the same physical trace (cyclicity, $[\,\rho_0, G\,] = 0$), leaving at most the single global calibration phase already fixed at baseline by Proposition 7.365. Therefore the quantities in eq. (7.535) are independent of gauge parameters and presentation choices.

(ii) Plateau robustness for regulator variations. Within a plateau window (Section 6.12.4), the tagged generators admit the BRST/Nielsen decomposition (cf. Lemma 7.366):

$$\partial_\kappa \mathcal{L}_a(t) = \zeta\, \mathcal{N}_{a,\kappa}(t) + \Delta_{a,\kappa}(t), \qquad \kappa \in \{\ln \lambda_{\mathrm{UV}}, \ln \ell\},$$

with $\mathrm{gh}(\mathcal{N}_{a,\kappa}) = -1$ and $\Delta_{a,\kappa}$ the plateau–suppressed remainder (bounded by the prescribed tolerances). Applying the Duhamel formula to each law–channel factor inside eq. (7.535), all BRST–exact insertions $\zeta\,\mathcal{N}_{a,\kappa}$ vanish on $\mathcal{H}_{\mathrm{phys}}$ as above, while the remaining $\Delta_{a,\kappa}$ contributions are uniformly bounded on the plateau. Hence

$$\partial_{\ln \lambda_{\mathrm{UV}}} E^{(\mathrm{init})}_{\mathrm{law}} = 0, \qquad \partial_{\ln \ell} E^{(\mathrm{init})}_{\mathrm{law}} = 0$$

in the ideal plateau limit, and remain within tolerance otherwise.

(iii) Stability of the state visibility. Under Definition 7.369, the state–channel visibility satisfies $\Lambda_{\mathrm{state}} = 1$ in the symmetric limit (unitarity and $\mathrm{Tr}\,\rho_0 = 1$; see also Proposition 7.370). Plateau variations enter as in (ii): BRST–exact insertions cancel on $\mathcal{H}_{\mathrm{phys}}$, and any residual regulator dependence is plateau–suppressed; therefore Λ_{state} stays within $\varepsilon_{\mathrm{init}}$ of unity, up to the same tolerances.

Combining (i)–(iii) yields the proposition. □

Intuition. The "init" observables are physical traces on $H^0(\hat{Q}_{\mathrm{BRST}})$. Gauge and presentation moves are BRST–exact or G–unitary, hence invisible; on a plateau, the only leftover regulator drift is uniformly small, so the law–deficit is flat and the state visibility hugs one.‘‘

Remark 7.373 (Choice of $\ell_{\min}$ and reciprocal resolution)**.** Choose $\ell_{\min}$ at the smallest scale that simultaneously satisfies the reciprocal–resolution limits of Proposition 4.436 *and* the plateau criterion of Section 6.12.4: (i) the UV projector $P_x(\lambda_{\mathrm{UV}})$ cleanly resolves modes down to $1/\ell_{\min}$ without aliasing or leakage (cf. Section 6.12.4); (ii) the IR window kernel W_ℓ with $\ell \geq \ell_{\min}$ preserves locality/cluster properties and avoids under–resolving Ward sources (cf. Section 6.12.4). With this choice—and with the baseline calibration fixed so that

$\Lambda_{\text{law}} = 1$ at $\varepsilon_B = 0$ (Proposition 7.367) and identity–state branches in place (Definition 7.369 and Proposition 7.370)—the meters are plateau–robust and presentation/gauge–independent:

$$\partial_{\ln \lambda_{\text{UV}}} \Lambda_{\text{law}} = \partial_{\ln \ell} \Lambda_{\text{law}} = 0 \text{ (up to plateau tolerances)}, \qquad \Lambda_{\text{state}} = 1 + \mathcal{O}(\text{tolerance}),$$

with invariance under presentation–equivalent changes guaranteed by Propositions 7.365 and 7.372. *Intuition.* $\ell_{\min}$ is set at the "reciprocal–resolution knee" where UV band–limit and IR smearing balance; below it, UV aliasing or regulator drift contaminates reads, while above it, IR averaging dilutes genuine G–breaking. Picking $\ell_{\min}$ at this knee lands the meters on a plateau where only physical law–channel effects can move the readout.

Diagnostic Hygiene.

Lemma 7.374 (On–shell gauge safety)**.** *Assume the QIII breaking operators satisfy* $\zeta\, \hat{\mathcal{O}}_B = \{\hat{Q}_{\text{BRST}}, \hat{\mathcal{O}}_B\} = 0$ *and* $\text{gh}(\hat{\mathcal{O}}_B) = 0$ *(cf. Definition 7.356). Then the Slavnov–Taylor identity* $\mathcal{S}(\Gamma) = 0$ *of eq. (7.16) holds on shell (anomaly–free Stage I); any nonzero law–channel deficit at small* ℓ *arises from* global *Ward sources (explicit breaking of* G*), not from gauge anomalies (which are excluded by Section 7.2.8).* Justification. *BRST closure prevents cohomological obstructions; anomaly freedom ensures ST exactness on shell [117, 442, 243].*

Proof. Work in the QIII setting with admissible breakings (Definition 7.356), i.e. $\zeta\, \hat{\mathcal{O}}_B = 0$ and $\text{gh}(\hat{\mathcal{O}}_B) = 0$. At the classical level the deformation

$$S_{\text{cl}} \longrightarrow S_{\text{cl}} + \varepsilon_B \int \hat{\mathcal{O}}_B$$

preserves BRST symmetry, since $\zeta S_{\text{cl}} = 0$ and $\zeta \hat{\mathcal{O}}_B = 0$. Therefore the Zinn–Justin (Slavnov–Taylor) identity holds for the tree functional $\Gamma^{(0)}$:

$$\mathcal{S}(\Gamma^{(0)}) = 0, \qquad \text{cf. (7.16)}.$$

At the quantum level let $\Gamma = \sum_{n \geq 0} \hbar^n \Gamma^{(n)}$ be the renormalized 1PI functional. If a breaking appears, organize it as

$$\mathcal{S}(\Gamma) = \hbar^n\, \Delta_{\text{ST}}^{(n)} + \mathcal{O}(\hbar^{n+1}),$$

with ghost number $\text{gh}(\Delta_{\text{ST}}^{(n)}) = 1$. The Wess–Zumino consistency condition (graded Jacobi identity) reads

$$\mathcal{B}_\Gamma\, \Delta_{\text{ST}}^{(n)} = 0,$$

where $\mathcal{B}_\Gamma$ is the linearized Slavnov operator (nilpotent on shell). By the Stage I anomaly–freedom hypothesis (cf. Section 7.2.8) the on–shell cohomology $H^1(\mathcal{B}_\Gamma)$ is trivial [117, 442, 243]. Hence there exists a local functional $\widehat{\Delta}_{\text{ST}}^{(n)}$ of ghost number 0 such that

$$\Delta_{\text{ST}}^{(n)} = \mathcal{B}_\Gamma\, \widehat{\Delta}_{\text{ST}}^{(n)} \; + \; (\text{terms} \propto \text{equations of motion}).$$

Adding the counterterm $-\hbar^n\, \widehat{\Delta}_{\text{ST}}^{(n)}$ to Γ removes the breaking at order $\hbar^n$. Inducting in n yields, *on shell*,

$$\mathcal{S}(\Gamma) = 0.$$

Thus: (i) since $\hat{\mathcal{O}}_B$ is BRST–closed with gh $= 0$, it cannot seed a ghost–number–one gauge anomaly; (ii) any surviving nonzero law–channel deficit at small ℓ must therefore originate from *global* Ward sources (explicit G–breaking), not from gauge anomalies excluded by Section 7.2.8. □

Notation. We reserve $\Delta_{a,\kappa}$ for the *plateau–suppressed remainder* in the regulator–derivative decomposition (Lemma 7.366), and $\Delta_{\mathrm{ST}}^{(n)}$ for potential Slavnov–Taylor breakings (anomaly candidates) at loop order n.

Definition 7.375 (Soft vs. hard breaking via the $\mathcal{K}$–seminorm)**.** Let $\|\cdot\|_{\mathcal{K}}$ be the seminorm of Definition 7.355. A tagged breaking $\varepsilon_B \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}$ is called *soft* if

$$\varepsilon_B \left\| \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)} \right\|_{\mathcal{K}} \le \varepsilon_{\mathrm{soft}} \ll 1$$

(eq. (7.526)); otherwise it is *hard*. Hard breakings—e.g. relevant operators that violate the small form bound or destabilise the spectrum—are *inadmissible* in QIII and excluded. *References:* standard soft–breaking posture in [14, 91, 82].

Definition 7.376 (Spurion ledger and IR restoration)**.** Assign spurion charges to each coupling ε_B so that the composite $\varepsilon_B S_B \hat{\mathcal{O}}_B$ is G–invariant (spurion S_B transforms in the compensating representation). Record the running $\varepsilon_B(\mu)$; *IR restoration* in Step 3 will be certified by $\varepsilon_B(\mu) \to 0$ as $\mu \to 0$ along the RG, consistent with Wilsonian folklore [389] and algebraic renormalisation [117].

Proposition 7.377 (Numerical/regularisation stability)**.** *Implement eq.* (7.522) *using the* same *tags* $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ *that define* $\hat{H}_0$ *in eq.* (7.241)*. If the pipeline* $(\lambda_{\mathrm{UV}},\ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell})$ *is applied as in eq.* (7.67)*, then under Definition 7.356 one has Kato continuity of the dynamics with respect to* $(\varepsilon_B, \lambda_{\mathrm{UV}}, \ell)$ *on the common form domain:*

$$\left\| U_{\mathrm{micro}}(t;\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - U_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) \right\| \;\le\; C\left(|t| \sum_B |\varepsilon_B|\, \delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} + \delta_{\mathrm{pipe}} \right),$$

where $\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}}$ *is the change of the seminorm under the pipeline and* δ_{pipe} *is controlled by the plateau bounds of Section 6.12.4.* Reason. *Use the form–boundedness in Definition 7.375 and Kato–Rellich/Dyson estimates [115]; identical tagging ensures law/state visibilities are comparable under eq.* (7.67)*.*

Proof. Implement eq. (7.522) with the *same* tags $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ that define $\hat{H}_0$ in eq. (7.241). For each $(\lambda_{\mathrm{UV}},\ell)$ set

$$\hat{H}_{\mathrm{micro}}(\lambda_{\mathrm{UV}},\ell) = \hat{H}_0(\lambda_{\mathrm{UV}},\ell) \;+\; \sum_B \varepsilon_B\, \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)},$$

with all operators implicitly band/projected by $P_x(\lambda_{\mathrm{UV}})$ and smeared by $K_{\mathrm{IR}}^{(\ell)}$. By Definitions 7.356 and 7.375, each $\hat{\mathcal{O}}_B$ is $\hat{H}_0$-form–bounded on the *common* quadratic–form domain $\mathcal{D}$ (the latter is common because the tags coincide with those of $\hat{H}_0$). Hence for $\sum_B |\varepsilon_B|\, a_B < 1$ (relative bound a_B of $\hat{\mathcal{O}}_B$), Kato–Rellich yields self–adjointness of $\hat{H}_{\mathrm{micro}}(\lambda_{\mathrm{UV}},\ell)$ on a domain with form core $\mathcal{D}$ and a unitary group $U_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) = e^{-it\hat{H}_{\mathrm{micro}}(\lambda_{\mathrm{UV}},\ell)}$ [115].

Consider now a pipeline move $(\lambda_{\mathrm{UV}},\ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell})$ as in eq. (7.67). Write the Hamiltonian difference on $\mathcal{D}$ as

$$\begin{aligned} \Delta\hat{H} &:= \hat{H}_{\mathrm{micro}}(\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - \hat{H}_{\mathrm{micro}}(\lambda_{\mathrm{UV}},\ell) \\ &= \underbrace{\left[\hat{H}_0(\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - \hat{H}_0(\lambda_{\mathrm{UV}},\ell)\right]}_{=\,\Delta\hat{H}_0} + \sum_B \varepsilon_B\, \underbrace{\left[\hat{\mathcal{O}}_B^{(\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell})} - \hat{\mathcal{O}}_B^{(\lambda_{\mathrm{UV}},\ell)}\right]}_{=\,\Delta\hat{\mathcal{O}}_B}. \end{aligned}$$

Because the tags (P_x, K_{IR}) are identical in the law/state constructions, the domains and the comparison are "like–for–like".

By the Duhamel (Dyson) formula, for time–independent generators

$$U_{\mathrm{micro}}(t;\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - U_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell) = -i\int_0^t ds\, U_{\mathrm{micro}}(t-s;\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell})\,\Delta\hat{H}\,U_{\mathrm{micro}}(s;\lambda_{\mathrm{UV}},\ell).$$

Taking operator norms and using unitarity gives

$$\left\|U_{\mathrm{micro}}(t;\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - U_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)\right\| \;\le\; |t|\;\|\Delta\hat{H}\|_{B(\mathcal{D}\to\mathcal{D}^*)}\,. \tag{7.536}$$

By Definition 7.375, the form–boundedness constants provide a seminorm $\|\cdot\|_{\mathcal{K}}$ on $\mathcal{D}$ such that, for some $C_1 > 0$,

$$\|\Delta\hat{H}\|_{B(\mathcal{D}\to\mathcal{D}^*)} \;\le\; C_1\left(\sum_B |\varepsilon_B|\,\|\Delta\hat{\mathcal{O}}_B\|_{\mathcal{K}} \;+\; \|\Delta\hat{H}_0\|_{\mathcal{K}}\right).$$

Define $\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} := \|\Delta\hat{\mathcal{O}}_B\|_{\mathcal{K}}$. Within a plateau window (Section 6.12.4) the tag–induced change of the baseline, $\|\Delta\hat{H}_0\|_{\mathcal{K}}$, is bounded by a pipeline tolerance δ_{pipe} controlled by the plateau bounds (uniform Lipschitz control of $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ with respect to $\ln\lambda_{\mathrm{UV}}$, $\ln\ell$; cf. Section 6.12.4). Therefore, for some constant $C > 0$ depending only on the form–bounds in Definition 7.375 (but not on t within compact intervals),

$$\|\Delta\hat{H}\|_{B(\mathcal{D}\to\mathcal{D}^*)} \;\le\; C\left(\sum_B |\varepsilon_B|\,\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} \;+\; \delta_{\mathrm{pipe}}\right).$$

Inserting this into (7.536) yields

$$\left\|U_{\mathrm{micro}}(t;\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - U_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)\right\| \;\le\; C\left(|t|\sum_B |\varepsilon_B|\,\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} \;+\; |t|\,\delta_{\mathrm{pipe}}\right).$$

Absorbing the harmless factor of $|t|$ multiplying δ_{pipe} into the overall constant (or using the plateau's uniform-in-t control when $|t| \le T$ is fixed in the protocol) gives the stated bound, i.e.

$$\left\|U_{\mathrm{micro}}(t;\tilde{\lambda}_{\mathrm{UV}},\tilde{\ell}) - U_{\mathrm{micro}}(t;\lambda_{\mathrm{UV}},\ell)\right\| \;\le\; C\left(|t|\sum_B |\varepsilon_B|\,\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} + \delta_{\mathrm{pipe}}\right).$$

This is precisely Kato continuity of the dynamics with respect to $(\varepsilon_B, \lambda_{\mathrm{UV}}, \ell)$ on the common form domain, with constants furnished by the relative form–bounds and the plateau tolerances [115]. □

Corollary 7.378 (Comparability of visibilities under the pipeline)**.** *With the hypothesis of Proposition 7.377, the law/state visibilities computed at $(\lambda_{\mathrm{UV}}, \ell)$ and $(\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$ differ at most by the plateau tolerances of Section 6.12.4, hence are operationally comparable across the pipeline.*

Proof. Let, for a channel $\mathrm{ch} \in \{\mathrm{law}, \mathrm{state}\}$,

$$\Lambda_{\mathrm{ch}}(T;\lambda_{\mathrm{UV}},\ell) := \mathrm{Tr}\Big[U_1^{(\mathrm{ch})\dagger}(T;\lambda_{\mathrm{UV}},\ell)\,U_0^{(\mathrm{ch})}(T;\lambda_{\mathrm{UV}},\ell)\,\rho_0\Big], \qquad \rho_0 = \mathsf{P}_{\mathrm{phys}}\rho_0\mathsf{P}_{\mathrm{phys}},\ \mathrm{gh}(\rho_0) = 0.$$

Consider a pipeline move $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$ as in eq. (7.67). By Proposition 7.377, for each branch $a \in \{0, 1\}$,

$$\left\| U_a^{(\mathrm{ch})}(T; \tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell}) - U_a^{(\mathrm{ch})}(T; \lambda_{\mathrm{UV}}, \ell) \right\| \;\le\; C\Big(|T| \sum_B |\varepsilon_B|\, \delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} + \delta_{\mathrm{pipe}} \Big),$$

with $\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}}$ the change of the seminorm under the pipeline and δ_{pipe} controlled by the plateau bounds of Section 6.12.4.

Write the visibility difference as

$$\begin{aligned}
\Lambda_{\mathrm{ch}}(T; \tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell}) - \Lambda_{\mathrm{ch}}(T; \lambda_{\mathrm{UV}}, \ell) &= \mathrm{Tr}\Big[\Big(U_1^{(\mathrm{ch})\dagger}(T; \tilde{\cdot})\, U_0^{(\mathrm{ch})}(T; \tilde{\cdot}) - U_1^{(\mathrm{ch})\dagger}(T; \cdot)\, U_0^{(\mathrm{ch})}(T; \cdot) \Big) \rho_0 \Big] \\
&= \mathrm{Tr}\Big[\Big(U_1^{(\mathrm{ch})\dagger}(T; \tilde{\cdot}) - U_1^{(\mathrm{ch})\dagger}(T; \cdot) \Big) U_0^{(\mathrm{ch})}(T; \tilde{\cdot})\, \rho_0 \Big] \\
&\quad + \mathrm{Tr}\Big[U_1^{(\mathrm{ch})\dagger}(T; \cdot) \Big(U_0^{(\mathrm{ch})}(T; \tilde{\cdot}) - U_0^{(\mathrm{ch})}(T; \cdot) \Big) \rho_0 \Big],
\end{aligned}$$

where $(\tilde{\cdot})$ abbreviates $(\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$ and $(\cdot)$ abbreviates $(\lambda_{\mathrm{UV}}, \ell)$. Using $\|\mathrm{Tr}(A\rho_0)\| \le \|A\|\, \|\rho_0\|_1 = \|A\|$ and $\|U\| = 1$ for unitaries,

$$\left| \Lambda_{\mathrm{ch}}(T; \tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell}) - \Lambda_{\mathrm{ch}}(T; \lambda_{\mathrm{UV}}, \ell) \right| \;\le\; \left\| U_1^{(\mathrm{ch})}(T; \tilde{\cdot}) - U_1^{(\mathrm{ch})}(T; \cdot) \right\| + \left\| U_0^{(\mathrm{ch})}(T; \tilde{\cdot}) - U_0^{(\mathrm{ch})}(T; \cdot) \right\|.$$

Applying the bound from Proposition 7.377 to each branch and combining,

$$\left| \Lambda_{\mathrm{ch}}(T; \tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell}) - \Lambda_{\mathrm{ch}}(T; \lambda_{\mathrm{UV}}, \ell) \right| \;\le\; 2C\Big(|T| \sum_B |\varepsilon_B|\, \delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}} + \delta_{\mathrm{pipe}} \Big).$$

Within a plateau window, both $\delta\|\hat{\mathcal{O}}_B\|_{\mathcal{K}}$ and δ_{pipe} are bounded by the prescribed tolerances of Section 6.12.4. Thus the visibilities computed at $(\lambda_{\mathrm{UV}}, \ell)$ and $(\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$ differ by at most a constant multiple of the plateau tolerances, and are therefore operationally comparable across the pipeline. This holds for both ch = law and ch = state (the latter also enjoying the baseline pinning of Proposition 7.370). □

Outcome of Step 1.

Proposition 7.379 (Deliverables of QIII Step 1)**.** *After calibration:*

(i) A fully specified micro–law $\hat{H}_{\mathrm{micro}}(t; \lambda_{\mathrm{UV}}, \ell)$ satisfying admissibility (Definition 7.356) and smallness (Definition 7.355), with BRST/ST consistency (Proposition 7.358).

(ii) Calibrated law– and state–branch unitaries in the sense of eqs. (7.125) and (7.527) (presentation–class invariance by Proposition 7.365).

(iii) Initial records at the minimal coarse–graining scale $\ell_{\min}$:

$$E_{\mathrm{law}}^{(\mathrm{init})}(\ell_{\min}) := 1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell_{\min}; T^\star) > 0, \qquad \left| 1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell_{\min}; T^\star) \right| \le \varepsilon_{\mathrm{init}},$$

as in eq. (7.535), with $\varepsilon_{\mathrm{init}}$ below the plateau thresholds of Section 6.12.4.

These outputs seed Step 2 (emergence diagnostics) and Step 3 (RG irrelevance) without *re–tuning phases or instruments; their gauge/presentation independence and plateau robustness follow from Proposition 7.372.*

Proof. Assume the QIII calibration has been performed: the state channel uses identity branches (Definition 7.369 and eq. (7.125)) and the law channel is phase–calibrated at the symmetric baseline so that $\Lambda_{\mathrm{law}} = 1$ for $\varepsilon_B = 0$ (Proposition 7.367), with tags BRST–closed and commuting with projectors (cf. Section 7.1.3).

(1) Existence and consistency of the micro–law. Define the micro–law Hamiltonian as in eq. (7.522), using the *same* tags $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ that specify $\hat{H}_0$ in eq. (7.241). By admissibility (Definition 7.356) the breaking operators $\hat{\mathcal{O}}_B$ are BRST–closed with $\mathrm{gh} = 0$; by the smallness/softness hypothesis (Definition 7.355) they are $\hat{H}_0$-form–bounded with relative bound < 1. Hence $\hat{H}_{\mathrm{micro}}(t; \lambda_{\mathrm{UV}}, \ell)$ is self–adjoint on the common form domain and generates a unitary dynamics; BRST/Slavnov–Taylor consistency follows from Proposition 7.358 (and the anomaly filters of Section 7.2.8), establishing item (i).

(2) Calibrated branch unitaries and presentation–class invariance. Let $U_a^{(\mathrm{law;micro})}(T)$ be defined by eq. (7.527) and $U_a^{(\mathrm{state})}(T)$ by eq. (7.125). By Proposition 7.365, any change of presentation within a class acts by G-unitary conjugations and BRST–exact coboundaries, affecting the interferometer only via a single global phase that has been fixed at baseline; hence the calibrated branch unitaries are well defined on the presentation class, proving item (ii).

(3) Initial records at ℓ_{min}. Choose ℓ_{min} as in Remark 7.373, i.e. at the reciprocal–resolution knee satisfying Proposition 4.436 and lying in a plateau window (Section 6.12.4). Set $\rho_0 = \mathsf{P}_{\mathrm{phys}} \rho_0 \mathsf{P}_{\mathrm{phys}}$ with $\mathrm{gh}(\rho_0) = 0$. Write the law–visibility as a Hilbert–Schmidt inner product

$$\Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell_{\mathrm{min}}; T) = \left\langle U_1^{(\mathrm{law})}(T) \rho_0^{1/2},\, U_0^{(\mathrm{law})}(T) \rho_0^{1/2} \right\rangle_{\mathrm{HS}},$$

so by Cauchy–Schwarz, $\Lambda_{\mathrm{law}} \le \|U_1 \rho_0^{1/2}\|_{\mathrm{HS}} \|U_0 \rho_0^{1/2}\|_{\mathrm{HS}} = \mathrm{Tr}\, \rho_0 = 1$, with equality iff $U_1^{(\mathrm{law})}(T) = e^{i\theta} U_0^{(\mathrm{law})}(T)$ on $\mathrm{supp}\, \rho_0$. In the presence of a nontrivial global Ward source (explicit G-breaking) and after the baseline calibration, the two branches are *not* related by a pure phase for some $T > 0$ (cf. the diagnostic hygiene in Lemma 7.374); by continuity in T, there exists $T^\star > 0$ with

$$E_{\mathrm{law}}^{(\mathrm{init})}(\ell_{\mathrm{min}}) := 1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell_{\mathrm{min}}; T^\star) > 0.$$

For the state channel, Proposition 7.370 gives $\Lambda_{\mathrm{state}} = 1$ in the symmetric limit; gauge/presentation independence and plateau robustness imply that at ℓ_{min},

$$\left| 1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell_{\mathrm{min}}; T^\star) \right| \le \varepsilon_{\mathrm{init}},$$

with $\varepsilon_{\mathrm{init}}$ below the plateau thresholds of Section 6.12.4. This establishes item (iii).

Finally, the gauge/presentation independence and plateau robustness of all these deliverables follow from Proposition 7.372 (and the comparability result of Corollary 7.378 when crossing pipeline steps). No re–tuning of phases or instruments is required after calibration, completing the proof. □

7.8.2 Tracking Law Emergence and Defining a Robust IR Slope

Objective. We quantify the *healing of the law* by measuring a *robust* logarithmic-scale slope of the law-visibility Λ_{law} (defined in eq. (7.122)) along coarse–graining length ℓ (with $v := \ln \ell$). The construction below is invariant under $\ell \mapsto a\,\ell$, is stable to measurement ripples via a light low–pass, and is compatible with the acceptance/plateau pipeline of Sections 6.12.4 and 7.3.9. RG consistency of trends is interpreted in the Wilsonian sense [389]; gauge/BRST safety is ensured by the on–shell posture of eq. (7.16) and the Nielsen protection of physical poles/residues [117, 243, 14, 82].

Low–pass (mollified) visibility.

Definition 7.380 (Low–pass operator and mollified visibilities)**.** Let $v = \ln \ell$. The low–pass operator LP_τ with bandwidth $\tau > 0$ acts by convolution

$$\boxed{\big(\mathsf{LP}_\tau f\big)(v) := \int_{\mathbb{R}} \mathrm{d}v'\, W_\tau(v - v')\, f(v'), \qquad W_\tau(v) = \tfrac{1}{\tau}\, W\big(\tfrac{v}{\tau}\big)\,.} \tag{7.537}$$

The kernel $W \in C_c^\infty(\mathbb{R})$ is even and normalised with vanishing first moment,

$$\boxed{\int_{\mathbb{R}} \mathrm{d}v\; W(v) = 1, \qquad \int_{\mathbb{R}} \mathrm{d}v\; v\, W(v) = 0, \qquad W(v) = W(-v).} \tag{7.538}$$

These conditions ensure that LP_τ preserves constants and linear trends in v while suppressing high–frequency ripples.

For any visibility meter $f(v) \in \{\Lambda_{\mathrm{law}}(v),\, \Lambda_{\mathrm{state}}(v)\}$, define its *mollified* (low–pass) version by

$$f^{\langle\tau\rangle}(v) := (\mathsf{LP}_\tau f)(v) = \int_{\mathbb{R}} \mathrm{d}v'\, W_\tau(v - v')\, f(v').$$

We abbreviate $\Lambda_{\mathrm{law}}^{\langle\tau\rangle} := \mathsf{LP}_\tau \Lambda_{\mathrm{law}}$ and $\Lambda_{\mathrm{state}}^{\langle\tau\rangle} := \mathsf{LP}_\tau \Lambda_{\mathrm{state}}$.

Clarification. The low–pass kernel W acts on the log–scale variable $v = \ln \ell$ and is independent of the spacetime IR window $K_{\mathrm{IR}}^{(\ell)}$ used in the joint coarse-graining of fields and correlators (see eqs. (6.364) and (6.366)). The former is a 1-D mollifier in scale; the latter is a geometric kernel on $\mathcal{X}_q$.

Intuition. Because W is even, normalized, and has vanishing first moment (7.538), LP_τ smooths ripples while exactly preserving constants and linear trends in v. This makes it ideal for plateau diagnostics that rely on first–derivative flatness.

Lemma 7.381 (Basic properties of LP_τ)**.** *Let $W \in C_c^\infty(\mathbb{R})$ satisfy eq. (7.538), and set $W_\tau(v) = \tau^{-1} W(v/\tau)$. With $\mathsf{LP}_\tau f := W_\tau * f$ as in Definition 7.380, the following hold:*

(i) Linearity and boundedness.
For each $1 \le p \le \infty$, $\mathsf{LP}_\tau : L^p(\mathbb{R}) \to L^p(\mathbb{R})$ is bounded with

$$\|\mathsf{LP}_\tau\|_{L^p \to L^p} \le \|W_\tau\|_{L^1} = \|W\|_{L^1}.$$

If $W \ge 0$ and $\int_{\mathbb{R}} W = 1$ (the zeroth-moment condition in eq. (7.538)), then $\|\mathsf{LP}_\tau\|_{L^p \to L^p} = 1$.

(ii) Self–adjointness on L^2.
If W is even, then LP_τ is self–adjoint on $L^2(\mathbb{R})$.

(iii) Reproduction of affine functions.
For all $a, b \in \mathbb{R}$,

$$\mathsf{LP}_\tau(a + b\,v) \;=\; a + b\,v.$$

(iv) Commutation with translations/derivatives.
If $f \in W^{1,p}_{\mathrm{loc}}(\mathbb{R})$, then

$$\frac{\mathrm{d}}{\mathrm{d}v}\Big(\mathsf{LP}_\tau f\Big) = \mathsf{LP}_\tau(f'), \qquad \mathsf{LP}_\tau\Big(f(\cdot + v_0)\Big) = \Big(\mathsf{LP}_\tau f\Big)(\cdot + v_0).$$

(v) Approximation identity.
If $f \in C^0(\mathbb{R})$ is uniformly continuous, then $\|\mathsf{LP}_\tau f - f\|_\infty \to 0$ as $\tau \to 0^+$.

Proof. **(1) Linearity and boundedness.** Linearity is immediate from the integral definition in Definition 7.380. For $1 \le p \le \infty$, Young's convolution inequality gives

$$\|W_\tau * f\|_{L^p} \le \|W_\tau\|_{L^1}\,\|f\|_{L^p},$$

so $\|\mathsf{LP}_\tau\|_{L^p \to L^p} \le \|W_\tau\|_{L^1}$. By the scaling $W_\tau(v) = \tau^{-1} W(v/\tau)$ we have $\|W_\tau\|_{L^1} = \|W\|_{L^1}$. If, in addition, $W \ge 0$ and $\int W = 1$ (zeroth moment in eq. (7.538)), then $\|W\|_{L^1} = 1$, hence $\|\mathsf{LP}_\tau\| \le 1$. Sharpness $\|\mathsf{LP}_\tau\| = 1$ follows by testing on approximate constants (e.g. normalized indicators of large intervals when $1 \le p < \infty$, or $f \equiv 1$ for $p = \infty$), using compact support of W to see the ratio $\|W_\tau * f\|_p / \|f\|_p \to 1$ as the interval length $\to \infty$ (standard convolution theory; see, e.g., [55, 446, 253, 433]).

(2) Self–adjointness on L^2. If W is even, then $W_\tau(v - v') = W_\tau(v' - v)$. For $f, g \in L^2$,

$$\langle \mathsf{LP}_\tau f, g\rangle = \int_{\mathbb{R}}\!\int_{\mathbb{R}} W_\tau(v - v')\, f(v')\, \overline{g(v)}\,\mathrm{d}v'\mathrm{d}v = \int_{\mathbb{R}}\!\int_{\mathbb{R}} W_\tau(v' - v)\, f(v')\, \overline{g(v)}\,\mathrm{d}v\mathrm{d}v' = \langle f, \mathsf{LP}_\tau g\rangle,$$

so LP_τ is self–adjoint. (Equivalently, $\widehat{W_\tau}$ is real and nonnegative, hence the Fourier multiplier is self–adjoint; cf. [55, 446].)

(3) Reproduction of affine functions. Let $f(v) = a + bv$. Using $\int W_\tau = 1$ and the vanishing first moment $\int v\, W(v)\,\mathrm{d}v = 0$ from eq. (7.538) (which is equivalent to $\int (v - v') W_\tau(v - v')\,\mathrm{d}v' = 0$ for each v), we compute

$$(W_\tau * 1)(v) = \int W_\tau(v - v')\,\mathrm{d}v' = 1, \qquad (W_\tau * v)(v) = \int v'\, W_\tau(v - v')\,\mathrm{d}v' = v.$$

Hence $\mathsf{LP}_\tau(a + bv) = a + bv$.

(4) Commutation with translations and derivatives. Translation invariance is standard for convolutions:

$$\Big(\mathsf{LP}_\tau(f(\cdot + v_0))\Big)(v) = \int W_\tau(v - v')\, f(v' + v_0)\,\mathrm{d}v' = (\mathsf{LP}_\tau f)(v + v_0).$$

For derivatives, if $f \in W^{1,p}_{\mathrm{loc}}$, the distributional derivative f' is locally L^p, and $W_\tau \in L^1$ with compact support. Differentiating under the integral is justified by dominated convergence and Fubini/Tonelli (all integrands are integrable on compact sets), giving

$$\frac{\mathrm{d}}{\mathrm{d}v}(W_\tau * f)(v) = \int \frac{\partial}{\partial v} W_\tau(v - v')\, f(v')\,\mathrm{d}v' = \int W_\tau(v - v')\, f'(v')\,\mathrm{d}v' = (W_\tau * f')(v).$$

A classical reference for these interchange rules is, e.g., [55, Chs. 1–2] or [446, §1.3].

(5) Approximation identity. The family $\{W_\tau\}_{\tau>0}$ is an approximate identity: $W_\tau \geq 0$, $\int W_\tau = 1$, and $\operatorname{supp} W_\tau \to \{0\}$ as $\tau \to 0^+$. If $f \in C^0(\mathbb{R})$ is uniformly continuous, then

$$\|W_\tau * f - f\|_\infty = \sup_v \left| \int W_\tau(z)\big(f(v-z) - f(v)\big)\,\mathrm{d}z \right| \leq \int W_\tau(z)\,\omega_f(|z|)\,\mathrm{d}z \xrightarrow[\tau\to 0^+]{} 0,$$

where ω_f is the modulus of continuity of f. This is the standard uniform convergence of mollifier averages; see, e.g., [446, §1.3] or [55, Ch. 1]. (Quantitative rates in terms of ω_f follow immediately.) □

Proposition 7.382 (Second–order accuracy and derivative neutrality)**.** *If $f \in C^2(\mathbb{R})$ and $m_2(W) := \int_{\mathbb{R}} v^2 W(v)\,\mathrm{d}v < \infty$, then for each v*

$$\big(\mathsf{LP}_\tau f\big)(v) = f(v) + \frac{\tau^2 m_2(W)}{2}\, f''(v) + \mathcal{O}(\tau^4),$$
$$\frac{\mathrm{d}}{\mathrm{d}v}\big(\mathsf{LP}_\tau f\big)(v) = f'(v) + \frac{\tau^2 m_2(W)}{2}\, f^{(3)}(v) + \mathcal{O}(\tau^4).$$

In particular, constants and linear trends are preserved exactly, and the first derivative is unbiased up to $\mathcal{O}(\tau^2)$.

Proof. Write the convolution with the change of variables $z = v - v' = \tau u$:

$$(\mathsf{LP}_\tau f)(v) = \int_{\mathbb{R}} W_\tau(z)\, f(v-z)\,\mathrm{d}z = \int_{\mathbb{R}} W(u)\, f(v-\tau u)\,\mathrm{d}u,$$

using $W_\tau(z) = \tau^{-1} W(z/\tau)$ from Definition 7.380. Since $f \in C^2$ and $W \in C_c^\infty$, Taylor's theorem with integral remainder at order 2 gives

$$f(v-\tau u) = f(v) - \tau u f'(v) + \tfrac{\tau^2 u^2}{2} f''(v) + R_4(v,u;\tau),$$

where, for some $\theta \in (0,1)$ depending on v, u, τ,

$$R_4(v,u;\tau) = \frac{\tau^3 u^3}{3!}\, f^{(3)}(v - \theta\tau u).$$

(We will refine this remainder below to expose the $\mathcal{O}(\tau^4)$ behavior using odd-moment cancellations.)

Zeroth and first moments; preservation of affine trends. Integrating termwise and using the moment conditions from eq. (7.538) (namely $\int W = 1$ and $\int u\,W(u)\,\mathrm{d}u = 0$) yields

$$(\mathsf{LP}_\tau f)(v) = f(v) + \frac{\tau^2}{2}\, f''(v) \int u^2 W(u)\,\mathrm{d}u \;+\; \int W(u)\, R_4(v,u;\tau)\,\mathrm{d}u.$$

Thus the constant and linear parts are reproduced exactly (see also Lemma 7.381(3)), and the explicit quadratic bias is $\frac{\tau^2 m_2(W)}{2} f''(v)$.

Odd–moment cancellation and $\mathcal{O}(\tau^4)$ remainder. To sharpen the remainder, expand $f^{(3)}(v - \theta\tau u) = f^{(3)}(v) + \mathcal{O}(\tau|u|)$ as $\tau \to 0^+$ (uniformly for u in $\operatorname{supp} W$), since $f^{(3)}$ is continuous wherever the second display is asserted. Plugging into R_4 and integrating:

$$\int W(u)\, R_4(v,u;\tau)\,\mathrm{d}u = \frac{\tau^3}{3!}\, f^{(3)}(v) \int u^3 W(u)\,\mathrm{d}u \;+\; \mathcal{O}\Big(\tau^4 \int |u|^4 |W(u)|\,\mathrm{d}u\Big).$$

The odd moment vanishes (either by the explicit $\int u^3 W = 0$ in eq. (7.538) or by evenness of W, used elsewhere for LP_τ in Lemma 7.381(2)), hence the leading term is zero and the remainder is $\mathcal{O}(\tau^4)$. Since $W \in C_c^\infty$, $\int |u|^4 |W(u)|\,\mathrm{d}u < \infty$, so the constant in $\mathcal{O}(\tau^4)$ depends on $\|f^{(3)}\|_{C^0(K_v)}$ on a small neighborhood K_v of v and the fourth moment of W (hidden in the big-O).

Altogether,

$$(\mathsf{LP}_\tau f)(v) = f(v) + \frac{\tau^2 m_2(W)}{2}\, f''(v) + \mathcal{O}(\tau^4).$$

Derivative neutrality. By Lemma 7.381(4), $\frac{\mathrm{d}}{\mathrm{d}v}(\mathsf{LP}_\tau f) = \mathsf{LP}_\tau(f')$. Apply the previous expansion to f' (which is C^2 wherever the second display is asserted), obtaining

$$\frac{\mathrm{d}}{\mathrm{d}v}\Big(\mathsf{LP}_\tau f\Big)(v) = (\mathsf{LP}_\tau f')(v) = f'(v) + \frac{\tau^2 m_2(W)}{2}\, f^{(3)}(v) + \mathcal{O}(\tau^4).$$

"In particular" clause. Setting $f(v) = a + bv$ gives $(\mathsf{LP}_\tau f)(v) = a + bv$ exactly by Lemma 7.381(3). The derivative statement shows that the slope estimator is unbiased up to $\mathcal{O}(\tau^2)$.

Remarks on regularity and references. We used the local boundedness/continuity of $f^{(3)}$ to promote the Taylor remainder to an $\mathcal{O}(\tau^4)$ term via odd–moment cancellation; with only $f \in C^2$, one still gets the displayed τ^2 bias and a smaller-order remainder $o(\tau^2)$ from approximate-identity arguments (cf. Lemma 7.381(5)). Standard convolution/Taylor moment expansions can be found in [55, Chs. 1–2] and [446, §1.3]. □

Proposition 7.383 (Compatibility with spectral/trace constructions)**.** *Let* $f(v) = \Lambda_{\mathrm{law}}(v) = \mathrm{Tr}\Big[U_1^{(\mathrm{law})\dagger}(T; e^v)\, U_0^{(\mathrm{law})}(T; e^v)\, \rho_0\Big]$ *with* $\rho_0 = \mathsf{P}_{\mathrm{phys}} \rho_0 \mathsf{P}_{\mathrm{phys}}$, $\mathrm{gh}(\rho_0) = 0$. *Assume the Kato continuity of the branch dynamics in* $v = \ln \ell$ *from Proposition 7.377. Then the Bochner integral*

$$\mathcal{U}(v) := \int_{\mathbb{R}} \mathrm{d}v'\; W_\tau(v - v')\, U_1^{(\mathrm{law})\dagger}(T; e^{v'})\, U_0^{(\mathrm{law})}(T; e^{v'})$$

exists in operator norm with $\|\mathcal{U}(v)\| \le \|W\|_1$, *and*

$$(\mathsf{LP}_\tau f)(v) = \mathrm{Tr}\Big[\mathcal{U}(v)\, \rho_0\Big].$$

Consequently, smoothing commutes with the trace/spectral construction of Λ_{law}, *and the same holds for* Λ_{state}.

Proof. Step 1: Operator–valued integrand and norm–continuity. By Proposition 7.377 the maps $v \mapsto U_a^{(\mathrm{law})}(T; e^v)$ are norm–continuous (Kato stability of the propagators). Therefore

$$A(v') \;:=\; U_1^{(\mathrm{law})\dagger}(T; e^{v'})\, U_0^{(\mathrm{law})}(T; e^{v'}) \in \mathcal{B}(\mathcal{H}_{\mathrm{em}})$$

is norm–continuous in v' and uniformly bounded by 1 because each factor is unitary. Hence $A(\cdot)$ is (strongly) measurable and $\|A(v')\| \le 1$ for all v' [115, Chap. IV].

Step 2: Existence and bound of the Bochner integral. With $W_\tau \in L^1(\mathbb{R})$ (see Definition 7.380 and eq. (7.538)) and $\|A(v')\| \le 1$,

$$\int_{\mathbb{R}} \| W_\tau(v - v')\, A(v') \|\, \mathrm{d}v' \;\le\; \int_{\mathbb{R}} |W_\tau(v - v')|\, \mathrm{d}v' \;=\; \|W_\tau\|_1 = \|W\|_1 < \infty,$$

so the Bochner integral

$$\mathcal{U}(v) \;:=\; \int_{\mathbb{R}} W_\tau(v-v')\,A(v')\,\mathrm{d}v'$$

exists in operator norm and satisfies $\|\mathcal{U}(v)\| \le \|W\|_1$. (Standard Bochner integration in Banach spaces; see, e.g., [433, §2.6].)

Step 3: Exchange of trace and Bochner integral. Let $\mathcal{S}_1(\mathcal{H}_{\mathrm{em}})$ denote the trace class. Define the bounded linear functional

$$\mathsf{Tr}_{\rho_0} : \mathcal{B}(\mathcal{H}_{\mathrm{em}}) \to \mathbb{C}, \qquad \mathsf{Tr}_{\rho_0}(B) := \mathrm{Tr}(B\,\rho_0).$$

By duality $\mathcal{B}(\mathcal{H}) = \mathcal{S}_1(\mathcal{H})^*$ (see [253, Thm. VI.26]), $|\mathsf{Tr}_{\rho_0}(B)| \le \|B\|\,\|\rho_0\|_{\mathcal{S}_1}$. Since $A(\cdot)$ is Bochner–integrable and Tr_{ρ_0} is continuous linear, we may pull Tr_{ρ_0} through the integral:

$$\mathsf{Tr}_{\rho_0}\Big(\int W_\tau(v-v')\,A(v')\,\mathrm{d}v'\Big) = \int W_\tau(v-v')\,\mathsf{Tr}_{\rho_0}\Big(A(v')\Big)\,\mathrm{d}v'.$$

Therefore,

$$\mathrm{Tr}\Big[\mathcal{U}(v)\,\rho_0\Big] = \int_{\mathbb{R}} W_\tau(v-v')\;\mathrm{Tr}\Big[A(v')\,\rho_0\Big]\,\mathrm{d}v' = (\mathsf{LP}_\tau f)(v),$$

which is precisely the desired identity (equivalently, Fubini/Tonelli for Bochner integrals paired with a bounded functional). *Notation.* We use Tr for the operator trace and $\mathsf{Tr}_{\rho_0}(B) := \mathrm{Tr}(B\rho_0)$ for the trace–pairing functional.

Step 4: "Spectral/trace" compatibility and the state channel. All steps above use only (i) Kato norm–continuity of the propagators, (ii) L^1–integrability of W_τ, and (iii) the trace–class pairing with $\rho_0 = \mathsf{P}_{\mathrm{phys}}\rho_0\mathsf{P}_{\mathrm{phys}}$ (cf. Section 7.1.3). Hence smoothing by LP_τ commutes with the trace construction of Λ_{law}. The same argument applies verbatim to Λ_{state} upon replacing $U_a^{(\mathrm{law})}$ by $U_a^{(\mathrm{state})}$ (and, in Quadrant II, still within the BRST–consistent reading).

This proves the proposition. □

Corollary 7.384 (Plateau preservation under low–pass)**.** *Let W have support in $[-R,R]$ and LP_τ be as in Definition 7.380. If f satisfies the plateau criterion on an interval $\mathcal{I}$ (cf. Section 6.12.4), then on the eroded window $\mathcal{I}^{-\tau R} := \{v \in \mathcal{I} : [v-\tau R, v+\tau R] \subset \mathcal{I}\}$ one has*

$$\sup_{v\in\mathcal{I}^{-\tau R}} \big|(\mathsf{LP}_\tau f)'(v)\big| \;\le\; \|W\|_1 \sup_{v\in\mathcal{I}} |f'(v)|.$$

In particular, for $f = \Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$ the derivative remains within the same plateau tolerance on $\mathcal{I}^{-\tau R}$; i.e. low–pass smoothing suppresses ripples without spoiling first–derivative flatness.

Proof. Step 1: Derivative commutation. By Lemma 7.381(4),

$$(\mathsf{LP}_\tau f)' \;=\; \mathsf{LP}_\tau(f') \;=\; W_\tau * f'.$$

Step 2: Young's inequality and the L^∞ bound. By Lemma 7.381(1) (Young's inequality) and $\|W_\tau\|_1 = \|W\|_1$ (Definition 7.380),

$$\|(\mathsf{LP}_\tau f)'\|_{L^\infty} = \|W_\tau * f'\|_{L^\infty} \le \|W_\tau\|_{L^1}\,\|f'\|_{L^\infty} = \|W\|_{L^1}\,\|f'\|_{L^\infty}.$$

Step 3: Restriction to the eroded plateau window. Since $\operatorname{supp} W \subset [-R,R]$, we have $\operatorname{supp} W_\tau \subset [-\tau R, \tau R]$. Thus for any $v \in \mathcal{I}^{-\tau R}$ the integrand in $(W_\tau * f')(v)$ samples f' only on $\mathcal{I}$. Hence

$$\sup_{v\in\mathcal{I}^{-\tau R}} \bigl|(\mathsf{LP}_\tau f)'(v)\bigr| = \sup_{v\in\mathcal{I}^{-\tau R}} \left| \int_{\mathbb{R}} W_\tau(v-v')\, f'(v')\,\mathrm{d}v' \right| \le \|W\|_1 \sup_{v'\in\mathcal{I}} |f'(v')|.$$

Step 4: Application to Λ_{law} and Λ_{state}. By the plateau criterion (cf. Section 6.12.4 and the acceptance region),

$$\sup_{v\in\mathcal{I}} |\Lambda'_{\mathrm{law}}(v)| \le \varepsilon_{\mathrm{grad}}, \qquad \sup_{v\in\mathcal{I}} |\Lambda'_{\mathrm{state}}(v)| \le \varepsilon_{\mathrm{grad}}.$$

Combining with Step 3 yields

$$\sup_{v\in\mathcal{I}^{-\tau R}} \bigl|(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})'(v)\bigr| \le \|W\|_1\,\varepsilon_{\mathrm{grad}}, \qquad \sup_{v\in\mathcal{I}^{-\tau R}} \bigl|(\mathsf{LP}_\tau\Lambda_{\mathrm{state}})'(v)\bigr| \le \|W\|_1\,\varepsilon_{\mathrm{grad}}.$$

In particular, if $W \ge 0$ and $\int W = 1$, then $\|W\|_1 = 1$ and the derivative bounds on $\mathcal{I}^{-\tau R}$ equal $\varepsilon_{\mathrm{grad}}$. □

Robust IR slope (definition).

Definition 7.385 (Robust IR law slope)**.** Let $v = \ln \ell$ and let LP_τ be the low–pass operator of Definition 7.380, defined by (7.537) with kernel moments (7.538). For the law–channel visibility $\Lambda_{\mathrm{law}}(v)$ (suppressing any fixed T), define the *robust IR law slope* by

$$\boxed{\varsigma^{(\tau)}_{\mathrm{law}}(\ell) := \frac{\partial}{\partial \ln \ell}\Bigl[\bigl(\mathsf{LP}_\tau\,\Lambda_{\mathrm{law}}\bigr)(\ell)\Bigr] = \frac{\mathrm{d}}{\mathrm{d}v}\Bigl[\bigl(\mathsf{LP}_\tau\,\Lambda_{\mathrm{law}}\bigr)(v)\Bigr].} \tag{7.539}$$

Intuition. LP_τ removes high–frequency ripples in $v = \ln \ell$ while preserving constants and linear trends (Lemma 7.381). Differentiating $\mathsf{LP}_\tau\Lambda_{\mathrm{law}}$ thus yields a stable estimator of the IR slope that is insensitive to small regulator wiggles but responsive to genuine drift off a plateau.

Lemma 7.386 (Well-posedness and convolution form)**.** *If Λ_{law} is locally absolutely continuous in v (which holds under the Kato continuity of Proposition 7.377 together with the trace exchange of Proposition 7.383), then*

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) = \bigl(\mathsf{LP}_\tau\,\Lambda'_{\mathrm{law}}\bigr)(v) = \int_{\mathbb{R}} W_\tau(v-v')\,\Lambda'_{\mathrm{law}}(v')\,\mathrm{d}v'. \tag{7.540}$$

Moreover, $\|\varsigma^{(\tau)}_{\mathrm{law}}\|_\infty \le \|W\|_1\,\|\Lambda'_{\mathrm{law}}\|_\infty$.

Proof. Preliminaries. Recall $\mathsf{LP}_\tau f := W_\tau * f$ from Definition 7.380 and the robust slope definition $\varsigma^{(\tau)}_{\mathrm{law}} := \frac{\mathrm{d}}{\mathrm{d}v}(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})$ from Definition 7.385. Assume $v \mapsto \Lambda_{\mathrm{law}}(v)$ is locally absolutely continuous. Then $\Lambda_{\mathrm{law}} \in W^{1,1}_{\mathrm{loc}}(\mathbb{R})$ and $\Lambda'_{\mathrm{law}} \in L^1_{\mathrm{loc}}(\mathbb{R})$.

Step 1: Differentiation commutes with LP_τ. By Lemma 7.381(4), if $f \in W^{1,p}_{\mathrm{loc}}(\mathbb{R})$ for some $1 \le p \le \infty$, then

$$\frac{\mathrm{d}}{\mathrm{d}v}\big(\mathsf{LP}_\tau f\big) = \mathsf{LP}_\tau(f') \quad \text{a.e. on } \mathbb{R}.$$

Applying this with $f = \Lambda_{\mathrm{law}}$ gives

$$\frac{\mathrm{d}}{\mathrm{d}v}\big(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}\big)(v) = \big(\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}\big)(v),$$

which is the integral representation in (7.540).

$$\frac{\mathrm{d}}{\mathrm{d}v}\big(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}\big)(v) = \big(\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}\big)(v).$$

By definition of $\varsigma^{(\tau)}_{\mathrm{law}}$ (see Definition 7.385), the left-hand side equals $\varsigma^{(\tau)}_{\mathrm{law}}(v)$.

Step 2: Convolution (integral) form. Using the definition of LP_τ and Fubini/Tonelli (here justified because $W_\tau \in L^1$ and $\Lambda'_{\mathrm{law}} \in L^1_{\mathrm{loc}}$ while W has compact support),

$$\big(\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}\big)(v) = (W_\tau * \Lambda'_{\mathrm{law}})(v) = \int_{\mathbb{R}} W_\tau(v - v')\, \Lambda'_{\mathrm{law}}(v')\, \mathrm{d}v',$$

which is (7.540). Equivalently, one can obtain the same identity by differentiating under the integral in the representation $(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v) = \int W_\tau(v - v')\Lambda_{\mathrm{law}}(v')\,\mathrm{d}v'$ (valid by Proposition 7.383) and using dominated convergence on compact v-intervals.

Step 3: Sup–norm bound. Young's convolution inequality (see Lemma 7.381(1)) gives, for any essentially bounded g, $\|W_\tau * g\|_{L^\infty} \le \|W_\tau\|_{L^1}\, \|g\|_{L^\infty}$. Applying this with $g = \Lambda'_{\mathrm{law}}$ yields

$$\|\varsigma^{(\tau)}_{\mathrm{law}}\|_\infty = \|\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}\|_\infty \le \|W_\tau\|_1\, \|\Lambda'_{\mathrm{law}}\|_\infty = \|W\|_1\, \|\Lambda'_{\mathrm{law}}\|_\infty,$$

using $\|W_\tau\|_1 = \|W\|_1$ from Definition 7.380.

Step 4: Well-posedness via the spectral/trace construction (context). Under Proposition 7.377, the maps $v \mapsto U^{(\mathrm{law})}_a(T; e^v)$ are norm-continuous. By Proposition 7.383, smoothing commutes with the physical trace, so $(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v) = \mathrm{Tr}[\mathcal{U}(v)\rho_0]$ for a Bochner-integrable $\mathcal{U}(v)$. These two ingredients ensure the local absolute continuity of Λ_{law} invoked at the start (and thus justify applying Lemma 7.381(4)).

This proves the lemma. □

Proposition 7.387 (Scale invariance and dimensionless character)**.** *Under rescaling* $\ell \mapsto a\,\ell$ *(i.e.* $v \mapsto v + \ln a$*), one has*

$$\boxed{\Lambda_{\mathrm{law}}(v) \;\mapsto\; \Lambda_{\mathrm{law}}(v + \ln a) \quad\Longrightarrow\quad \varsigma^{(\tau)}_{\mathrm{law}}(v) \;\mapsto\; \varsigma^{(\tau)}_{\mathrm{law}}(v + \ln a),} \tag{7.541}$$

hence $\varsigma^{(\tau)}_{\mathrm{law}}$ *is dimensionless.*

Proof. Setup and notation. Let $c := \ln a$ and write the translation operator T_c by $(T_c f)(v) := f(v + c)$. Recall $\mathsf{LP}_\tau f = W_\tau * f$ (Definition 7.380) and the robust slope $\varsigma^{(\tau)}_{\mathrm{law}} = \frac{\mathrm{d}}{\mathrm{d}v}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})$ (Definition 7.385).

Step 1: Low–pass commutes with translations. For any f,

$$(\mathsf{LP}_\tau T_c f)(v) = \int_{\mathbb{R}} W_\tau(v - v')\, f(v' + c)\, \mathrm{d}v' = \int_{\mathbb{R}} W_\tau\big(v - (u + c)\big)\, f(u)\, \mathrm{d}u = (T_c \mathsf{LP}_\tau f)(v),$$

using the change of variables $u = v' - c$. This is $\mathsf{LP}_\tau T_c = T_c \mathsf{LP}_\tau$, i.e. the translation covariance in Lemma 7.381(4).

Step 2: Derivatives commute with translations. For any differentiable g, $\frac{\mathrm{d}}{\mathrm{d}v}(T_c g) = T_c\big(\frac{\mathrm{d}}{\mathrm{d}v} g\big)$, since constant shifts of the argument commute with differentiation.

Step 3: Covariance of $\varsigma^{(\tau)}_{\mathrm{law}}$. Under $\ell \mapsto a\ell$ we have $\Lambda_{\mathrm{law}} \mapsto T_c \Lambda_{\mathrm{law}}$. Define the rescaled slope by

$$\varsigma^{(\tau)}_{\mathrm{law},a}(v) := \frac{\mathrm{d}}{\mathrm{d}v}\Big(\mathsf{LP}_\tau(T_c \Lambda_{\mathrm{law}})\Big)(v).$$

Using Steps 1–2,

$$\varsigma^{(\tau)}_{\mathrm{law},a}(v) = \frac{\mathrm{d}}{\mathrm{d}v}\Big(T_c \mathsf{LP}_\tau \Lambda_{\mathrm{law}}\Big)(v) = T_c\left(\frac{\mathrm{d}}{\mathrm{d}v} \mathsf{LP}_\tau \Lambda_{\mathrm{law}}\right)(v) = (T_c\, \varsigma^{(\tau)}_{\mathrm{law}})(v) = \varsigma^{(\tau)}_{\mathrm{law}}(v + c).$$

Thus (7.541) holds.

Step 4: Dimensionless character. The coordinate $v = \ln \ell$ is dimensionless, so $\frac{\mathrm{d}}{\mathrm{d}v}$ is dimensionless. The kernel W_τ is normalized with $\int W_\tau = 1$ and lives in the dimensionless v-domain, and Λ_{law} is a (dimensionless) visibility. Hence $\varsigma^{(\tau)}_{\mathrm{law}} = \frac{\mathrm{d}}{\mathrm{d}v}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})$ is itself dimensionless. Equivalently, writing $\frac{\mathrm{d}}{\mathrm{d}v} = \ell \frac{\mathrm{d}}{\mathrm{d}\ell}$ shows that under $\ell \mapsto a\ell$ the factor of ℓ compensates the scale of $\frac{\mathrm{d}}{\mathrm{d}\ell}$, leaving a pure, unitless quantity; Step 3 then asserts it transforms by translation $v \mapsto v + \ln a$, as claimed. □

Remark 7.388 (Convolution form makes the scale covariance immediate)**.** Let T_c denote translation by $c \in \mathbb{R}$, $(T_c f)(v) := f(v + c)$, and set $c = \ln a$ for the rescaling $\ell \mapsto a\ell$ (i.e. $v \mapsto v + \ln a$). By Lemma 7.386, $\varsigma^{(\tau)}_{\mathrm{law}} = W_\tau * \Lambda'_{\mathrm{law}}$. Then

$$\varsigma^{(\tau)}_{\mathrm{law},a} := W_\tau * (T_c \Lambda_{\mathrm{law}})' = W_\tau * T_c(\Lambda'_{\mathrm{law}}) = T_c\Big(W_\tau * \Lambda'_{\mathrm{law}}\Big) = T_c\, \varsigma^{(\tau)}_{\mathrm{law}},$$

where we used $(T_c \Lambda_{\mathrm{law}})' = T_c(\Lambda'_{\mathrm{law}})$ and the translation–covariance of convolution $W_\tau * T_c = T_c * W_\tau$ (cf. Lemma 7.381(4)). Equivalently,

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) \;\mapsto\; \varsigma^{(\tau)}_{\mathrm{law}}(v + \ln a),$$

which is precisely the covariance stated in Proposition 7.387. No evenness or higher moment of W is required for this covariance—only $W_\tau \in L^1$ and translation invariance of convolution.

Proposition 7.389 (Plateau neutrality and accuracy)**.** *If Λ_{law} is computed within a plateau window (Section 6.12.4), then*

$$\sup_{v \in \mathit{window}} \big|\varsigma^{(\tau)}_{\mathrm{law}}(v)\big| \le \|W\|_1 \sup_{v \in \mathit{window}} |\Lambda'_{\mathrm{law}}(v)|,$$

so $\varsigma^{(\tau)}_{\mathrm{law}}(v) = 0$ up to the same plateau tolerances (Corollary 7.384). If, in addition, $\Lambda_{\mathrm{law}} \in C^3$ in a neighborhood of v and the kernel satisfies the moment conditions of eq. (7.538) (in particular $\int W = 1$, $\int u\, W(u)\, du = 0$, and $\int u^3 W(u)\, du = 0$) with $m_2(W) < \infty$, then

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) = \Lambda'_{\mathrm{law}}(v) + \frac{\tau^2 m_2(W)}{2}\, \Lambda^{(3)}_{\mathrm{law}}(v) + \mathcal{O}(\tau^4),$$

so the first–derivative bias is $\mathcal{O}(\tau^2)$ (by Proposition 7.382).

Proof. Step 1 (slope as low–pass of the derivative). By Lemma 7.386, $\varsigma^{(\tau)}_{\mathrm{law}} = \mathsf{LP}_\tau(\Lambda'_{\mathrm{law}}) = W_\tau * \Lambda'_{\mathrm{law}}$.

Step 2 (plateau bound). Apply Young's inequality as in Corollary 7.384 to obtain $\sup_{\mathrm{window}} |\varsigma^{(\tau)}_{\mathrm{law}}| \le \|W\|_1 \sup_{\mathrm{window}} |\Lambda'_{\mathrm{law}}|$.

Step 3 (second–order accuracy). Under the stated smoothness and moment conditions, Proposition 7.382 with $f = \Lambda_{\mathrm{law}}$ yields

$$(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v) = \Lambda_{\mathrm{law}}(v) + \frac{\tau^2 m_2(W)}{2}\,\Lambda''_{\mathrm{law}}(v) + \mathcal{O}(\tau^4).$$

Differentiate in v and use Lemma 7.381(4) to commute the derivative with LP_τ:

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) = \frac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v) = \Lambda'_{\mathrm{law}}(v) + \frac{\tau^2 m_2(W)}{2}\,\Lambda^{(3)}_{\mathrm{law}}(v) + \mathcal{O}(\tau^4).$$

This is the claimed bias. □

Proposition 7.390 (Gauge/presentation independence and pipeline comparability)**.** *With BRST–closed tags and calibrated branches, $\varsigma^{(\tau)}_{\mathrm{law}}$ is independent of gauge parameters and presentation–equivalent choices (Propositions 7.365, 7.367 and 7.372). Across a pipeline move $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde\lambda_{\mathrm{UV}}, \tilde\ell)$, one has*

$$\Big\|\varsigma^{(\tau)}_{\mathrm{law}}(\cdot; \tilde\lambda_{\mathrm{UV}}, \tilde\ell) - \varsigma^{(\tau)}_{\mathrm{law}}(\cdot; \lambda_{\mathrm{UV}}, \ell)\Big\|_\infty \;\le\; \|W\|_1 \sup_v \Big|\Lambda'_{\mathrm{law}}(v; \tilde{\cdot}) - \Lambda'_{\mathrm{law}}(v; \cdot)\Big|,$$

and the right–hand side is bounded by a constant multiple of the plateau tolerances (Corollary 7.378).

Proof. Step 1: Slope defined as a low–pass of the derivative. By Lemma 7.386 (using Definition 7.380), for every admissible parameter pair,

$$\varsigma^{(\tau)}_{\mathrm{law}}(\,\cdot\,; \lambda_{\mathrm{UV}}, \ell) = \frac{\mathrm{d}}{\mathrm{d}v}\Big(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}(\,\cdot\,; \lambda_{\mathrm{UV}}, \ell)\Big) = \mathsf{LP}_\tau\Big(\Lambda'_{\mathrm{law}}(\,\cdot\,; \lambda_{\mathrm{UV}}, \ell)\Big) = W_\tau * \Lambda'_{\mathrm{law}}(\,\cdot\,; \lambda_{\mathrm{UV}}, \ell).$$

Step 2: Gauge/presentation independence. On certified plateaus, Λ_{law} is independent of gauge parameters and presentation–equivalent choices once the calibration phase is fixed; see Proposition 7.367 (gauge/presentation independence on plateaus) and Proposition 7.372 (robustness at initialization). Since LP_τ and $\frac{\mathrm{d}}{\mathrm{d}v}$ act only on the scale variable v and commute with each other (Lemma 7.381(4)), they preserve these invariances:

$$\partial_\xi \varsigma^{(\tau)}_{\mathrm{law}} = \partial_\xi\Big(\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}\Big) = \mathsf{LP}_\tau\Big(\partial_\xi \Lambda'_{\mathrm{law}}\Big) = \mathsf{LP}_\tau\Big(\frac{\mathrm{d}}{\mathrm{d}v}(\partial_\xi \Lambda_{\mathrm{law}})\Big) = \frac{\mathrm{d}}{\mathrm{d}v}\Big(\mathsf{LP}_\tau(\partial_\xi \Lambda_{\mathrm{law}})\Big) = 0,$$

and similarly for presentation changes (replace ∂_ξ by the variation within the presentation class, which vanishes on $\mathcal{H}_{\mathrm{phys}}$ by Propositions 7.365 and 7.367). Hence $\varsigma^{(\tau)}_{\mathrm{law}}$ inherits gauge/presentation independence.

Step 3: Pipeline comparability — algebraic reduction. Fix two admissible pipeline choices $(\lambda_{\mathrm{UV}}, \ell)$ and $(\tilde\lambda_{\mathrm{UV}}, \tilde\ell)$. Using Step 1 and linearity,

$$\varsigma^{(\tau)}_{\mathrm{law}}(\cdot; \tilde{\cdot}) - \varsigma^{(\tau)}_{\mathrm{law}}(\cdot; \cdot) = W_\tau * \Big(\Lambda'_{\mathrm{law}}(\cdot; \tilde{\cdot}) - \Lambda'_{\mathrm{law}}(\cdot; \cdot)\Big).$$

Taking the L^∞ norm and applying Young's inequality (Lemma 7.381(1)) plus $\|W_\tau\|_1 = \|W\|_1$ (Definition 7.380) yields

$$\left\|\varsigma^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \varsigma^{(\tau)}_{\mathrm{law}}(\cdot;\cdot)\right\|_\infty \le \|W\|_1 \left\|\Lambda'_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \Lambda'_{\mathrm{law}}(\cdot;\cdot)\right\|_\infty,$$

which is the displayed bound (dropping the centered dot notation in the statement for readability).

Step 4: Pipeline comparability — tolerance control. By the comparability result for visibilities *and their first derivatives* along admissible pipeline moves (Corollary 7.378), there is a constant C (depending only on the certified plateau budgets and the move class) such that

$$\left\|\Lambda'_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \Lambda'_{\mathrm{law}}(\cdot;\cdot)\right\|_\infty \;\le\; C\,(\text{tolerances}),$$

where "tolerances" abbreviates the plateau budgets (e.g. $\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{curv}}$, and the regulator/oscillation budgets specified in the acceptance pipeline). Combining with Step 3 gives

$$\left\|\varsigma^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \varsigma^{(\tau)}_{\mathrm{law}}(\cdot;\cdot)\right\|_\infty \;\le\; \|W\|_1\, C\,(\text{tolerances}).$$

If $W \ge 0$ and $\int W = 1$ (zeroth moment in eq. (7.538)), then $\|W\|_1 = 1$ by Lemma 7.381(1), so the constant is just C.

This proves the proposition. □

Remark 7.391 (Eroded intersection window for pipeline moves)**.** Assume $\operatorname{supp} W \subset [-R, R]$, hence $\operatorname{supp} W_\tau \subset [-\tau R, \tau R]$. Let $\mathcal{I}$ and $\tilde{\mathcal{I}}$ be certified plateau windows for the two pipeline choices. Define the *eroded intersection window*

$$(\mathcal{I} \cap \tilde{\mathcal{I}})^{-\tau R} := \Big\{ v \in \mathcal{I} \cap \tilde{\mathcal{I}} \;:\; [\,v - \tau R,\, v + \tau R\,] \subset \mathcal{I} \cap \tilde{\mathcal{I}} \Big\}.$$

cf. the buffer convention in Corollary 7.384. Then the comparability bound of Proposition 7.390 holds verbatim with localized sup–norms:

$$\left\|\varsigma^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \varsigma^{(\tau)}_{\mathrm{law}}(\cdot;\cdot)\right\|_{L^\infty\left((\mathcal{I}\cap\tilde{\mathcal{I}})^{-\tau R}\right)} \;\le\; \|W\|_1 \left\|\Lambda'_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \Lambda'_{\mathrm{law}}(\cdot;\cdot)\right\|_{L^\infty(\mathcal{I}\cap\tilde{\mathcal{I}})}.$$

This guarantees that, for every v where the slope difference is evaluated, the convolution kernel $W_\tau(v - \cdot)$ samples the derivatives only inside certified plateau regions. If $W \ge 0$ and $\int W = 1$, then $\|W\|_1 = 1$ by Lemma 7.381, so the prefactor is unity.

IR window and acceptance threshold.

Definition 7.392 (IR window and acceptance threshold)**.** Let $v = \ln \ell$ and let LP_τ be as in Definition 7.380. Fix tolerances $\varepsilon_{\mathrm{curv}} > 0$ and a positivity threshold $\varsigma_{\min} > 0$, chosen consistently with the plateau criteria of Section 6.12.4 and the acceptance pipeline in Section 7.3.9. Define the IR window $\mathcal{I}_{\mathrm{IR}} \subset \mathbb{R}$ and the acceptance condition by

$$\boxed{\mathcal{I}_{\mathrm{IR}} := \left\{ v :\; \frac{\mathrm{d}^2}{\mathrm{d}v^2}\Big(\mathsf{LP}_\tau\, \Lambda_{\mathrm{law}}\Big)(v) \;\le\; \varepsilon_{\mathrm{curv}} \right\}, \qquad \varsigma^{(\tau)}_{\mathrm{law}}(v) \;\ge\; \varsigma_{\min} \;>\; 0 \quad \forall\, v \in \mathcal{I}_{\mathrm{IR}},} \tag{7.542}$$

where $\varsigma^{(\tau)}_{\mathrm{law}}$ is the robust slope of Definition 7.385.

Intuition. Inside $\mathcal{I}_{\mathrm{IR}}$, the low–passed visibility $(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v)$ bends only mildly (curvature bounded) and climbs with a strictly positive, ripple–insensitive slope (Lemma 7.386 and Proposition 7.389). This encodes a controlled, monotone approach toward the plateau value (unity), in line with Section 6.12.4.

Lemma 7.393 (Scale covariance)**.** *Under $\ell \mapsto a\,\ell$ (i.e. $v \mapsto v+\ln a$), the window and acceptance test translate rigidly:*

$$\mathcal{I}_{\mathrm{IR}} \;\mapsto\; \mathcal{I}_{\mathrm{IR}} + \ln a, \qquad \varsigma^{(\tau)}_{\mathrm{law}}(v) \;\mapsto\; \varsigma^{(\tau)}_{\mathrm{law}}(v + \ln a),$$

as in Proposition 7.387.

Proof. Convolution with $W_\tau(v - v')$ and differentiation commute with translations in v (Lemma 7.381(4)), which yields the stated covariance. □

Proposition 7.394 (Non–emptiness on plateaus and robustness)**.** *Assume the plateau conditions of Section 6.12.4 and Kato–type continuity for Λ_{law} (Propositions 7.377 and 7.383). Then for any $\varepsilon_{\mathrm{curv}}$ above the plateau curvature tolerance and any $\varsigma_{\min}$ below the plateau slope tolerance, there exists a (possibly disconnected) window $\mathcal{I}_{\mathrm{IR}} \neq \varnothing$ satisfying Definition 7.392. Moreover, $\mathcal{I}_{\mathrm{IR}}$ is stable under small changes of τ and under pipeline moves $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$, up to shifts bounded by the plateau tolerances.*

Proof. On a plateau, $|\Lambda'_{\mathrm{law}}(v)|$ and $|\Lambda''_{\mathrm{law}}(v)|$ are uniformly bounded by the tolerance. By Proposition 7.382, smoothing preserves constants/linear trends and perturbs derivatives by $\mathcal{O}(\tau^2)$, hence $(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})''$ and $\varsigma^{(\tau)}_{\mathrm{law}}$ inherit the same bounds for sufficiently small (but fixed) τ, giving non–emptiness. Pipeline comparability of Λ_{law} and its derivatives follows from Corollary 7.378 and Proposition 7.390, implying stability of the inequalities that define $\mathcal{I}_{\mathrm{IR}}$. □

Lemma 7.395 (Law–deficit decay on the window)**.** *Let $D(v) := 1 - (\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v) \in [0,1]$. If $v \in \mathcal{I}_{\mathrm{IR}}$, then $D'(v) = -\varsigma^{(\tau)}_{\mathrm{law}}(v) \le -\varsigma_{\min}$. Hence for any $v_1 \ge v_0$ in the same connected component of $\mathcal{I}_{\mathrm{IR}}$,*

$$D(v_1) \;\le\; \max\Big\{\, D(v_0) - \varsigma_{\min}(v_1 - v_0),\; 0 \,\Big\}.$$

Proof. Set $D(v) := 1 - (\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v)$. By definition of $\varsigma^{(\tau)}_{\mathrm{law}}$ (cf. Definition 7.385), on $\mathcal{I}_{\mathrm{IR}}$ we have

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) = \Big(\mathsf{LP}_\tau\Lambda_{\mathrm{law}}\Big)'(v) \ge \varsigma_{\min}.$$

Hence $D'(v) = -\varsigma^{(\tau)}_{\mathrm{law}}(v) \le -\varsigma_{\min}$. Integrating from v_0 to v_1 yields

$$D(v_1) - D(v_0) = \int_{v_0}^{v_1} D'(v)\,\mathrm{d}v \le -\,\varsigma_{\min}\,(v_1 - v_0),$$

i.e.

$$D(v_1) \le \max\Big\{\, D(v_0) - \varsigma_{\min}(v_1 - v_0),\; 0 \,\Big\}.$$

□

Corollary 7.396 (Hitting–length criterion)**.** *Fix v_0 in a connected component of $\mathcal{I}_{\mathrm{IR}}$ and let $L_{\mathrm{hit}} := D(v_0)/\varsigma_{\min}$. If the component length L to the right of v_0 satisfies $L \geq L_{\mathrm{hit}}$, then $D(v) = 0$ for some $v \in [v_0, v_0 + L]$; equivalently, $(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v)$ reaches 1 within the window.*

Proof. Immediate from Lemma 7.395 and the bound $D \geq 0$. □

Proposition 7.397 (Gauge/presentation independence and pipeline comparability)**.** *With BRST–closed tags and calibrated branches, the IR window $\mathcal{I}_{\mathrm{IR}}$ and the thresholds in (7.542) are independent of gauge parameters and presentation–equivalent choices (Propositions 7.365, 7.367 and 7.372). Across any admissible pipeline move $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$,*

$$\mu\Big(\mathcal{I}_{\mathrm{IR}}(\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell}) \triangle \mathcal{I}_{\mathrm{IR}}(\lambda_{\mathrm{UV}}, \ell)\Big) \;\leq\; C\Big(\varepsilon_{\mathrm{grad}} + \varepsilon_{\mathrm{curv}} + \varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}} + \varepsilon_{\mathrm{swap}}\Big),$$

for Lebesgue measure μ and a constant C depending only on $\|W\|_1$ and the local Lipschitz/crossing bounds from Section 6.12.4 (and the acceptance pipeline in Section 7.3.9).

Proof. Step 1: Gauge/presentation invariance. By Propositions 7.367 and 7.372, once the calibration phase is fixed, Λ_{law} is invariant under gauge–parameter changes and presentation–equivalent choices on certified plateaus. Since LP_τ and $\frac{d}{dv}$ act only on $v = \ln \ell$ and commute (Lemma 7.381(4)), the defining quantities

$$\varphi(v) := (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})''(v), \qquad \psi(v) := (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})'(v) = \varsigma^{(\tau)}_{\mathrm{law}}(v)$$

inherit the same invariances. Hence the curvature sublevel $\{\, \varphi \leq \varepsilon_{\mathrm{curv}} \,\}$, the slope–positivity set $\{\, \psi \geq \varsigma_{\min} \,\}$, and their intersection $\mathcal{I}_{\mathrm{IR}}$ (cf. (7.542)) are gauge/presentation independent.

Step 2: Pipeline perturbations of slope and curvature. For an admissible pipeline move, write

$$\tilde{\psi} - \psi = (\mathsf{LP}_\tau \tilde{\Lambda}'_{\mathrm{law}}) - (\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}) = \mathsf{LP}_\tau\Big(\tilde{\Lambda}'_{\mathrm{law}} - \Lambda'_{\mathrm{law}}\Big), \quad \tilde{\varphi} - \varphi = \mathsf{LP}_\tau\Big(\tilde{\Lambda}''_{\mathrm{law}} - \Lambda''_{\mathrm{law}}\Big),$$

using the commutation in Lemma 7.381(4). Young's inequality and $\|W_\tau\|_1 = \|W\|_1$ (Definition 7.380) imply

$$\|\tilde{\psi} - \psi\|_\infty \leq \|W\|_1 \, \|\tilde{\Lambda}'_{\mathrm{law}} - \Lambda'_{\mathrm{law}}\|_\infty, \qquad \|\tilde{\varphi} - \varphi\|_\infty \leq \|W\|_1 \, \|\tilde{\Lambda}''_{\mathrm{law}} - \Lambda''_{\mathrm{law}}\|_\infty.$$

By the pipeline comparability of visibilities and their derivatives (Corollary 7.378), there exist constants C_ψ, C_φ (depending only on the certified budgets) such that

$$\delta_\psi := \|\tilde{\psi} - \psi\|_\infty \leq C_\psi \|W\|_1 \Big(\varepsilon_{\mathrm{grad}} + \varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}} + \varepsilon_{\mathrm{swap}}\Big),$$

$$\delta_\varphi := \|\tilde{\varphi} - \varphi\|_\infty \leq C_\varphi \|W\|_1 \Big(\varepsilon_{\mathrm{curv}} + \varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}} + \varepsilon_{\mathrm{swap}}\Big).$$

Step 3: From function perturbations to set perturbations. Let

$$\mathcal{I}_{\mathrm{IR}} = \underbrace{\{\, \varphi \leq \varepsilon_{\mathrm{curv}} \,\}}_{=:E_{\mathrm{curv}}} \cap \underbrace{\{\, \psi \geq \varsigma_{\min} \,\}}_{=:E_{\mathrm{slope}}}, \qquad \tilde{\mathcal{I}}_{\mathrm{IR}} = \{\, \tilde{\varphi} \leq \varepsilon_{\mathrm{curv}} \,\} \cap \{\, \tilde{\psi} \geq \varsigma_{\min} \,\}.$$

A pointwise inclusion holds for any real $g, \tilde{g}$ and threshold t:

$$\{g \le t\} \triangle \{\tilde{g} \le t\} \subset \{|g - t| \le \|g - \tilde{g}\|_\infty\}, \qquad \{g \ge t\} \triangle \{\tilde{g} \ge t\} \subset \{|g - t| \le \|g - \tilde{g}\|_\infty\}.$$

Therefore,

$$\mathcal{I}_{\mathrm{IR}} \triangle \tilde{\mathcal{I}}_{\mathrm{IR}} \;\subset\; \{\,|\varphi - \varepsilon_{\mathrm{curv}}| \le \delta_\varphi\,\} \;\cup\; \{\,|\psi - \varsigma_{\min}| \le \delta_\psi\,\}.$$

Step 4: Lipschitz band–measure estimate and collection of constants. By Section 6.12.4, φ and ψ are locally Lipschitz on the operational v-range; let $L_{\mathrm{curv}}, L_{\mathrm{slope}} > 0$ be corresponding bounds, and let $\mathsf{N}(\cdot)$ denote the finite crossing-count guards from the acceptance pipeline (Section 7.3.9). On any compact interval $\mathcal{J}$,

$$\mu\Big(\{|h - t| \le \delta\} \cap \mathcal{J}\Big) \;\le\; \frac{2\,\delta}{L}\,\mathsf{N}(h; \mathcal{J}) \quad \text{for Lipschitz } h \text{ with bound } L.$$

Applying this to $h = \varphi$, $t = \varepsilon_{\mathrm{curv}}$ and $h = \psi$, $t = \varsigma_{\min}$, summing, and inserting the bounds for $\delta_\varphi, \delta_\psi$ from Step 2 yields

$$\mu\Big(\mathcal{I}_{\mathrm{IR}}(\tilde{\cdot}) \triangle \mathcal{I}_{\mathrm{IR}}(\cdot)\Big) \;\le\; C\,\Big(\varepsilon_{\mathrm{grad}} + \varepsilon_{\mathrm{curv}} + \varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}} + \varepsilon_{\mathrm{swap}}\Big),$$

with C depending only on $\|W\|_1$, $L_{\mathrm{curv}}, L_{\mathrm{slope}}$, and the crossing–count bounds $\mathsf{N}(\cdot)$. (If $W \ge 0$ and $\int W = 1$, then $\|W\|_1 = 1$ by Lemma 7.381(1).)

The proposition follows. □

Definition 7.398 (Cell-averaged stencil from the continuum kernel)**.** Let $W \in C_c^\infty(\mathbb{R})$ be even with $\operatorname{supp} W \subset [-R, R]$ and define $W_\tau(s) = \tau^{-1} W(s/\tau)$. For grid step $h > 0$ and radius $m \in \mathbb{N}$, set the weights

$$\boxed{\,w_j := \frac{\displaystyle\int_{(j-\frac{1}{2})h}^{(j+\frac{1}{2})h} W_\tau(s)\,ds}{\displaystyle\sum_{r=-m}^{m} \int_{(r-\frac{1}{2})h}^{(r+\frac{1}{2})h} W_\tau(s)\,ds}, \qquad j = -m, \dots, m.\,} \tag{7.543}$$

Intuition. These w_j are the cell-averages of W_τ over the grid cells; this ties the discrete low–pass $\mathsf{LP}_{\tau,h}$ directly to the continuum operator in eq. (7.537).

Lemma 7.399 (Moment inheritance)**.** *With w_j from Definition 7.398 one has*

$$\sum_{j=-m}^{m} w_j = 1, \qquad \sum_{j=-m}^{m} j\,w_j = 0, \qquad w_{-j} = w_j.$$

Proof. Evenness of W_τ gives $w_{-j} = w_j$. The denominator in eq. (7.543) is a common positive scalar, so $\sum_j w_j = 1$ by construction and $\sum_j j\,w_j = \sum_{j=1}^{m} j(w_j - w_{-j}) = 0$. □

Corollary 7.400 (Affine preservation of $\mathsf{LP}_{\tau,h}$)**.** *Let $(\mathsf{LP}_{\tau,h} f)_k := \sum_{j=-m}^{m} w_j f_{k-j}$ with w_j as above and $v_k = v_0 + k\,h$. If $f(v) = a + b\,v$ and $f_k = f(v_k)$, then $(\mathsf{LP}_{\tau,h} f)_k = a + b\,v_k$.*

Intuition. Lemma 7.399 is the discrete analogue of eq. (7.538); it ensures constant/linear trends in $v = \ln \ell$ pass unchanged through the discrete low–pass.

Proposition 7.401 (Discrete–continuum correspondence)**.** *Let $f \in C^2$ on a neighborhood of v_k. With w_j from Definition 7.398, one has*

$$(\mathsf{LP}_{\tau,h} f)_k \;=\; (\mathsf{LP}_\tau f)(v_k) \;+\; O(h^2) \quad \text{as } h \to 0,$$

and, if $m = m(h)$ with $mh \to \infty$, then $(\mathsf{LP}_{\tau,h} f)_k \to (\mathsf{LP}_\tau f)(v_k)$ uniformly on compact v-sets.

Proof sketch. Write $(\mathsf{LP}_{\tau,h} f)_k = \sum_j f\big(v_k - jh\big)\, \overline{W}_{\tau,h}(j)$ where $\overline{W}_{\tau,h}(j)$ are the normalized cell-averages from eq. (7.543). This is a Riemann-sum for $(\mathsf{LP}_\tau f)(v_k) = \int W_\tau(s) f(v_k - s)\, ds$. Evenness and vanishing first moment yield the $O(h^2)$ local error by Taylor expansion. □

Intuition. The discrete filter is a faithful, second-order accurate proxy for the continuum mollifier; increasing the stencil radius with h^{-1} recovers the full integral.

$$\boxed{\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) := \big(\mathsf{D}_0\, \mathsf{LP}_{\tau,h}\, \Lambda_{\mathrm{law}}\big)_k.} \tag{7.544}$$

Intuition. This is the low–pass–then–central–difference readout in v; by Corollary 7.400 and Definition 7.406, it is unbiased on affine trends.

Remark 7.402 (Continuum vs. discrete slope: same concept, distinct objects)**.** The continuum robust slope is defined in Definition 7.385 by $\varsigma^{(\tau)}_{\mathrm{law}}(v) = \frac{d}{dv}\big(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}\big)(v)$ (see eq. (7.539)), with the convolution representation given in Lemma 7.386. The discrete readout displayed above is the grid estimator $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = (\mathsf{D}_0\, \mathsf{LP}_{\tau,h} \Lambda_{\mathrm{law}})_k$, for which the canonical label is eq. (7.547). These two quantities represent the same conceptual observable but are not the same mathematical object or label. With the cell-average stencil from Definition 7.398 and smooth Λ_{law} at fixed τ,

$$(\mathsf{D}_0\, \mathsf{LP}_{\tau,h} \Lambda_{\mathrm{law}})_k \;=\; \varsigma^{(\tau)}_{\mathrm{law}}(v_k) \;+\; O(h^2),$$

so the discrete estimator is second–order accurate and, by Lemma 7.412 and Corollary 7.400, exact on affine trends.

Definition 7.403 (Admissible boundary extension)**.** Let $I = \{k_{\min}, \dots, k_{\max}\}$. A linear map $E : \mathbb{R}^I \to \mathbb{R}^{\mathbb{Z}}$ is an admissible extension if (i) E agrees with the identity on I, and (ii) E is fixed independently of f (e.g., periodic wrap, zero–padding, or mirrored/Neumann ghosts). Let $R : \mathbb{R}^{\mathbb{Z}} \to \mathbb{R}^I$ be the restriction $R(g) = g|_I$.

Intuition. E specifies a boundary rule so that discrete convolutions can be applied on the whole grid and then restricted back.

Proposition 7.404 (Commutation survives extension–restriction)**.** *Let w and d denote the finite-support kernels of $\mathsf{LP}_{\tau,h}$ and D_0, respectively. For any admissible E and restriction R,*

$$R\Big(d * (w * Ef)\Big) \;=\; R\Big(w * (d * Ef)\Big) \qquad \text{for all } f \in \mathbb{R}^I.$$

Proof. Associativity and commutativity of discrete convolution on $\mathbb{Z}$ yield $d * (w * Ef) = (w * d) * Ef$. Apply R. □

Remark 7.405 (Affine exactness at the edges)**.** With eroded indices, Lemma 7.412 gives exact affine readout everywhere used. Under extensions: periodic/zero–padding preserve commutation but may lose affine exactness at the first/last indices; mirrored/Neumann also preserve commutation but flip the slope at the boundary. State affine exactness claims on the eroded set or specify the extension.

Discrete estimator for audit and numerics.

Definition 7.406 (Central difference on the log–scale grid)**.** Let $v_k = v_0 + k\,h$ with $v = \ln \ell$. The operator $\mathsf{D}_0 : \{f_k\} \mapsto \{(\mathsf{D}_0 f)_k\}$ is

$$\boxed{(\mathsf{D}_0 f)_k := \frac{f_{k+1} - f_{k-1}}{2h}.} \tag{7.545}$$

Remark 7.407 (Meaning and basic properties)**.** D_0 is the standard symmetric, linear time-invariant (LTI) first-difference on the uniform grid in v. It is second-order accurate for $\mathrm{d}/\mathrm{d}v$ (local truncation error $O(h^2)$), annihilates constants, and returns the exact slope on affine trends: if $f(v) = a + b\,v$ and $f_k = f(v_k)$, then $(\mathsf{D}_0 f)_k = b$. Equivalently, $\mathsf{D}_0 = d*$ with $d_{+1} = 1/(2h)$, $d_{-1} = -1/(2h)$, else 0; this convolution form underlies the commutation with discrete low-pass filters used in Lemma 7.412. Boundary handling is via the usual eroded index set or mirrored/Neumann ghost points (as declared later).

Definition 7.408 (Discrete stencil on the log–scale grid)**.** On a uniform grid $v_k = v_0 + k\,h$, a (centered) stencil is a finite set of offsets $\{-m, \dots, m\} \subset \mathbb{Z}$ with coefficients $\{a_j\}_{j=-m}^{m}$ defining a linear, shift–invariant operator

$$(Af)_k := \sum_{j=-m}^{m} a_j\, f_{k-j}.$$

It is *symmetric* if $a_{-j} = a_j$. In this work:

- the low–pass uses the stencil $w = \{w_j\}_{-m}^{m}$ from Definition 7.409, with continuum anchoring via the cell averages eq. (7.543);
- the central difference uses $d_{-1} = -\frac{1}{2h}$, $d_0 = 0$, $d_{+1} = \frac{1}{2h}$ from Definition 7.406;
- the mollified–slope readout $(\mathsf{D}_0 \mathsf{LP}_{\tau,h})$ is the *composed stencil* $c = d * w$, i.e.

$$(\mathsf{D}_0 \mathsf{LP}_{\tau,h} f)_k = \sum_{j=-(m+1)}^{m+1} c_j\, f_{k-j}, \qquad c_j := \sum_{r\in\{-1,0,1\}} d_r\, w_{j-r}. \tag{7.546}$$

Definition 7.409 (Discrete low–pass and robust–slope estimator)**.** Fix a uniform grid $v_k = v_0 + k\,h$ (so $\ell_k = e^{v_k}$), and let $W \in C_c^\infty(\mathbb{R})$ have support in $[-R, R]$. Choose a symmetric, compact stencil $\{w_j\}_{j=-m}^{m}$ with

$$\sum_{j=-m}^{m} w_j = 1, \qquad \sum_{j=-m}^{m} j\, w_j = 0, \qquad w_{-j} = w_j,$$

approximating the continuous kernel in eq. (7.537); take $m = \lceil (\tau R)/h \rceil$. Define the discrete low–pass $\mathsf{LP}_{\tau,h}$ by

$$(\mathsf{LP}_{\tau,h} f)_k := \sum_{j=-m}^{m} w_j \, f_{k-j},$$

and use the central difference D_0 from Definition 7.406. Assume indices k satisfy $\{k-m, \dots, k+m\} \cup \{k \pm 1\}$ lie inside the data window. The *discrete robust law slope* is

$$\boxed{\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) := \Big(\mathsf{D}_0 \, \mathsf{LP}_{\tau,h} \, \Lambda_{\mathrm{law}}\Big)_k = \frac{1}{2h}\left[\sum_{j=-m}^{m} w_j \, \Lambda_{\mathrm{law}}(v_{k+1-j}) - \sum_{j=-m}^{m} w_j \, \Lambda_{\mathrm{law}}(v_{k-1-j})\right],} \tag{7.547}$$

which is the discrete counterpart of the robust slope in Definition 7.385 (cf. the convolution form (7.540)).

Intuition. The operator $\mathsf{LP}_{\tau,h}$ is a compact, symmetric average that preserves constants and linear trends (the discrete analogue of the continuous moment conditions in eqs. (7.537) and (7.538)), while D_0 is the standard second–order central derivative. Their composition $\mathsf{D}_0 \, \mathsf{LP}_{\tau,h}$ filters grid–scale ripples yet tracks the IR slope faithfully, yielding a robust discrete counterpart of the continuous slope in Definition 7.385 (see Definitions 7.406 and 7.409).

Stencil intuition. In Definition 7.409, the *stencil* is the finite pattern of offsets $\{-m, \dots, m\}$ and weights $\{w_j\}$ slid along the log–grid $v_k = v_0 + k\,h$. It may be viewed as a compact "mask": symmetry $w_{-j} = w_j$ and the moment constraints $\sum_j w_j = 1$, $\sum_j j\, w_j = 0$ enforce unbiased averaging, exact reproduction of affine trends, and zero phase distortion, so grid–scale oscillations are suppressed without shifting IR features. The half–width $m \simeq \lceil \tau R/h \rceil$ ties the spatial reach of the mask to the IR scale τ, matching the continuous construction in eq. (7.537). Composing the low–pass with the central difference produces a single derivative–stencil with coefficients

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \sum_{r=-(m+1)}^{m+1} c_r \, \Lambda_{\mathrm{law}}(v_{k-r}), \qquad c_r = \frac{w_{r+1} - w_{r-1}}{2h} \quad (w_j := 0 \text{ for } |j| > m),$$

which is antisymmetric ($c_{-r} = -c_r$), kills constants, and reproduces linear trends with second–order accuracy. The index condition in Definition 7.409 (the "eroded" set) ensures all offsets required by the stencil remain within the available data window, avoiding boundary artefacts. By stabilising the slope $\psi(v) = (\mathsf{D}_0 \, \mathsf{LP}_{\tau,h} \Lambda_{\mathrm{law}})(v)$, the stencil integrates seamlessly with the curvature and total–variation (TV) guards (Definition 7.420 and Lemma 7.423), thereby reducing false positives in emergent–trend detection and providing a phase–neutral, bias–controlled, IR–faithful estimator suitable for certified plateau diagnostics.

Proposition 7.410 (Discrete robust-slope error)**.** *Let $W \in C_c^\infty(\mathbb{R})$ be even with $\int W = 1$, $\int v\, W(v)\, dv = 0$, and finite $m_2(W)$, and let the stencil $\{w_j\}_{-m}^{m}$ be symmetric with $\sum w_j = 1$, $\sum j\, w_j = 0$, $m = \lceil \tau R/h \rceil$. On an eroded index set (to avoid edges),*

$$\left\| \widehat{\varsigma}^{(\tau)}_{\mathrm{law}} - \varsigma^{(\tau)}_{\mathrm{law}} \right\|_\infty \;\le\; C\Big(h^2 + \tau^2\Big) \left\| \Lambda^{(3)}_{\mathrm{law}} \right\|_\infty \;+\; E_{\ker}(h, \tau),$$

where $E_{\ker}(h,\tau)$ is the kernel-discretization error (zero if $w_j \propto h\,W_\tau(jh)$ are used and renormalized). If, moreover, $\Lambda_{\mathrm{law}} \in C^5$ and $m_4(W) < \infty$, then the continuous mollifier bias improves to $\mathcal{O}(\tau^4)$ and

$$\left\| \widehat{\varsigma}^{(\tau)}_{\mathrm{law}} - \varsigma^{(\tau)}_{\mathrm{law}} \right\|_\infty \;\le\; C\Big(h^2 \left\| \Lambda^{(3)}_{\mathrm{law}} \right\|_\infty + \tau^4 \left\| \Lambda^{(5)}_{\mathrm{law}} \right\|_\infty \Big) \;+\; E_{\ker}(h,\tau).$$

Proof. Write $f := \Lambda_{\mathrm{law}}$, $v_k = v_0 + kh$, and set

$$g(v) := (\mathsf{LP}_\tau f)(v), \qquad g_k := (\mathsf{LP}_{\tau,h} f)_k = \sum_{j=-m}^{m} w_j\, f(v_{k-j}).$$

Recall the robust slope and its discrete estimator:

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) = g'(v), \qquad \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = (\mathsf{D}_0 g_\bullet)_k = \frac{g_{k+1} - g_{k-1}}{2h}$$
$$\text{with } g_{k\pm1} \text{ understood as } \sum_j w_j f(v_{k\pm1-j}).$$

We decompose the error by adding and subtracting $f'(v_k)$:

$$\left| \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) - \varsigma^{(\tau)}_{\mathrm{law}}(v_k) \right| \;\le\; \underbrace{\left| \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) - f'(v_k) \right|}_{\text{(A) discrete vs. true derivative}} \;+\; \underbrace{\left| f'(v_k) - g'(v_k) \right|}_{\text{(B) continuous mollifier bias}}.$$

(B) Continuous mollifier bias. By Proposition 7.382 (applied to f and differentiated using Lemma 7.381(4)),

$$g'(v) = f'(v) + \frac{\tau^2 m_2(W)}{2}\, f^{(3)}(v) + \mathcal{O}(\tau^4),$$

hence

$$\sup_k |f'(v_k) - g'(v_k)| \;\le\; C\,\tau^2\, \|f^{(3)}\|_\infty$$
$$\text{(and improves to } C\,\tau^4\, \|f^{(5)}\|_\infty \text{ if } f \in C^5,\ m_4(W) < \infty).$$

(A) Discrete vs. true derivative. Split (A) further by inserting the continuous smoothed profile g sampled on the grid:

$$\left| \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) - f'(v_k) \right| \;\le\; \underbrace{\left| (\mathsf{D}_0 g_\bullet)_k - (\mathsf{D}_0 g(v_\bullet))_k \right|}_{\text{(A1) kernel discretization}} \;+\; \underbrace{\left| (\mathsf{D}_0 g(v_\bullet))_k - g'(v_k) \right|}_{\text{(A2) central-difference error}}.$$

(A2) *Central-difference error.* Since $g \in C^3$ and D_0 is the second–order central scheme,

$$\left| (\mathsf{D}_0 g(v_\bullet))_k - g'(v_k) \right| \;\le\; C\,h^2\, \|g^{(3)}\|_\infty.$$

By Lemma 7.381(4), derivatives commute with LP_τ, so $g^{(3)} = \mathsf{LP}_\tau(f^{(3)})$, whence $\|g^{(3)}\|_\infty \le \|W\|_1\, \|f^{(3)}\|_\infty = \|f^{(3)}\|_\infty$. Thus

$$\sup_k \left| (\mathsf{D}_0 g(v_\bullet))_k - g'(v_k) \right| \;\le\; C\,h^2\, \|f^{(3)}\|_\infty.$$

(A1) *Kernel discretization.* Define the kernel-discretization residual

$$E_{\mathrm{ker}}(h,\tau) := \left\| \mathsf{D}_0\Big(\mathsf{LP}_{\tau,h} f - \mathsf{S}_h(\mathsf{LP}_\tau f)\Big)\right\|_\infty,$$

where S_h is the sampling operator $(\mathsf{S}_h g)_k := g(v_k)$. This term captures the effect of replacing the continuous convolution by a discrete stencil before differencing. By construction,

$$\sup_k \left|(\mathsf{D}_0 g_\bullet)_k - (\mathsf{D}_0 g(v_\bullet))_k\right| \;\le\; E_{\mathrm{ker}}(h,\tau).$$

Moreover, if one *chooses* the stencil via sampled kernel weights, $w_j \propto h\, W_\tau(jh)$ and renormalizes to enforce $\sum w_j = 1$ and symmetry (the audit/numerics convention), then $\mathsf{LP}_{\tau,h}$ is, by definition, the discrete counterpart of LP_τ used in the pipeline, and the above residual is set to zero: $E_{\mathrm{ker}}(h,\tau) = 0$. (If one prefers an analytical bound instead of this convention, standard quadrature estimates give $E_{\mathrm{ker}}(h,\tau) \le C_W\, h^2\, \|f''\|_\infty$ for smooth f and compactly supported W, which can be absorbed into the $Ch^2\|f^{(3)}\|_\infty$ term using $\|f''\|_\infty \le \|f^{(3)}\|_\infty$ on the eroded window up to a multiplicative constant from the local scale.)

Collecting the bounds. Combining (B), (A2), and (A1) via the triangle inequality gives

$$\left\| \widehat{\varsigma}^{(\tau)}_{\mathrm{law}} - \varsigma^{(\tau)}_{\mathrm{law}} \right\|_\infty \;\le\; C\, h^2\, \|f^{(3)}\|_\infty \;+\; C\, \tau^2\, \|f^{(3)}\|_\infty \;+\; E_{\mathrm{ker}}(h,\tau),$$

which is the first displayed estimate. Under $f \in C^5$ and $m_4(W) < \infty$, the τ^2 term improves to $C\,\tau^4\,\|f^{(5)}\|_\infty$, yielding the second estimate. All constants are independent of h, τ and of k, and the bounds hold on the eroded index set $\{k : k \pm m$ remain inside the window$\}$ to avoid edge effects. □

Remark 7.411 (When to ask for higher smoothness)**.** Use C^3 when we want the robust, practical bound $\mathcal{O}(h^2{+}\tau^2)$ for the discrete robust–slope error. **Bump to** C^5 (plus $m_4(W) < \infty$) only if we really want the $\mathcal{O}(\tau^4)$ continuous-bias term spelled out; otherwise the C^3 hypothesis suffices.

Lemma 7.412 (Commutation and affine exactness)**.** *Let f_k be a grid function on the uniform log–scale grid $v_k = v_0 + k\,h$ (with $v = \ln \ell$). Let the discrete low–pass $\mathsf{LP}_{\tau,h}$ with symmetric stencil $\{w_j\}_{j=-m}^{m}$ be as in Definition 7.409 (and hence $\sum_j w_j = 1$, $\sum_j j\, w_j = 0$, $w_{-j} = w_j$), and let the central difference D_0 be as in Definition 7.406. For all interior indices k with available samples (i.e. $\{k \pm 1\} \cup \{k-m, \dots, k+m\}$ lie in the data window), the following hold:*

Commutation.

$$\mathsf{D}_0\Big(\mathsf{LP}_{\tau,h} f\Big) = \mathsf{LP}_{\tau,h}\Big(\mathsf{D}_0 f\Big).$$

Affine exactness.

If $f(v) = a + b\,v$ and $f_k = f(v_k)$, then $(\mathsf{LP}_{\tau,h} f)_k = a + b\,v_k$ and $(\mathsf{D}_0 f)_k = b$. Consequently, the discrete robust law slope $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$ in eq. (7.547) returns b exactly on affine trends.

Proof. (1) Using finite support of $\{w_j\}$ and linearity,

$$\begin{aligned}\big(\mathsf{D}_0\,\mathsf{LP}_{\tau,h}f\big)_k &= \frac{1}{2h}\left[\sum_{j=-m}^{m} w_j\, f_{k+1-j} - \sum_{j=-m}^{m} w_j\, f_{k-1-j}\right]\\ &= \sum_{j=-m}^{m} w_j\,\frac{f_{k+1-j}-f_{k-1-j}}{2h}\\ &= \big(\mathsf{LP}_{\tau,h}\,\mathsf{D}_0 f\big)_k.\end{aligned}$$

Equivalently, with discrete convolution $(w*f)_k := \sum_j w_j f_{k-j}$, $\mathsf{LP}_{\tau,h} = w*$ and $\mathsf{D}_0 = d*$ where $d_{+1} = 1/(2h)$, $d_{-1} = -1/(2h)$, else 0; associativity/commutativity of finite-support convolution gives $d*w = w*d$.

(2) For $f_k = a + b\,v_k$ and $v_{k-j} = v_k - jh$,

$$\begin{aligned}(\mathsf{LP}_{\tau,h}f)_k &= \sum_{j=-m}^{m} w_j\big(a + b(v_k - jh)\big)\\ &= a\sum_j w_j + b\,v_k\sum_j w_j - bh\sum_j j\,w_j\\ &= a + b\,v_k,\end{aligned}$$

using $\sum_j w_j = 1$ and $\sum_j j\,w_j = 0$. From Definition 7.406, $(\mathsf{D}_0 f)_k = b$. Combining these with part (1) and eq. (7.547) gives the claim about $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$. □

Intuition. This is the discrete shadow of Definition 7.380: symmetry and the first-moment cancellation mirror eq. (7.538), so $\mathsf{LP}_{\tau,h}$ preserves constants/lines in $v = \ln \ell$ and commutes with any LTI first-difference like D_0. It ensures your low-pass slope $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$ is an *unbiased* estimator on plateaus/ramps before we look at higher-order structure.

Proposition 7.413 (Consistency and bias)**.** *Assume $\Lambda_{\mathrm{law}} \in C^3$ in v and the discrete weights approximate the continuous kernel of eq. (7.537) (moment conditions as in eq. (7.538)). Then*

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \varsigma^{(\tau)}_{\mathrm{law}}(v_k) \;+\; \mathcal{O}(h^2) \;+\; \mathcal{O}(\tau^2),$$

where $\varsigma^{(\tau)}_{\mathrm{law}}$ is the continuous robust slope of Definition 7.385.

Remark 7.414 (On the C^3 regularity in Proposition 7.413)**.** The requirement $\Lambda_{\mathrm{law}} \in C^3$ controls *both* sources of error that appear in

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \varsigma^{(\tau)}_{\mathrm{law}}(v_k) + \mathcal{O}(h^2) + \mathcal{O}(\tau^2).$$

(i) Smoothing bias $\mathcal{O}(\tau^2)$. Using the kernel moment conditions in eq. (7.538) and the Taylor expansion of $\Lambda_{\mathrm{law}}(v-s)$ to second order yields the standard bias formula $(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v) = \Lambda_{\mathrm{law}}(v) + \frac{\tau^2 m_2(W)}{2}\Lambda''_{\mathrm{law}}(v) + \mathcal{O}(\tau^4)$ (Proposition 7.382). Differentiating in v and commuting the derivative with LP_τ (Lemma 7.381) gives $\varsigma^{(\tau)}_{\mathrm{law}}(v) = \Lambda'_{\mathrm{law}}(v) + \frac{\tau^2 m_2(W)}{2}\Lambda^{(3)}_{\mathrm{law}}(v) + \mathcal{O}(\tau^4)$. Bounding this term uniformly requires $\Lambda_{\mathrm{law}} \in C^3$.

(ii) Discretization error $\mathcal{O}(h^2)$. Two second–order contributions are present: (a) the Riemann–cell discretization of LP_τ via the weights w_j from Definition 7.398 yields $(\mathsf{LP}_{\tau,h} f)_k = (\mathsf{LP}_\tau f)(v_k) + \mathcal{O}(h^2)$ for smooth f (Proposition 7.401); (b) the central difference D_0 (Definition 7.406) approximates $\frac{d}{dv}$ with local error $\mathcal{O}(h^2)$, whose control involves the third derivative of the target function. Applying (a)–(b) to $f = \Lambda_{\mathrm{law}}$ (and using the commutation in Lemma 7.412) shows that $(\mathsf{D}_0 \mathsf{LP}_{\tau,h} \Lambda_{\mathrm{law}})_k$ deviates from $\frac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v_k)$ by $\mathcal{O}(h^2)$, with bounds depending on $\sup |\Lambda^{(3)}_{\mathrm{law}}|$.

Summary. The τ-bias term involves $\Lambda^{(3)}_{\mathrm{law}}$ after differentiating the continuum bias; the h-discretization term for D_0 also depends on a third derivative. Hence C^3 is the natural minimal regularity ensuring the stated $\mathcal{O}(h^2) + \mathcal{O}(\tau^2)$ accuracy. (On affine trends, exactness holds by Corollary 7.400 and Definition 7.406.)

Proof. Write $f := \Lambda_{\mathrm{law}}$, $v_k = v_0 + kh$. Work on the eroded index set so that all stencil points are available (cf. the buffer convention used with the continuous τR window).

Step 1: Move the discrete derivative inside the low–pass. By the commutation identity in Lemma 7.412(1),

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \big(\mathsf{D}_0\, \mathsf{LP}_{\tau,h} f\big)_k = \big(\mathsf{LP}_{\tau,h}\, \mathsf{D}_0 f\big)_k.$$

Step 2: Central difference error $\mathcal{O}(h^2)$. Since $f \in C^3$,

$$(\mathsf{D}_0 f)_k = \frac{f(v_{k+1}) - f(v_{k-1})}{2h} = f'(v_k) + \mathcal{O}(h^2) \qquad \text{(uniformly in } k\text{)}.$$

Applying $\mathsf{LP}_{\tau,h}$ and using $\sum_j |w_j| = \sum_j w_j = 1$ (nonnegative symmetric stencil) yields

$$\big(\mathsf{LP}_{\tau,h}\, \mathsf{D}_0 f\big)_k = \big(\mathsf{LP}_{\tau,h} f'\big)_k + \mathcal{O}(h^2).$$

Step 3: Discrete vs. continuous low–pass $\mathcal{O}(h^2)$. Let $g := f'$. The weights $\{w_j\}$ approximate the continuous kernel W_τ and satisfy the discrete moment conditions $\sum w_j = 1$, $\sum j\, w_j = 0$ (discrete analog of $\int W = 1$, $\int vW = 0$; cf. eq. (7.538)). With $g \in C^2$ (since $f \in C^3$) and compact stencil, a standard quadrature/Taylor estimate gives

$$\big(\mathsf{LP}_{\tau,h} g\big)_k = \big(\mathsf{LP}_\tau g\big)(v_k) + \mathcal{O}(h^2),$$

uniformly for k in the eroded set. Hence

$$\big(\mathsf{LP}_{\tau,h}\, \mathsf{D}_0 f\big)_k = \big(\mathsf{LP}_\tau f'\big)(v_k) + \mathcal{O}(h^2).$$

Step 4: Identify the continuous robust slope. By the differentiation–commutation lemma Lemma 7.386,

$$\big(\mathsf{LP}_\tau f'\big)(v) = \frac{d}{dv}\big(\mathsf{LP}_\tau f\big)(v) = \varsigma^{(\tau)}_{\mathrm{law}}(v),$$

so

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \varsigma^{(\tau)}_{\mathrm{law}}(v_k) + \mathcal{O}(h^2).$$

Step 5: Add the mollifier bias if comparing to f'. While Step 4 shows $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}} = \varsigma^{(\tau)}_{\mathrm{law}} + \mathcal{O}(h^2)$, one often also reports the bias relative to the *unsmoothed* slope $f' = \Lambda'_{\mathrm{law}}$. By Proposition 7.382 (applied to f and then differentiated),

$$\varsigma^{(\tau)}_{\mathrm{law}}(v) = \big(\mathsf{LP}_\tau f\big)'(v) = f'(v) + \mathcal{O}(\tau^2),$$

so, by the triangle inequality,

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \varsigma^{(\tau)}_{\mathrm{law}}(v_k) \;+\; \mathcal{O}(h^2) \;+\; \mathcal{O}(\tau^2).$$

All big-O constants are uniform on the eroded index set and depend only on local C^3-bounds for f and on the (fixed) kernel/stencil parameters. *Note.* The $\mathcal{O}(\tau^2)$ term reflects the *continuous* low–pass bias relative to the raw derivative $f' = \Lambda'_{\mathrm{law}}$; if one measures error against the robust slope itself, $\varsigma^{(\tau)}_{\mathrm{law}} = (\mathsf{LP}_\tau f)'$, then $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}} = \varsigma^{(\tau)}_{\mathrm{law}} + \mathcal{O}(h^2)$. □

Lemma 7.415 (Stability and ripple suppression)**.** *Let $\mathsf{LP}_{\tau,h}$ and D_0 be as in Definitions 7.406 and 7.409, with stencil $\{w_j\}_{j=-m}^{m}$ (e.g. the cell–average choice of Definition 7.398). For any admissible index k (on the eroded set so all required samples exist),*

$$\left|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k)\right| \;\le\; \sum_{j=-m}^{m} |w_j| \sup_{\xi\in[v_{k-1-j},\,v_{k+1-j}]} \left|\Lambda'_{\mathrm{law}}(\xi)\right| \;\le\; \|w\|_{\ell^1}\,\|\Lambda'_{\mathrm{law}}\|_\infty,$$

where $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) := (\mathsf{D}_0\,\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k$ (cf. eq. (7.547)) and $\|w\|_{\ell^1} := \sum_{j=-m}^{m}|w_j|$. In the discrete Fourier domain (grid frequency $\xi \in [-\pi,\pi]$), the estimator has symbol

$$\widehat{\varsigma}(\xi) \;=\; \frac{i\sin\xi}{h}\,\widehat{W}(\xi), \qquad \widehat{W}(\xi) := \sum_{j=-m}^{m} w_j\, e^{-i\xi j},$$

so symmetric stencils ($w_{-j} = w_j$, cf. Lemma 7.399) attenuate high–$|\xi|$ components by the factor $|\widehat{W}(\xi)|$ while preserving DC gain $\widehat{W}(0) = \sum_j w_j = 1$.

Proof. Pointwise stability bound. By Definitions 7.406 and 7.409 (or Lemma 7.412(1)),

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = \sum_{j=-m}^{m} w_j\,\frac{\Lambda_{\mathrm{law}}(v_{k+1-j}) - \Lambda_{\mathrm{law}}(v_{k-1-j})}{2h}.$$

For each fixed j, apply the mean–value theorem to Λ_{law} on $[\,v_{k-1-j},\,v_{k+1-j}\,]$ to obtain some $\xi_{k,j}$ in that interval with

$$\frac{\Lambda_{\mathrm{law}}(v_{k+1-j}) - \Lambda_{\mathrm{law}}(v_{k-1-j})}{2h} = \Lambda'_{\mathrm{law}}(\xi_{k,j}).$$

Hence

$$\left|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k)\right| \le \sum_{j=-m}^{m} |w_j| \sup_{\xi\in[\,v_{k-1-j},\,v_{k+1-j}\,]} \left|\Lambda'_{\mathrm{law}}(\xi)\right| \le \Big(\sum_{j=-m}^{m}|w_j|\Big)\,\|\Lambda'_{\mathrm{law}}\|_\infty = \|w\|_{\ell^1}\,\|\Lambda'_{\mathrm{law}}\|_\infty.$$

If, in addition, the stencil is constructed from a nonnegative W via Definition 7.398 (so $w_j \ge 0$) and normalized as in eq. (7.538), then $\|w\|_{\ell^1} = \sum_j w_j = 1$.

Fourier symbol and ripple suppression. Write $(\mathsf{D}_0 f)_k = (d * f)_k$ and $(\mathsf{LP}_{\tau,h} f)_k = (w * f)_k$ (discrete convolution), with $d_{-1} = -\frac{1}{2h}$, $d_{+1} = \frac{1}{2h}$, otherwise 0 (cf. Definition 7.406), and $w = \{w_j\}$ as above. On a periodic (or ℓ^2) grid, the DTFT maps convolution to multiplication, hence the symbol of $\mathsf{D}_0\,\mathsf{LP}_{\tau,h}$ is

$$\widehat{\varsigma}(\xi) = \widehat{d}(\xi)\,\widehat{W}(\xi) = \frac{e^{i\xi} - e^{-i\xi}}{2h}\,\widehat{W}(\xi) = \frac{i\sin\xi}{h}\,\widehat{W}(\xi).$$

If $w_{-j} = w_j$ (guaranteed, e.g., by Lemma 7.399 when using Definition 7.398 and an even W per eq. (7.538)), then $\widehat{W}(\xi) = \sum_j w_j \cos(\xi j)$ is real, even, satisfies $|\widehat{W}(\xi)| \le \sum_j |w_j| = \|w\|_{\ell^1}$, and $\widehat{W}(0) = \sum_j w_j = 1$. Thus $\widehat{W}$ damps high–frequency content (large $|\xi|$ near π) while leaving DC unchanged, establishing ripple suppression by the low–pass stage. □

Remark 7.416 (Eroded index set and frequency response).

- The *eroded index set* mirrors the continuous τR buffer (cf. the low–pass support in Definition 7.380): it guarantees all entries $k \pm j$ used by the stencil and $k \pm 1$ used by D_0 lie inside the available window, so no boundary artefacts appear (see also Corollary 7.384).
- If the weights are constructed from sampled W_τ and renormalized ($w_j \propto h\, W_\tau(jh)$), then the discrete frequency response $\widehat{W}(\xi) = \sum_{j=-m}^{m} w_j e^{-i\xi j}$ closely matches the continuous kernel's response, and the attenuation profile inherits the desired low–pass shape.

Corollary 7.417 (IR acceptance via discrete tests). *Define the discrete curvature with the second–difference* $\mathsf{D}_2 f_k := (f_{k+1} - 2f_k + f_{k-1})/h^2$. *Then the discrete IR window*

$$\mathcal{I}_{\mathrm{IR}}^{(h)} := \left\{ k : \ \left| \mathsf{D}_2 (\mathsf{LP}_{\tau,h} \Lambda_{\mathrm{law}})_k \right| \le \varepsilon_{\mathrm{curv}} \right\}$$

approximates $\mathcal{I}_{\mathrm{IR}}$ *of Definition 7.392 with error* $\mathcal{O}(h^2) + \mathcal{O}(\tau^2)$. *Moreover,*

$$\min_{k \in \mathcal{I}_{\mathrm{IR}}^{(h)}} \widehat{\varsigma}_{\mathrm{law}}^{(\tau)}(v_k) = \min_{v \in \mathcal{I}_{\mathrm{IR}}} \varsigma_{\mathrm{law}}^{(\tau)}(v) \ + \ \mathcal{O}(h^2) + \mathcal{O}(\tau^2),$$

so the windowed minimum reported in practice is a consistent diagnostic.

Proof. Write $f := \Lambda_{\mathrm{law}}$, $v_k = v_0 + kh$. Set

$$\phi(v) := (\mathsf{LP}_\tau f)''(v), \qquad \phi_h(k) := \big(\mathsf{D}_2\, \mathsf{LP}_{\tau,h} f\big)_k.$$

By Lemma 7.381(4), differentiation commutes with LP_τ, so $\phi = \mathsf{LP}_\tau(f'')$. Also, since both D_2 and $\mathsf{LP}_{\tau,h}$ are discrete convolutions with finite support, they commute:

$$\phi_h = \mathsf{D}_2(\mathsf{LP}_{\tau,h} f) = \mathsf{LP}_{\tau,h}(\mathsf{D}_2 f).$$

Step 1: Uniform curvature consistency. Assume $f \in C^4$ in a neighborhood of the (compact) operational window.[10] Then the second–difference satisfies

$$(\mathsf{D}_2 g)(v_k) = g''(v_k) + \mathcal{O}(h^2) \quad \text{uniformly in } k \text{ whenever } g \in C^4.$$

Apply this twice with commutations:

$$\phi_h(k) = \big(\mathsf{LP}_{\tau,h}\, \mathsf{D}_2 f\big)_k = \big(\mathsf{LP}_\tau \mathsf{D}_2 f\big)(v_k) + \mathcal{O}(h^2) = \big(\mathsf{LP}_\tau f''\big)(v_k) + \mathcal{O}(h^2) = \phi(v_k) + \mathcal{O}(h^2).$$

[10] This is the standard smoothness for the second–difference truncation error; see also the discussion under Proposition 7.410.

If one wishes to compare ϕ back to the *unsmoothed* curvature f'', then by the bias expansion (the second–derivative version of Proposition 7.382, using evenness and finite $m_2(W)$)

$$\phi(v) - f''(v) = \frac{\tau^2 m_2(W)}{2}\, f^{(4)}(v) + \mathcal{O}(\tau^4),$$

so overall

$$\sup_k \left|\phi_h(k) - \phi(v_k)\right| = \mathcal{O}(h^2), \qquad \sup_k \left|\phi_h(k) - f''(v_k)\right| = \mathcal{O}(h^2) + \mathcal{O}(\tau^2).$$

Step 2: Set approximation for the curvature test. The continuous window is $\mathcal{I}_{\mathrm{IR}} = \{\, v : |\phi(v)| \le \varepsilon_{\mathrm{curv}} \,\}$. Define the grid–indexed window by the curvature test $\mathcal{I}_{\mathrm{IR}}^{(h)} = \{\, k : \ |\phi_h(k)| \le \varepsilon_{\mathrm{curv}} \,\}$. Let $\delta_\phi := \sup_k |\phi_h(k) - \phi(v_k)| = \mathcal{O}(h^2)$ from Step 1. Then for all k,

$$|\phi(v_k)| \le \varepsilon_{\mathrm{curv}} - \delta_\phi \implies k \in \mathcal{I}_{\mathrm{IR}}^{(h)}, \qquad k \in \mathcal{I}_{\mathrm{IR}}^{(h)} \implies |\phi(v_k)| \le \varepsilon_{\mathrm{curv}} + \delta_\phi.$$

Viewing the grid as a partition of the line and using the Lipschitz regularity of ϕ on the operational window (cf. Section 6.12.4), the standard "band–measure'' estimate (as in Proposition 7.397, Step 4) implies that the symmetric difference between the continuous window and the stepwise-constant embedding of the discrete window has measure

$$\mu\Big(\mathcal{I}_{\mathrm{IR}} \,\triangle\, \mathcal{I}_{\mathrm{IR}}^{(h)}\Big) \ \le\ C\,\delta_\phi \ =\ \mathcal{O}(h^2).$$

If one compares against the *unsmoothed* curvature set $\{\, |f''| \le \varepsilon_{\mathrm{curv}} \,\}$, the additional mollifier bias produces the stated $\mathcal{O}(\tau^2)$ contribution.

Step 3: Consistency of the windowed minimum. Let $\psi(v) := \varsigma_{\mathrm{law}}^{(\tau)}(v) = (\mathsf{LP}_\tau f)'(v)$ and $\widehat{\psi}_k := \widehat{\varsigma}_{\mathrm{law}}^{(\tau)}(v_k)$. By Proposition 7.413 we have the uniform approximation

$$\sup_k |\widehat{\psi}_k - \psi(v_k)| \le C\,h^2 \quad (\text{and } +\ \mathcal{O}(\tau^2) \text{ if compared to } f').$$

Let $k^\star \in \mathcal{I}_{\mathrm{IR}}^{(h)}$ realize the discrete minimum. Then

$$\min_{k \in \mathcal{I}_{\mathrm{IR}}^{(h)}} \widehat{\psi}_k = \widehat{\psi}_{k^\star} = \psi(v_{k^\star}) + \mathcal{O}(h^2) \ \ge\ \min_{v \in \mathcal{I}_{\mathrm{IR}}} \psi(v) + \mathcal{O}(h^2),$$

where we used that the discrete window is embedded in a small $\mathcal{O}(h^2)$-band around the continuous window (Step 2) and ψ is locally Lipschitz on the operational window (from Section 6.12.4 and Lemma 7.386). For the reverse inequality, take $v^\star \in \mathcal{I}_{\mathrm{IR}}$ achieving the minimum of ψ, pick a nearest grid index k (within distance $\le h$), and note that $k \in \mathcal{I}_{\mathrm{IR}}^{(h)}$ once h is small enough by Step 2; then

$$\min_{k \in \mathcal{I}_{\mathrm{IR}}^{(h)}} \widehat{\psi}_k \ \le\ \widehat{\psi}_k = \psi(v_k) + \mathcal{O}(h^2) \ =\ \psi(v^\star) + \mathcal{O}(h^2) \ =\ \min_{v \in \mathcal{I}_{\mathrm{IR}}} \psi(v) + \mathcal{O}(h^2).$$

Combining both directions yields

$$\min_{k \in \mathcal{I}_{\mathrm{IR}}^{(h)}} \widehat{\varsigma}_{\mathrm{law}}^{(\tau)}(v_k) = \min_{v \in \mathcal{I}_{\mathrm{IR}}} \varsigma_{\mathrm{law}}^{(\tau)}(v) \ +\ \mathcal{O}(h^2),$$

and the additional $\mathcal{O}(\tau^2)$ term appears only if the minimum is compared against the *unsmoothed* slope $f' = \Lambda'_{\mathrm{law}}$ (cf. Proposition 7.382). □

Note. The $\mathcal{O}(\tau^2)$ contributions above reflect the *continuous* low–pass bias relative to the raw (unsmoothed) derivative or curvature. If one measures both the window and the minimum against the robust (smoothed) quantities $(\mathsf{LP}_\tau f)''$ and $(\mathsf{LP}_\tau f)'$, then the discrete errors are $\mathcal{O}(h^2)$ alone.

Proposition 7.418 (Gauge/presentation independence; pipeline comparability)**.** *With BRST-closed tags and calibrated branches, the estimator* $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$ *and the discrete window* $\mathcal{I}^{(h)}_{\mathrm{IR}}$ *are independent of gauge parameters and presentation-equivalent choices, and are comparable across pipeline moves* $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$ *up to the plateau tolerances, with discretization errors* $\mathcal{O}(h^2) + \mathcal{O}(\tau^2)$.

Proof. Preliminaries and notation. Let $f := \Lambda_{\mathrm{law}}$, and recall the discrete operators $\mathsf{LP}_{\tau,h}$ and D_0, and the estimator $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}} = \mathsf{D}_0\,\mathsf{LP}_{\tau,h} f$. Work on the eroded index set so all stencil samples exist (cf. Remark 7.416).

Step 1: Gauge/presentation independence (discrete). By Propositions 7.367 and 7.372, once branches are calibrated and tags are BRST–closed, $f = \Lambda_{\mathrm{law}}$ is independent (on certified plateaus) of gauge parameters and presentation–equivalent choices. The discrete map $f \mapsto \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$ is linear, grid-local, and depends only on the sampled values of f through fixed, gauge–independent coefficients $\{w_j\}$. Hence $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$ inherits the same independence.

For the discrete IR window, use Corollary 7.417: the grid-defined set $\mathcal{I}^{(h)}_{\mathrm{IR}} = \{\, k : |\mathsf{D}_2(\mathsf{LP}_{\tau,h} f)_k| \le \varepsilon_{\mathrm{curv}} \,\}$ approximates the continuous window $\mathcal{I}_{\mathrm{IR}} = \{\, v : |(\mathsf{LP}_\tau f)''(v)| \le \varepsilon_{\mathrm{curv}} \,\}$. Since $\mathcal{I}_{\mathrm{IR}}$ is gauge/presentation independent by Proposition 7.397, the discrete window $\mathcal{I}^{(h)}_{\mathrm{IR}}$ inherits this independence up to $\mathcal{O}(h^2) + \mathcal{O}(\tau^2)$.

Step 2: Pipeline comparability for the estimator (discrete). Let $\tilde{f}(v) = \Lambda_{\mathrm{law}}(v; \tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$. By Lemma 7.412(1),

$$\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\cdot) = \mathsf{LP}_{\tau,h}\Big(\mathsf{D}_0\big(\tilde{f} - f\big)\Big).$$

Discrete Young's inequality (convolution $\ell^1 \to \ell^\infty$) and $\|\mathsf{LP}_{\tau,h}\|_{\ell^\infty \to \ell^\infty} = \|w\|_{\ell^1}$ give

$$\Big\|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\cdot)\Big\|_{\ell^\infty} \;\le\; \|w\|_{\ell^1}\,\Big\|\mathsf{D}_0(\tilde{f} - f)\Big\|_{\ell^\infty}.$$

Central differences approximate derivatives with $\mathcal{O}(h^2)$, hence

$$\Big\|\mathsf{D}_0(\tilde{f} - f)\Big\|_{\ell^\infty} \;\le\; \|\tilde{f}' - f'\|_{L^\infty} \;+\; C\,h^2\,\|f^{(3)}\|_{L^\infty},$$

uniformly on the eroded set. By the continuous pipeline comparability bound (Proposition 7.390 together with Corollary 7.378), $\|\tilde{f}' - f'\|_{L^\infty}$ is bounded by a constant multiple of the plateau budgets $(\varepsilon_{\mathrm{grad}}, \varepsilon_{\mathrm{osc}}, \varepsilon_{\mathrm{reg}}, \varepsilon_{\mathrm{swap}})$. Therefore

$$\Big\|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot}) - \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\cdot)\Big\|_{\ell^\infty} \;\le\; C\,(\text{plateau tolerances}) \;+\; C\,h^2.$$

If one prefers to compare via the continuous robust slope $\varsigma^{(\tau)} = (\mathsf{LP}_\tau f)'$, use the consistency $\|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}} - \varsigma^{(\tau)}_{\mathrm{law}}\|_\infty = \mathcal{O}(h^2) + \mathcal{O}(\tau^2)$ from Proposition 7.413, obtaining the same tolerance bound plus $\mathcal{O}(h^2) + \mathcal{O}(\tau^2)$.

Step 3: Pipeline comparability for the discrete IR window. By Corollary 7.417, $\mathcal{I}_{\mathrm{IR}}^{(h)}$ is an $\mathcal{O}(h^2)+\mathcal{O}(\tau^2)$ approximation of the continuous window $\mathcal{I}_{\mathrm{IR}}$. Apply the continuous window comparability bound of Proposition 7.397 to the two pipelines and then transfer back to the discrete index set via the grid embedding (as in the proof of Corollary 7.417, Step 2). This yields that the symmetric difference of the discrete windows (measured either in index count times h, or via stepwise-constant embeddings) is controlled by a constant times the plateau tolerances, up to $\mathcal{O}(h^2)+\mathcal{O}(\tau^2)$.

Combining Steps 1–3 proves the proposition: both the discrete estimator and the discrete IR window are gauge/presentation independent on plateaus and are comparable across admissible pipeline moves, up to the plateau budgets, with discretization errors $\mathcal{O}(h^2)+\mathcal{O}(\tau^2)$. □

Remark 7.419 (Explicit estimator comparability bound)**.** On the eroded index set (so all stencil samples exist), the intermediate estimate from Step 2 of the proof of Proposition 7.418 reads

$$\left\|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\tilde{\cdot})-\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(\cdot;\cdot)\right\|_{\ell^\infty} \;\le\; \|w\|_{\ell^1}\left\|\Lambda'_{\mathrm{law}}(\tilde{\cdot})-\Lambda'_{\mathrm{law}}(\cdot)\right\|_{L^\infty} \;+\; C\,(h^2+\tau^2),$$

where $\|w\|_{\ell^1}:=\sum_{j=-m}^{m}|w_j|$ (in particular $\|w\|_{\ell^1}=1$ if $w_j\ge 0$ and $\sum_j w_j=1$). The first term on the right-hand side is controlled by the pipeline comparability of visibilities (Corollary 7.378); the $\mathcal{O}(h^2+\tau^2)$ term comes from the discrete consistency error (Proposition 7.413).

Monotonicity and false–positive guard.

Definition 7.420 (IR monotonicity/false–positive guard)**.** Let $\mathcal{I}_{\mathrm{IR}}$ be an IR window as in Definition 7.392, and set $\psi(v):=\varsigma^{(\tau)}_{\mathrm{law}}(v)=\frac{\mathrm{d}}{\mathrm{d}v}(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v)$. We say that $\mathcal{I}_{\mathrm{IR}}$ passes the *monotonicity/false–positive guard* if

$$\boxed{\sup_{v\in\mathcal{I}_{\mathrm{IR}}}\left|(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})''(v)\right|\le\varepsilon_{\mathrm{curv}},\qquad \mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi]:=\int_{\mathcal{I}_{\mathrm{IR}}}|\psi'(v)|\,\mathrm{d}v\;\le\;\varepsilon_{\mathrm{tv}}.}\tag{7.548}$$

Remark 7.421 (Total variation (TV))**.** Throughout Chapter 7, "TV" abbreviates the *total variation* of the low–pass slope $\psi(v):=\varsigma^{(\tau)}_{\mathrm{law}}(v)=\frac{d}{dv}(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v)$ (cf. Definitions 7.380 and 7.385 and Lemma 7.386). The *continuous* TV over an IR interval $\mathcal{I}_{\mathrm{IR}}\subset\mathbb{R}$ is introduced in Definition 7.420 and used in (7.548):

$$\mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi]:=\int_{\mathcal{I}_{\mathrm{IR}}}\left|\psi'(v)\right|dv,$$

which equals the standard BV definition $\sup_{\{v_i\}}\sum_i|\psi(v_i)-\psi(v_{i-1})|$ for absolutely continuous ψ (guaranteed here by low–pass smoothing; cf. Lemma 7.381).

For *discrete* guards on a grid $v_k=v_0+k\,h$, we use the discrete TV (introduced with the discrete monotonicity/false–positive guard in Definition 7.438 and applied in Proposition 7.442):

$$\mathrm{TV}_{h;[k_R,\infty)}[\psi]\;:=\;\sum_{j\ge k_R}\left|\psi_{j+1}-\psi_j\right|,\qquad \psi_j:=\psi(v_j).$$

For smooth ψ, $\mathrm{TV}_{h;[k_R,\infty)}[\psi]$ is a consistent Riemann–sum approximation of $\mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi]$. Both the continuous and discrete TV enter the stability bounds of Lemma 7.423.

Remark 7.422 (Intuitive reading: total variation (TV))**.** Total variation of a function f on $[a,b]$ is the cumulative amount it changes: $\mathrm{TV}_{[a,b]}[f] = \int_a^b |f'(x)|\,dx$ when f is absolutely continuous; for a discrete sample $\{f_k\}$ it is $\mathrm{TV}_{[k_0,k_1]}[f] = \sum_{k=k_0}^{k_1-1} |f_{k+1} - f_k|$. If f is monotone, $\mathrm{TV} = |f(b) - f(a)|$; oscillations increase TV because up–down increments add. In this chapter we apply TV to the low–pass slope $\psi(v) = \varsigma_{\mathrm{law}}^{(\tau)}(v) = \frac{d}{dv}\big(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}\big)(v)$ on an IR interval $\mathcal{I}_{\mathrm{IR}}$ (see Definition 7.420), so a small $\mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi]$ certifies a stable, nearly monotone slope (no spurious sign flips) and guards against false positives. Heuristically, for $f(v) = A\sin(\omega v)$ on a long interval, TV scales like $A\,\omega$ times the interval length; low–pass filtering (LP_τ) suppresses the high–frequency part, reducing TV and stabilising the trend. In short, TV measures cumulative wiggliness; combined with the curvature bound it yields a robust, scale–aware monotonicity test for ψ (cf. Lemma 7.423).

Lemma 7.423 (Stability from curvature and TV guards)**.** *Let $\mathcal{I}_{\mathrm{IR}}$ and $\psi(v) := \varsigma_{\mathrm{law}}^{(\tau)}(v) = \frac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v)$ be as in Definition 7.420 (cf. Definition 7.385 and Lemma 7.386). If $\mathcal{I}_{\mathrm{IR}}$ satisfies the guard (7.548), then:*

(i) Lipschitz control

For all $v_1, v_2 \in \mathcal{I}_{\mathrm{IR}}$,

$$|\psi(v_2) - \psi(v_1)| \;\le\; \varepsilon_{\mathrm{curv}}\,|v_2 - v_1|.$$

(ii) Total–variation control

For all $v \in \mathcal{I}_{\mathrm{IR}}$ and any $v_0 \in \mathcal{I}_{\mathrm{IR}}$,

$$|\psi(v) - \psi(v_0)| \;\le\; \mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi] \;\le\; \varepsilon_{\mathrm{tv}}.$$

(iii) Positivity stability

If, in addition, $\psi(v) \ge \varsigma_{\min} > 0$ for all $v \in \mathcal{I}_{\mathrm{IR}}$ (cf. Definition 7.392) and $\varepsilon_{\mathrm{tv}} < \varsigma_{\min}$, then

$$\inf_{v \in \mathcal{I}_{\mathrm{IR}}} \psi(v) \;\ge\; \varsigma_{\min} - \varepsilon_{\mathrm{tv}} \;>\; 0,$$

so ψ cannot change sign inside $\mathcal{I}_{\mathrm{IR}}$.

Proof. Preliminaries. By Definition 7.385, $\psi = \frac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})$. Differentiating once more and using the derivative–commutation property of LP_τ (see Lemma 7.381(4) and Lemma 7.386), one has $\psi' = (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})''$ on $\mathcal{I}_{\mathrm{IR}}$. The curvature guard in (7.548) asserts $\sup_{\mathcal{I}_{\mathrm{IR}}} |\psi'| \le \varepsilon_{\mathrm{curv}}$, while the TV guard gives $\mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi] = \int_{\mathcal{I}_{\mathrm{IR}}} |\psi'| \le \varepsilon_{\mathrm{tv}}$.

(1) *Lipschitz control.* For any $v_1, v_2 \in \mathcal{I}_{\mathrm{IR}}$,

$$\psi(v_2) - \psi(v_1) = \int_{v_1}^{v_2} \psi'(s)\,ds,$$

hence $|\psi(v_2) - \psi(v_1)| \le \int_{v_1}^{v_2} |\psi'(s)|\,ds \le \sup_{\mathcal{I}_{\mathrm{IR}}} |\psi'|\,|v_2 - v_1| \le \varepsilon_{\mathrm{curv}} |v_2 - v_1|$.

(2) *Total–variation control.* For any $v, v_0 \in \mathcal{I}_{\mathrm{IR}}$,

$$|\psi(v) - \psi(v_0)| \le \int_{[v_0, v]} |\psi'(s)|\,ds \le \int_{\mathcal{I}_{\mathrm{IR}}} |\psi'(s)|\,ds = \mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi] \le \varepsilon_{\mathrm{tv}},$$

using the TV guard in (7.548). Absolute continuity of ψ needed for the line integral follows from $\psi = \mathsf{LP}_\tau(\Lambda'_{\mathrm{law}})$ and Lemma 7.386 (with Λ_{law} locally absolutely continuous per the standing regularity assumptions used in Lemma 7.386 and Proposition 7.383).

(3) *Positivity stability.* Under Definition 7.392, $\psi(v) \geq \varsigma_{\min}$ on $\mathcal{I}_{\mathrm{IR}}$. Fix any $v_0 \in \mathcal{I}_{\mathrm{IR}}$; then by (2), for all $v \in \mathcal{I}_{\mathrm{IR}}$,

$$\psi(v) \;\geq\; \psi(v_0) - \varepsilon_{\mathrm{tv}} \;\geq\; \varsigma_{\min} - \varepsilon_{\mathrm{tv}}.$$

If $\varepsilon_{\mathrm{tv}} < \varsigma_{\min}$, the right–hand side is strictly positive, hence ψ cannot cross or touch zero on $\mathcal{I}_{\mathrm{IR}}$. Taking the infimum over v yields the stated bound. □

Proposition 7.424 (Gauge/presentation safety of the guard)**.** *Let $\mathcal{I}_{\mathrm{IR}}$ be an IR window as in Definition 7.392 and let the guard quantities be those in Definition 7.420, namely*

$$\sup_{v\in\mathcal{I}_{\mathrm{IR}}} \left|(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})''(v)\right| \quad \textit{and} \quad \mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi], \quad \psi := \varsigma^{(\tau)}_{\mathrm{law}} = \tfrac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}).$$

Under BRST–closed tags and calibrated branches, these guard quantities:

(i) are independent *of gauge parameters and presentation–equivalent choices on certified plateaus (Propositions 7.367 and 7.372);*

(ii) are comparable across admissible pipeline moves $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde\lambda_{\mathrm{UV}}, \tilde\ell)$ *in the sense that on the eroded intersection window $(\mathcal{I}_{\mathrm{IR}} \cap \tilde{\mathcal{I}}_{\mathrm{IR}})^{-\tau R}$ (cf. Remark 7.391),*

$$\boxed{\begin{aligned} \left|\sup_J|\psi'_\cdot| - \sup_J|\psi'_\cdot|\right| &\leq \|W\|_1 \sup_J \left|\Lambda''_{\mathrm{law}}(\,\cdot\,;\tilde\cdot) - \Lambda''_{\mathrm{law}}(\,\cdot\,;\cdot)\right|, && (7.549)\\ \left|\,\mathrm{TV}_J[\psi_\cdot] - \mathrm{TV}_J[\psi_\cdot]\,\right| &\leq \mu(J)\,\|W\|_1 \sup_J \left|\Lambda''_{\mathrm{law}}(\,\cdot\,;\tilde\cdot) - \Lambda''_{\mathrm{law}}(\,\cdot\,;\cdot)\right|, && (7.550)\end{aligned}}$$

where $J := (\mathcal{I}_{\mathrm{IR}} \cap \tilde{\mathcal{I}}_{\mathrm{IR}})^{-\tau R}$ and $\mu(J)$ is its Lebesgue measure. In particular, the right–hand sides are controlled by the plateau budgets via Corollary 7.378 and Proposition 7.397.

If $W \geq 0$ and $\int W = 1$ (cf. eq. (7.538)), then $\|W\|_1 = 1$ by Lemma 7.381(1).

Proof. Preliminaries. By Definition 7.385 and Lemma 7.386,

$$\psi = \mathsf{LP}_\tau(\Lambda'_{\mathrm{law}}), \qquad \psi' = (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})'' = \mathsf{LP}_\tau(\Lambda''_{\mathrm{law}}).$$

The operator LP_τ is convolution by W_τ (Definition 7.380), hence bounded on L^∞ with $\|\mathsf{LP}_\tau g\|_\infty \leq \|W_\tau\|_1 \|g\|_\infty = \|W\|_1 \|g\|_\infty$ (Lemma 7.381(1)) and commutes with d/dv on the stated regularity class (Lemma 7.381(4)).

(1) *Gauge/presentation independence.* On certified plateaus, Λ_{law} is invariant under gauge–parameter variations and presentation–equivalent choices once calibration is fixed (Propositions 7.367 and 7.372). Thus, for any such variation ∂_ξ,

$$\partial_\xi \Lambda_{\mathrm{law}} = 0 \quad \Rightarrow \quad \partial_\xi \psi = \partial_\xi\big(\mathsf{LP}_\tau \Lambda'_{\mathrm{law}}\big) = \mathsf{LP}_\tau(\partial_\xi \Lambda'_{\mathrm{law}}) = 0,$$

and analogously $\partial_\xi \psi' = \mathsf{LP}_\tau(\partial_\xi \Lambda''_{\mathrm{law}}) = 0$, using the commutation noted above. Consequently, $\sup_{\mathcal{I}_{\mathrm{IR}}} |\psi'|$ and $\mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi] = \int_{\mathcal{I}_{\mathrm{IR}}} |\psi'|$ (by absolute continuity and $\psi' = \frac{d}{dv}\psi$) are invariant. This proves Item 1.

(2) *Pipeline comparability on a common window.* Consider an admissible move $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\tilde{\lambda}_{\mathrm{UV}}, \tilde{\ell})$. By Corollary 7.378, for $k = 1, 2$ there exist constants C_k (depending only on the certified budgets) with

$$\sup_J \left|\Lambda^{(k)}_{\mathrm{law}}(\,\cdot\,;\tilde{\cdot}) - \Lambda^{(k)}_{\mathrm{law}}(\,\cdot\,;\cdot)\right| \;\le\; C_k\Big(\varepsilon_{\mathrm{grad}} + \varepsilon_{\mathrm{curv}} + \varepsilon_{\mathrm{osc}} + \varepsilon_{\mathrm{reg}} + \varepsilon_{\mathrm{swap}}\Big),$$

when $J = (\mathcal{I}_{\mathrm{IR}} \cap \tilde{\mathcal{I}}_{\mathrm{IR}})^{-\tau R}$ (cf. Remark 7.391 ensuring that $W_\tau(v - \cdot)$ samples inside certified windows). Applying LP_τ and using the L^1–L^∞ bound,

$$\sup_J \left|\psi'_{\tilde{\cdot}} - \psi'_{\cdot}\right| = \sup_J \left|\mathsf{LP}_\tau(\Lambda''_{\mathrm{law}}(\tilde{\cdot}) - \Lambda''_{\mathrm{law}}(\cdot))\right| \le \|W\|_1 \sup_J \left|\Lambda''_{\mathrm{law}}(\tilde{\cdot}) - \Lambda''_{\mathrm{law}}(\cdot)\right|.$$

This yields (7.549) after taking suprema.

For the total variation, use the triangle inequality and absolute continuity:

$$\mathrm{TV}_J[\psi_{\tilde{\cdot}}] = \int_J |\psi'_{\tilde{\cdot}}| \le \int_J |\psi'_{\cdot}| + \int_J |\psi'_{\tilde{\cdot}} - \psi'_{\cdot}| \le \mathrm{TV}_J[\psi_{\cdot}] + \mu(J) \sup_J |\psi'_{\tilde{\cdot}} - \psi'_{\cdot}|.$$

Insert the previous bound on $\sup_J |\psi'_{\tilde{\cdot}} - \psi'_{\cdot}|$ to obtain

$$\mathrm{TV}_J[\psi_{\tilde{\cdot}}] - \mathrm{TV}_J[\psi_{\cdot}] \;\le\; \mu(J)\,\|W\|_1 \sup_J \left|\Lambda''_{\mathrm{law}}(\tilde{\cdot}) - \Lambda''_{\mathrm{law}}(\cdot)\right|.$$

Swapping the roles of $(\cdot)$ and $(\tilde{\cdot})$ gives the reverse inequality and hence (7.550).

(3) *Windows under pipeline moves.* When comparing on the native windows $\mathcal{I}_{\mathrm{IR}}$ and $\tilde{\mathcal{I}}_{\mathrm{IR}}$, use Proposition 7.397 to bound the symmetric difference $\mu(\mathcal{I}_{\mathrm{IR}} \triangle \tilde{\mathcal{I}}_{\mathrm{IR}})$ by a constant times the plateau budgets. This, together with the bounds on J above, establishes comparability "up to the plateau budgets" in the proposition statement. □

Intuition. The guard depends only on ψ and ψ', i.e. on Λ'_{law} and Λ''_{law} after a fixed mollifier LP_τ. Gauge/presentation invariances of Λ_{law} on plateaus propagate through LP_τ and differentiation. Across pipeline moves, LP_τ is L^1-bounded, so differences of ψ and ψ' are controlled by differences of Λ'_{law} and Λ''_{law}, which are already bounded by the acceptance/plateau budgets.

Remark 7.425 (Discrete implementation)**.** Let $\widehat{\psi}_k := \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k)$ and define the discrete total variation on the eroded index set by

$$\mathrm{TV}^{(h)}_{\mathcal{I}^{(h)}_{\mathrm{IR}}}[\widehat{\psi}] := \sum_{k \in \mathcal{I}^{(h)}_{\mathrm{IR}} \setminus \{k_{\max}\}} \left|\widehat{\psi}_{k+1} - \widehat{\psi}_k\right|.$$

By Proposition 7.413 and Corollary 7.417, $\mathrm{TV}^{(h)}_{\mathcal{I}^{(h)}_{\mathrm{IR}}}[\widehat{\psi}] \to \mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi]$ with error $\mathcal{O}(h^2) + \mathcal{O}(\tau^2)$, and $\min_{k \in \mathcal{I}^{(h)}_{\mathrm{IR}}} \widehat{\psi}_k \to \min_{v \in \mathcal{I}_{\mathrm{IR}}} \psi(v)$ at the same rate. Hence the discrete guard is a consistent proxy for (7.548).

Compatibility with identity ledger and gauge safety.

Remark 7.426 (Compatibility with identity ledger and gauge safety)**.** The law–channel visibility Λ_{law} is constructed on shell from calibrated branches (cf. eqs. (7.122) and (7.527)) with BRST/Nielsen protections in place; hence a positive, stable trend certified by Definitions 7.392 and 7.420 diagnoses the emergence of a *global* G–Ward structure rather than a gauge artefact (see Lemma 7.374 and the standard BRST accounts [117, 442, 243]). The renormalisation–group reading used in Step 3 follows the standard linearisation near IR fixed points [389, 91].

Operational outputs for Step 2. Outputs comprise: (i) plots of $v \mapsto \Lambda_{\mathrm{law}}(v)$ and $v \mapsto \varsigma^{(\tau)}_{\mathrm{law}}(v)$ with the accepted IR window $\mathcal{I}_{\mathrm{IR}}$ shaded (cf. Definitions 7.385 and 7.392); (ii) a compact table reporting $\min_{v\in\mathcal{I}_{\mathrm{IR}}} \varsigma^{(\tau)}_{\mathrm{law}}(v)$, together with the curvature and TV guard values from (7.548), and their spreads under admissible coarse–graining choices $(P_x, K^{(\ell)}_{\mathrm{IR}})$ (cf. the joint coarse–graining maps eqs. (6.364) and (6.366)); (iii) an audit record listing $(\tau, h, \{w_j\})$ as defined in Definitions 7.380, 7.398, 7.406 and 7.409. By Lemma 7.423 and Proposition 7.424, these diagnostics suffice to certify monotonicity and gauge/presentation safety on $\mathcal{I}_{\mathrm{IR}}$.

Acceptance criterion for Step 2. QIII Step 2 is accepted if there exists an IR window $\mathcal{I}_{\mathrm{IR}} \subset \mathbb{R}$ such that the positivity condition of Definition 7.392 and the monotonicity/TV guard of Definition 7.420 hold with tolerances compatible with Section 6.12.4. When accepted, the window $\mathcal{I}_{\mathrm{IR}}$ and the associated parameters $(\tau, h, \{w_j\}, P_x, K^{(\ell)}_{\mathrm{IR}})$ become the input mask for Step 3 (RG irrelevance analysis), with robustness and gauge/presentation safety inherited from Proposition 7.424.

Proposition 7.427 (Mask soundness for Step 3)**.** *Let $\mathcal{I}_{\mathrm{IR}}$ be an accepted IR window with parameters $(\tau, h, \{w_j\}, P_x, K^{(\ell)}_{\mathrm{IR}})$ from Step 2 (cf. Definitions 7.392 and 7.420). Then:*

Kernel support safety.
For every $v \in (\mathcal{I}_{\mathrm{IR}})^{-\tau R}$, the sampling kernel $W_\tau(v-\cdot)$ stays inside $\mathcal{I}_{\mathrm{IR}}$; hence all mollified quantities used in Step 3 depend only on certified data (cf. Remark 7.391).

Gauge/presentation safety.
All Step 3 readouts are invariant under gauge parameters and presentation–equivalent choices on plateaus (cf. Proposition 7.424).

Pipeline stability.
Under admissible pipeline moves, windows and readouts remain comparable up to the plateau budgets (cf. Propositions 7.397 and 7.424).

Scaling and tolerance monotonicity.
The restoration sets and their first–attainment points respect scaling covariance and tolerance monotonicity (cf. Lemma 7.433).

UV–uniform option.
For UV strips $\mathcal{U}$, the uniform restoration length obeys the bounds/monotonicity of Proposition 7.435.

Continuum–discrete coherence.

The discrete audit estimators are consistent with the continuum ones and admit the stated error rates (cf. Lemma 7.440 and Corollary 7.436).

Proof. (1) is Remark 7.391. (2)–(3) follow from Propositions 7.397 and 7.424. (4) is Lemma 7.433. (5) is Proposition 7.435. (6) is Lemma 7.440 and Corollary 7.436. □

7.8.3 Restoration Length

Objective. We turn the qualitative notion of "law healing in the IR'' into a *scale* extracted from the law–visibility Λ_{law} (cf. eq. (7.122)) and the robust slope $\varsigma_{\mathrm{law}}^{(\tau)}$ introduced in eq. (7.539). Throughout we keep the state coherent (uniformly in the volume V) as in Section 6.12.4 and eq. (7.535) so that the diagnostic is purely *law*-channel.

Pointwise restoration length).

Definition 7.428 (Pointwise restoration length)**.** Let $E_{\mathrm{law}}(\ell) := 1 - \Lambda_{\mathrm{law}}(\lambda_{\mathrm{UV}}, \ell; T^\star)$ (cf. eq. (7.535)) and fix tolerances $(\varepsilon_{\mathrm{plat}}, \varsigma_{\min})$ consistent with Section 7.3.9. The *restoration length* is

$$\boxed{\ell_R := \inf\Big\{\ell \geq \ell_{\min} :\ E_{\mathrm{law}}(\ell) \leq \varepsilon_{\mathrm{plat}} \ \text{ and } \ \varsigma_{\mathrm{law}}^{(\tau)}(\ell') \geq \varsigma_{\min} \ \ \forall\, \ell' \geq \ell\Big\},} \tag{7.551}$$

with $\varsigma_{\mathrm{law}}^{(\tau)}$ as in eq. (7.539) and the monotonicity/curvature guards of eq. (7.548). If the set is empty we set $\ell_R := +\infty$ and classify as non-restoring at the probed scales. The definition is invariant under reparametrisations $\ell \mapsto a\,\ell$ (cf. eq. (7.541)).

Intuition. ℓ_R is the first coarse-graining scale beyond which the law-deficit stays within the plateau tolerance while the robust slope remains above threshold, i.e. the law keeps healing monotonically in the IR.

Robust variant (mollified deficit).

Definition 7.429 (Robust restoration length (mollified deficit))**.** To desensitise E_{law} to high–frequency readout ripples, work with the smoothed deficit

$$E_{\mathrm{law}}^{(\tau_E)}(\ell) := 1 - (\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(\ell),$$

with kernel properties as in eqs. (7.537) and (7.538). Define

$$\boxed{\ell_R^{(\tau_E)} := \inf\Big\{\ell \geq \ell_{\min} :\ E_{\mathrm{law}}^{(\tau_E)}(\ell) \leq \varepsilon_{\mathrm{plat}} \ \text{ and } \ \varsigma_{\mathrm{law}}^{(\tau)}(\ell') \geq \varsigma_{\min} \ \ \forall\, \ell' \geq \ell\Big\}.} \tag{7.552}$$

Here $\varsigma_{\mathrm{law}}^{(\tau)}$ is as in eq. (7.539), with the monotonicity/curvature guards of eq. (7.548). These guards ensure that $\ell_R^{(\tau_E)}$ agrees with the pointwise definition eq. (7.551) up to $\mathcal{O}(\tau_E^2)$ bias; admissibility of the smoothing and exchange of limits follows from Kato continuity [115].

Intuition. Light mollification suppresses readout ripples without moving the attainment scale: $\ell_R^{(\tau_E)}$ tracks ℓ_R to second order in the smoothing width, provided the curvature/TV guards hold.

Uniformity across UV slices.

Definition 7.430 (Uniform restoration length over UV strips)**.** Because QIII certification must not hinge on a special UV projector, require *uniform* restoration over an admissible UV strip $\mathcal{U} = [u_{\min}, u_{\max}]$ in $u := \ln \lambda_{\mathrm{UV}}$ (cf. Section 6.12.4 and eq. (7.67)). Define

$$\boxed{\ell_R^{[\mathcal{U}]} := \inf\Big\{\ell \geq \ell_{\min} : \sup_{u\in\mathcal{U}} E_{\mathrm{law}}(\ell; u) \leq \varepsilon_{\mathrm{plat}} \quad \text{and} \quad \inf_{\substack{u\in\mathcal{U}\\ \ell'\geq\ell}} \varsigma_{\mathrm{law}}^{(\tau)}(\ell'; u) \;\geq\; \varsigma_{\min}\Big\}.} \tag{7.553}$$

Intuition. The same ℓ must certify restoration for *every* admissible UV slice in $\mathcal{U}$; by construction $\ell_R^{[\mathcal{U}]} \geq \sup_{u\in\mathcal{U}} \ell_R(u)$ and it reduces to eq. (7.551) when $|\mathcal{U}| = 0$. Moreover, if $\mathcal{U}_1 \subseteq \mathcal{U}_2$ then $\ell_R^{[\mathcal{U}_2]} \geq \ell_R^{[\mathcal{U}_1]}$, and the definition is invariant under $\ell \mapsto a\,\ell$ (cf. eq. (7.541)).

Dual RG scale.

Definition 7.431 (Restoration scale in RG units)**.** With the fixed identification $\mu = \kappa/\ell$ (recorded once for audit), define

$$\boxed{\mu_R := \kappa/\ell_R, \qquad \mu_R^{[\mathcal{U}]} := \kappa/\ell_R^{[\mathcal{U}]}.} \tag{7.554}$$

Intuition. μ_R (and its UV–uniform counterpart) is the RG scale beyond which explicitly broken law-couplings that are RG-irrelevant have become numerically suppressed (Step 4 RG analysis), in line with standard RG flow expectations [389, 91, 82].

Proposition 7.432 (Existence, first–attainment uniqueness, and stability of ℓ_R)**.** *Work with $v := \ln \ell$. Assume on an IR window $\mathcal{I}_{\mathrm{IR}} = [v_\star, \infty)$ that: (i) $E_{\mathrm{law}}(e^v) \in C^1(\mathcal{I}_{\mathrm{IR}})$, $E_{\mathrm{law}} \geq 0$, and E_{law} is nonincreasing; (ii) $\varsigma_{\mathrm{law}}^{(\tau)}(e^v) \geq \varsigma_{\min} > 0$ for all $v \in \mathcal{I}_{\mathrm{IR}}$ (as in Definition 7.392); (iii) the curvature/TV guards (7.548) hold on $\mathcal{I}_{\mathrm{IR}}$. Then the admissible set in eq. (7.551) is nonempty, its infimum is attained, and ℓ_R is the unique* first *scale at which $E_{\mathrm{law}}(\ell) \leq \varepsilon_{\mathrm{plat}}$ and the slope constraint holds thereafter. Moreover, ℓ_R depends continuously on $(\varepsilon_{\mathrm{plat}}, \varsigma_{\min})$ and on E_{law} under C^0 perturbations dominated by the curvature guard (Kato–type continuity).*

Proof. Step 0 (link to the law deficit and slope). In QIII the "law deficit" is $D(v) := 1 - (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v)$ (cf. Lemma 7.395), so

$$D'(v) = -\varsigma_{\mathrm{law}}^{(\tau)}(v) =: -\psi(v) \quad \text{with} \quad \psi(v) = \tfrac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v) \text{ from Definition 7.385.}$$

When $E_{\mathrm{law}} = D$, item (ii) reads $\psi \geq \varsigma_{\min} > 0$ on $\mathcal{I}_{\mathrm{IR}}$, and (7.548) gives $\sup_{\mathcal{I}_{\mathrm{IR}}} |\psi'| \leq \varepsilon_{\mathrm{curv}}$ and $\mathrm{TV}_{\mathcal{I}_{\mathrm{IR}}}[\psi] \leq \varepsilon_{\mathrm{tv}}$ (see also Lemma 7.423).

Step 1 (nonemptiness). By (i), E_{law} is bounded below and nonincreasing, hence the limit $E_\infty := \lim_{v\to\infty} E_{\mathrm{law}}(e^v) \geq 0$ exists. If $E_\infty > \varepsilon_{\mathrm{plat}}$ then the admissible set in eq. (7.551) is empty and, by definition, $\ell_R = +\infty$. Otherwise there exists $v_1 \geq v_\star$ with $E_{\mathrm{law}}(e^{v_1}) \leq \varepsilon_{\mathrm{plat}}$. Item (ii) ensures the slope constraint $\psi \geq \varsigma_{\min}$ holds on all of $\mathcal{I}_{\mathrm{IR}}$ (and, more generally, cannot be violated within the window by Lemma 7.423(3)). Hence every $v \geq v_1$ satisfies both constraints in eq. (7.551), so the admissible set is nonempty.

Step 2 (attainment of the infimum). The sublevel set $\{\, v \in \mathcal{I}_{\mathrm{IR}} : E_{\mathrm{law}}(e^v) \le \varepsilon_{\mathrm{plat}} \,\}$ is closed by continuity (i), and intersecting with the ray $[v_\star, \infty)$ yields a closed ray $[v_R, \infty)$. Since the slope constraint is already ensured on $\mathcal{I}_{\mathrm{IR}}$ by (ii), the admissible set equals $[v_R, \infty)$. Therefore its infimum is attained at v_R, and setting $\ell_R := e^{v_R}$ produces the claimed attainment.

Step 3 (first–attainment uniqueness). Nonincreasing E_{law} implies that once the inequality $E_{\mathrm{law}}(e^v) \le \varepsilon_{\mathrm{plat}}$ holds, it holds for all larger v. Thus v_R is the unique *first* point where the sublevel set begins (no earlier point can satisfy the bound), giving the stated uniqueness. Equivalently, when $E_{\mathrm{law}} = D$ one has $D'(v) = -\psi(v) \le -\varsigma_{\min} < 0$ by (ii), so D is strictly decreasing on $\mathcal{I}_{\mathrm{IR}}$ and the crossing with the level $\varepsilon_{\mathrm{plat}}$ is unique.

Step 4 (stability / Kato–type continuity). Consider a perturbation $E_{\mathrm{law}} \mapsto \widetilde{E}_{\mathrm{law}} = E_{\mathrm{law}} + \delta E$ with $\|\delta E\|_{C^0(\mathcal{I}_{\mathrm{IR}})} \le \eta$, preserving (ii)–(iii) (this is ensured by Proposition 7.424 together with the curvature/TV guard). Let v_R and $\tilde{v}_R$ be the corresponding first–attainment points. By the mean–value theorem applied to D (or more generally to E_{law} identified with D in Step 0),

$$\varepsilon_{\mathrm{plat}} - E_{\mathrm{law}}(e^{\tilde{v}_R}) = D(e^{v_R}) - D(e^{\tilde{v}_R}) = -\psi(\xi)\,(\tilde{v}_R - v_R) \quad \text{for some } \xi \in [v_R, \tilde{v}_R],$$

hence $|\tilde{v}_R - v_R| \le \frac{|\widetilde{E}_{\mathrm{law}}(e^{\tilde{v}_R}) - E_{\mathrm{law}}(e^{\tilde{v}_R})|}{\psi(\xi)} \le \eta/\varsigma_{\min}$ using (ii). The curvature bound $\sup_{\mathcal{I}_{\mathrm{IR}}} |\psi'| \le \varepsilon_{\mathrm{curv}}$ (from (7.548)) provides a Lipschitz control on ψ (Lemma 7.423(1)), ensuring that linearization errors in the above argument remain uniformly controlled on compact subintervals of $\mathcal{I}_{\mathrm{IR}}$. Therefore v_R (and thus $\ell_R = e^{v_R}$) depends continuously on $(\varepsilon_{\mathrm{plat}}, \varsigma_{\min})$ and on E_{law} under C^0 perturbations dominated by the guard; this is the asserted Kato–type continuity.

All statements persist under admissible pipeline moves by Proposition 7.424 and Remark 7.391, which keep the guards and windows comparable up to the plateau budgets. □

Intuition. Inside the IR window, the guard (7.548) and the positivity condition of Definition 7.392 yield a uniformly positive robust slope $\psi = \varsigma^{(\tau)}_{\mathrm{law}}$ with controlled curvature/TV, so the law deficit $D(v) = 1 - (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v)$ decreases monotonically: $D'(v) = -\psi(v) \le -\varsigma_{\min}$ (Definition 7.385 and Lemmas 7.395 and 7.423). Consequently, the first entry into the tolerance band $D \le \varepsilon_{\mathrm{plat}}$ is unique and attained at v_R (hence $\ell_R = e^{v_R}$); see Proposition 7.432. Moreover, perturbations upstream (gauge/presentation or admissible pipeline moves) change ψ and ψ' only within the plateau budgets, so v_R shifts by at most a controlled amount (Kato-type continuity), cf. Proposition 7.424 and Remark 7.391.

Lemma 7.433 (Scaling covariance and tolerance monotonicity)**.** *Let the restoration set be*

$$\mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}) := \Big\{\, v \in \mathcal{I}_{\mathrm{IR}} \;:\; E_{\mathrm{law}}(e^v) \le \varepsilon_{\mathrm{plat}} \;\; \textit{and} \;\; \psi(v) \ge \varsigma_{\min} \,\Big\}, \qquad \psi(v) := \varsigma^{(\tau)}_{\mathrm{law}}(v),$$

and define $v_R := \inf \mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min})$ *with* $\ell_R := e^{v_R}$ *as in eq. (7.551). Then:*

Scaling covariance in v; invariance of the physical ℓ_R.

For any $a > 0$, under $\ell \mapsto a\,\ell$ one has $v \mapsto v + \ln a$ and

$$\psi(\,\cdot\,) \;\mapsto\; \psi(\,\cdot\, + \ln a) \quad \textit{and} \quad \mathcal{I}_{\mathrm{IR}} \;\mapsto\; \mathcal{I}_{\mathrm{IR}} + \ln a,$$

by Proposition 7.387 and Lemma 7.393. Consequently,

$$\mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}) \;\mapsto\; \mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}) - \ln a, \quad \textit{so} \quad v_R \;\mapsto\; v_R - \ln a.$$

Therefore the physical restoration length $\ell_R = e^{v_R}$ is invariant under $\ell \mapsto a\,\ell$. (Equivalently, in the purely numerical ℓ-coordinate without unit conversion, v-translation by $+\ln a$ sends ℓ_R to ℓ_R/a; restoring the units recovers the same physical ℓ_R.)

Tolerance monotonicity.

If $\varepsilon_{\mathrm{plat}}$ increases and/or $\varsigma_{\min}$ decreases, then v_R does not increase (hence ℓ_R does not increase). Conversely, tightening either tolerance makes v_R (and thus ℓ_R) weakly larger.

Proof. (1) The covariance statements for ψ and $\mathcal{I}_{\mathrm{IR}}$ follow from Proposition 7.387 and Lemma 7.393. Since E_{law} is a function of e^v, the inequality $E_{\mathrm{law}}(e^v) \le \varepsilon_{\mathrm{plat}}$ is likewise invariant under the translation $v \mapsto v + \ln a$. Hence the restoration set translates rigidly:

$$v \in \mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}) \iff v + \ln a \in \mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}) + \ln a,$$

so inf shifts by $-\ln a$. Passing back to $\ell = e^v$ gives $\ell'_R = e^{v_R - \ln a} = \ell_R/a$ at the level of the raw coordinate; interpreting the map $\ell \mapsto a\ell$ as a change of units recovers the same physical ℓ_R.

(2) Write explicitly

$$\mathcal{A}(\varepsilon, \sigma) = \Big(\underbrace{\{v \in \mathcal{I}_{\mathrm{IR}} : E_{\mathrm{law}}(e^v) \le \varepsilon\}}_{=:A_\varepsilon} \Big) \cap \Big(\underbrace{\{v \in \mathcal{I}_{\mathrm{IR}} : \psi(v) \ge \sigma\}}_{=:B_\sigma} \Big).$$

If $\varepsilon_2 \ge \varepsilon_1$, then $A_{\varepsilon_1} \subseteq A_{\varepsilon_2}$; if $\sigma_2 \le \sigma_1$, then $B_{\sigma_1} \subseteq B_{\sigma_2}$. Therefore $\mathcal{A}(\varepsilon_1, \sigma_1) \subseteq \mathcal{A}(\varepsilon_2, \sigma_2)$ whenever $\varepsilon_2 \ge \varepsilon_1$ and $\sigma_2 \le \sigma_1$, which yields

$$\inf \mathcal{A}(\varepsilon_2, \sigma_2) \le \inf \mathcal{A}(\varepsilon_1, \sigma_1).$$

Thus relaxing tolerances cannot increase v_R (and hence cannot increase $\ell_R = e^{v_R}$). The converse inclusion for tightened tolerances is immediate. These set–inclusion arguments apply whether $\mathcal{A}$ is empty (interpreting $\inf \varnothing = +\infty$) or nonempty; when nonempty, existence/attainment and "first" uniqueness follow from Proposition 7.432. □

Intuition. Changing the ruler (scale translation in v) shifts where the conditions are met in v but leaves the physical ℓ_R unchanged; loosening the bounds enlarges the admissible set, so the first attainment cannot move to the right.

Lemma 7.434 (Mollified vs. pointwise restoration lengths)**.** *Let LP_{τ_E} be as in Definition 7.380 with kernel moments eq. (7.538) and finite second moment $m_2(W) := \int u^2 W(u)\,du < \infty$. On an IR window $\mathcal{I}_{\mathrm{IR}}$ where $\Lambda_{\mathrm{law}} \in C^2$ and the guards (7.548) hold, the pointwise bias satisfies*

$$\boxed{\left|(\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(v) - \Lambda_{\mathrm{law}}(v)\right| \le \frac{m_2(W)}{2}\,\tau_E^2 \sup_{s \in \mathcal{I}_{\mathrm{IR}}} \left|\Lambda''_{\mathrm{law}}(s)\right| + \mathcal{O}(\tau_E^4),} \tag{7.555}$$

uniformly on compact v-subsets of $\mathcal{I}_{\mathrm{IR}}$ (Proposition 7.382 and Lemma 7.381). Let v_R (resp. $v_R^{(\tau_E)}$) be the first–attainment point of the restoration set $\mathcal{A}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min})$ in eq. (7.551) when

$E_{\mathrm{law}}(v) = 1 - \Lambda_{\mathrm{law}}(v)$ *(resp.* $E^{(\tau_E)}_{\mathrm{law}}(v) := 1 - (\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(v)$*). If, in addition, the slope guard holds with* $\psi(v) := \varsigma^{(\tau)}_{\mathrm{law}}(v) \geq \varsigma_{\min} > 0$ *on* $\mathcal{I}_{\mathrm{IR}}$ *(Definitions 7.385 and 7.392), then*

$$\boxed{\left| v_R^{(\tau_E)} - v_R \right| \;\leq\; \frac{m_2(W)}{2}\,\frac{\tau_E^2}{\varsigma_{\min}}\,\sup_{s\in\mathcal{I}_{\mathrm{IR}}}\left|\Lambda''_{\mathrm{law}}(s)\right| \;+\; \mathcal{O}\Big(\frac{\tau_E^4}{\varsigma_{\min}}\Big).} \tag{7.556}$$

Consequently,

$$\ell_R^{(\tau_E)} = e^{v_R^{(\tau_E)}} = e^{v_R + \mathcal{O}(\tau_E^2/\varsigma_{\min})} = \ell_R\Big(1 + \mathcal{O}\big(\tfrac{\tau_E^2}{\varsigma_{\min}}\big)\Big), \tag{7.557}$$

i.e. the mollified and pointwise restoration lengths differ by a second–order amount controlled by $\tau_E^2/\varsigma_{\min}$ *(cf. Lemma 7.433 for the* $v \leftrightarrow \ell$ *translation).*

Proof. Bias bound (7.555). Apply Proposition 7.382 with $f = \Lambda_{\mathrm{law}}$: under eq. (7.538) and $m_2(W) < \infty$,

$$(\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(v) = \Lambda_{\mathrm{law}}(v) + \frac{\tau_E^2 m_2(W)}{2}\,\Lambda''_{\mathrm{law}}(v) + \mathcal{O}(\tau_E^4)$$

uniformly on compact v-ranges; taking absolute values and a supremum over $s \in \mathcal{I}_{\mathrm{IR}}$ yields (7.555). (Regularity on $\mathcal{I}_{\mathrm{IR}}$ follows from the acceptance/guard pipeline and the Kato–type exchange used in Proposition 7.383.)

Shift of the first–attainment point (7.556). Let $D(v) := 1 - \Lambda_{\mathrm{law}}(v)$, $D^{(\tau_E)}(v) := 1 - (\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(v)$. By (7.555), $\Delta(v) := D^{(\tau_E)}(v) - D(v)$ satisfies $\|\Delta\|_{L^\infty(\mathcal{I}_{\mathrm{IR}})} \leq C_2\,\tau_E^2 + \mathcal{O}(\tau_E^4)$ with $C_2 := \frac{m_2(W)}{2}\sup_{\mathcal{I}_{\mathrm{IR}}}|\Lambda''_{\mathrm{law}}|$. Let v_R be the (unique, attained) first solution of $D(v) \leq \varepsilon_{\mathrm{plat}}$ that also meets the slope guard on $\mathcal{I}_{\mathrm{IR}}$ (Proposition 7.432). By the slope positivity $\psi \geq \varsigma_{\min}$ on $\mathcal{I}_{\mathrm{IR}}$ (Definition 7.392) and $\psi = \frac{d}{dv}(\mathsf{LP}_\tau\Lambda_{\mathrm{law}})$ (Definition 7.385), one has $D'(v) = -\psi(v) \leq -\varsigma_{\min}$. A mean–value argument gives, for v near v_R,

$$D(v) - \varepsilon_{\mathrm{plat}} = \Big(D'(v^*)\Big)\,(v - v_R) \quad \text{for some } v^* \text{ between } v \text{ and } v_R,$$

hence $|v - v_R| \leq |D(v) - \varepsilon_{\mathrm{plat}}|/\varsigma_{\min}$. Evaluating at any v with $D^{(\tau_E)}(v) = \varepsilon_{\mathrm{plat}}$ (in particular $v = v_R^{(\tau_E)}$, the first such point for $D^{(\tau_E)}$),

$$|v_R^{(\tau_E)} - v_R| \leq \frac{|D^{(\tau_E)}(v_R^{(\tau_E)}) - D(v_R^{(\tau_E)})|}{\varsigma_{\min}} = \frac{|\Delta(v_R^{(\tau_E)})|}{\varsigma_{\min}} \leq \frac{C_2}{\varsigma_{\min}}\,\tau_E^2 + \mathcal{O}\Big(\frac{\tau_E^4}{\varsigma_{\min}}\Big),$$

which is (7.556). (Existence/uniqueness of $v_R^{(\tau_E)}$ follows as in Proposition 7.432, since the guard (7.548) is unaffected by the auxiliary smoothing LP_{τ_E}.)

From v *to* ℓ. Writing $\ell_R^{(\tau_E)} = e^{v_R^{(\tau_E)}} = e^{v_R + \delta v}$ with $|\delta v| = \mathcal{O}(\tau_E^2/\varsigma_{\min})$, a first–order expansion yields $\ell_R^{(\tau_E)} = \ell_R(1 + \mathcal{O}(\tau_E^2/\varsigma_{\min}))$, which is (7.557); cf. Lemma 7.433 for scaling covariance between v and ℓ. □

Intuition. The low–pass LP_{τ_E} preserves mass and first moment (eq. (7.538)), so with bounded curvature the bias is second order in τ_E (Proposition 7.382). A vertical perturbation of size $\mathcal{O}(\tau_E^2)$ shifts the first crossing by at most $\mathcal{O}(\tau_E^2/\varsigma_{\min})$, thanks to the uniform slope floor on $\mathcal{I}_{\mathrm{IR}}$ (Definition 7.392, Lemma 7.423, and Proposition 7.432).

Proposition 7.435 (UV–uniform restoration: bounds and monotonicity)**.** *Let $\mathcal{U} \subset \mathbb{R}$ be an admissible UV strip in $u = \ln \lambda_{\mathrm{UV}}$. For each $u \in \mathcal{U}$, let*

$$\psi(v;u) := \varsigma_{\mathrm{law}}^{(\tau)}(v;u) = \tfrac{d}{dv}\big(\mathsf{LP}_\tau \Lambda_{\mathrm{law}}\big)(v;u) \quad \textit{(cf. Definition 7.385 and Lemma 7.386)},$$

and define the per–slice admissible set

$$\mathcal{A}(u;\varepsilon_{\mathrm{plat}},\varsigma_{\min}) := \Big\{ v \in \mathcal{I}_{\mathrm{IR}}(u) \ : \ E_{\mathrm{law}}(e^v;u) \le \varepsilon_{\mathrm{plat}} \ \ \textit{and} \ \ \psi(v;u) \ge \varsigma_{\min} \Big\}$$

(cf. Definitions 7.392 and 7.420), with per–slice restoration point $v_R(u) := \inf \mathcal{A}(u;\varepsilon_{\mathrm{plat}},\varsigma_{\min})$ (so $\ell_R(u) = e^{v_R(u)}$; eq. (7.551)). Define the UV–uniform admissible set and restoration point as

$$\mathcal{A}[\mathcal{U};\varepsilon_{\mathrm{plat}},\varsigma_{\min}] := \bigcap_{u\in\mathcal{U}} \mathcal{A}(u;\varepsilon_{\mathrm{plat}},\varsigma_{\min}), \qquad v_R^{[\mathcal{U}]} := \inf \mathcal{A}[\mathcal{U};\varepsilon_{\mathrm{plat}},\varsigma_{\min}],$$

so that $\ell_R^{[\mathcal{U}]} := e^{v_R^{[\mathcal{U}]}}$ (cf. eq. (7.553)). Then:

(i) $\ell_R^{[\mathcal{U}]} \ge \sup_{u\in\mathcal{U}} \ell_R(u)$.

(ii) If $\mathcal{U}_1 \subseteq \mathcal{U}_2$ then $\ell_R^{[\mathcal{U}_2]} \ge \ell_R^{[\mathcal{U}_1]}$.

(iii) $\ell_R^{[\mathcal{U}]}$ obeys the scaling covariance and tolerance monotonicity of Lemma 7.433.

Proof. Preliminaries. By construction, $\mathcal{A}[\mathcal{U};\varepsilon,\sigma] = \bigcap_{u\in\mathcal{U}} \mathcal{A}(u;\varepsilon,\sigma)$ and $v_R^{[\mathcal{U}]} = \inf \mathcal{A}[\mathcal{U};\varepsilon,\sigma]$, while $v_R(u) = \inf \mathcal{A}(u;\varepsilon,\sigma)$ for each u. Throughout, interpret $\inf \varnothing = +\infty$.

(1) *Lower bound by the worst slice.* Let $v^\sharp := \sup_{u\in\mathcal{U}} v_R(u)$. If $v < v^\sharp$ then there exists u^* with $v < v_R(u^*)$, hence $v \notin \mathcal{A}(u^*;\varepsilon_{\mathrm{plat}},\varsigma_{\min})$. Therefore $v \notin \bigcap_{u\in\mathcal{U}} \mathcal{A}(u;\varepsilon_{\mathrm{plat}},\varsigma_{\min})$, so $v < \inf \mathcal{A}[\mathcal{U};\varepsilon_{\mathrm{plat}},\varsigma_{\min}] = v_R^{[\mathcal{U}]}$. Taking the contrapositive gives $v_R^{[\mathcal{U}]} \ge \sup_u v_R(u)$. Exponentiating yields the stated inequality for ℓ_R.

(2) *Monotonicity in the UV strip.* If $\mathcal{U}_1 \subseteq \mathcal{U}_2$, then

$$\mathcal{A}[\mathcal{U}_2;\varepsilon,\sigma] = \bigcap_{u\in\mathcal{U}_2} \mathcal{A}(u;\varepsilon,\sigma) \ \subseteq \ \bigcap_{u\in\mathcal{U}_1} \mathcal{A}(u;\varepsilon,\sigma) = \mathcal{A}[\mathcal{U}_1;\varepsilon,\sigma].$$

Hence $\inf \mathcal{A}[\mathcal{U}_2;\varepsilon,\sigma] \ge \inf \mathcal{A}[\mathcal{U}_1;\varepsilon,\sigma]$, i.e. $v_R^{[\mathcal{U}_2]} \ge v_R^{[\mathcal{U}_1]}$, and thus $\ell_R^{[\mathcal{U}_2]} \ge \ell_R^{[\mathcal{U}_1]}$.

(3) *Scaling covariance and tolerance monotonicity.* Fix $a > 0$. By Proposition 7.387 and Lemma 7.393, under $\ell \mapsto a\ell$ one has $v \mapsto v + \ln a$, $\psi(\cdot;u) \mapsto \psi(\cdot + \ln a;u)$, and $\mathcal{I}_{\mathrm{IR}}(u) \mapsto \mathcal{I}_{\mathrm{IR}}(u) + \ln a$, so each $\mathcal{A}(u;\varepsilon,\sigma)$ translates rigidly by $-\ln a$ in v. Intersections commute with translations; hence $\mathcal{A}[\mathcal{U};\varepsilon,\sigma] \mapsto \mathcal{A}[\mathcal{U};\varepsilon,\sigma] - \ln a$ and $v_R^{[\mathcal{U}]} \mapsto v_R^{[\mathcal{U}]} - \ln a$. Passing back to $\ell = e^v$ gives invariance of the *physical* $\ell_R^{[\mathcal{U}]}$, as in Lemma 7.433(1).

For tolerances, write $\mathcal{A}(u;\varepsilon,\sigma) = A_\varepsilon(u) \cap B_\sigma(u)$ with $A_\varepsilon(u) := \{v : E_{\mathrm{law}}(e^v;u) \le \varepsilon\}$ and $B_\sigma(u) := \{v : \psi(v;u) \ge \sigma\}$. If $\varepsilon_2 \ge \varepsilon_1$ and $\sigma_2 \le \sigma_1$, then $A_{\varepsilon_1}(u) \subseteq A_{\varepsilon_2}(u)$ and $B_{\sigma_1}(u) \subseteq B_{\sigma_2}(u)$ for every u, hence

$$\mathcal{A}[\mathcal{U};\varepsilon_1,\sigma_1] = \bigcap_u \big(A_{\varepsilon_1}(u) \cap B_{\sigma_1}(u)\big) \ \subseteq \ \bigcap_u \big(A_{\varepsilon_2}(u) \cap B_{\sigma_2}(u)\big) = \mathcal{A}[\mathcal{U};\varepsilon_2,\sigma_2].$$

Thus $\inf \mathcal{A}[\mathcal{U};\varepsilon_2,\sigma_2] \le \inf \mathcal{A}[\mathcal{U};\varepsilon_1,\sigma_1]$, i.e. relaxing tolerances cannot increase $v_R^{[\mathcal{U}]}$ (nor $\ell_R^{[\mathcal{U}]}$), and tightening them cannot decrease it—exactly as in Lemma 7.433(2). □

Intuition. A single restoration length must satisfy the constraints for *every* UV slice in $\mathcal{U}$, so it cannot be smaller than the worst per–slice requirement and increases when the strip widens; changing rulers only translates v and leaves the physical $\ell_R^{[\mathcal{U}]}$ unchanged, while looser thresholds enlarge the admissible intersection and can only move the first attainment to the left.

Existence and stability.

Corollary 7.436 (Existence and stability summary)**.** *Assume the hypotheses of Proposition 7.432 on an IR window $\mathcal{I}_{\mathrm{IR}}$ and the kernel conditions of Definition 7.380 and eq. (7.538) (with finite $m_2(W)$). Then the restoration length $\ell_R = e^{v_R}$ exists, is the unique first–attainment of the tolerance $\varepsilon_{\mathrm{plat}}$, and the map*

$$(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}, \tau, \tau_E) \;\longmapsto\; \ell_R^{(\tau_E)}(\varepsilon_{\mathrm{plat}}, \varsigma_{\min}, \tau)$$

is continuous at $\tau_E = 0$, where $\ell_R^{(0)} = \ell_R$. Moreover, as $\tau_E \to 0$,

$$\boxed{\ell_R^{(\tau_E)} = \ell_R\Big(1 + \mathcal{O}\Big(\tfrac{\tau_E^2}{\varsigma_{\min}}\Big)\Big),} \tag{7.558}$$

with the implicit constant depending on $m_2(W)$ and $\sup_{\mathcal{I}_{\mathrm{IR}}} |\Lambda''_{\mathrm{law}}|$ (cf. Lemma 7.434).

Proof. Existence/first–attainment and tolerance continuity. By Proposition 7.432, the admissible set in eq. (7.551) is nonempty whenever $E_\infty \le \varepsilon_{\mathrm{plat}}$, its infimum is attained at v_R, and v_R is the unique first–attainment point. The same proposition yields (Kato–type) continuity of v_R (hence ℓ_R) with respect to $\varepsilon_{\mathrm{plat}}$ and $\varsigma_{\min}$ under the slope floor and curvature/TV guards (7.548).

Continuity in τ. The robust slope $\psi(v;\tau) = \varsigma_{\mathrm{law}}^{(\tau)}(v) = \frac{d}{dv}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v)$ depends continuously on τ in L^∞, since $\|W_\tau - W_{\tilde\tau}\|_{L^1} \to 0$ as $\tilde\tau \to \tau$ and $\|\mathsf{LP}_\tau f - \mathsf{LP}_{\tilde\tau} f\|_\infty \le \|W_\tau - W_{\tilde\tau}\|_1 \|f\|_\infty$ (Lemma 7.381(1),(4)). The guard quantities in (7.548) thus vary continuously with τ, and the first–attainment map inherits continuity by the same Kato–type argument used in Proposition 7.432.

Continuity in τ_E and bias rate. Let $D(v) = 1 - \Lambda_{\mathrm{law}}(v)$ and $D^{(\tau_E)}(v) = 1 - (\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(v)$. By Lemma 7.434,

$$\|D^{(\tau_E)} - D\|_{L^\infty(\mathcal{I}_{\mathrm{IR}})} \;\le\; C_2\, \tau_E^2 + \mathcal{O}(\tau_E^4),$$

with $C_2 = \frac{m_2(W)}{2} \sup_{\mathcal{I}_{\mathrm{IR}}} |\Lambda''_{\mathrm{law}}|$. The first–attainment shift in v is bounded by the vertical bias divided by the slope floor:

$$|v_R^{(\tau_E)} - v_R| \;\le\; \frac{\|D^{(\tau_E)} - D\|_{L^\infty(\mathcal{I}_{\mathrm{IR}})}}{\varsigma_{\min}} \;=\; \mathcal{O}\Big(\frac{\tau_E^2}{\varsigma_{\min}}\Big),$$

using $\psi \ge \varsigma_{\min}$ on $\mathcal{I}_{\mathrm{IR}}$ (Definitions 7.385 and 7.392) and the mean–value estimate as in Proposition 7.432. Passing to $\ell = e^v$ gives (7.558) (cf. Lemma 7.433 for the $v \leftrightarrow \ell$ translation). This shows continuity at $\tau_E = 0$ and the stated bias rate.

All statements are compatible with gauge/presentation safety and pipeline moves by Proposition 7.424 and Remark 7.391. □

Discrete estimator (audit path).

Definition 7.437 (Discrete restoration length estimator)**.** Let $v_k = v_0 + k\,h$ (so $\ell_k = e^{v_k}$) be a uniform log–scale grid. Let $\mathsf{LP}_{\tau,h}$ and $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}$ be as in Definition 7.409 and eq. (7.547), with D_0 from Definition 7.406. Working on the eroded index set so that $\{k \pm 1\} \cup \{k-m, \dots, k+m\}$ exist, define

$$\boxed{k_R := \min\Big\{k \geq k_{\min} :\ E_{\mathrm{law}}(v_k) \leq \varepsilon_{\mathrm{plat}} \ \text{ and } \ \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_j) \geq \varsigma_{\min} \ \ \forall\, j \geq k\Big\}, \qquad \widehat{\ell}_R := e^{v_{k_R}}.} \tag{7.559}$$

Definition 7.438 (Discrete curvature/TV guards (audit guard))**.** On an index interval $I = \{k_a, \dots, k_b\}$ (with $k_a \leq k_b$ in the eroded set), let

$$\psi_k := \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k) = (\mathsf{D}_0\,\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k, \quad (\mathsf{D}_2 f)_k := \frac{f_{k+1} - 2f_k + f_{k-1}}{h^2}.$$

Define the discrete guards (mirroring eq. (7.548)) by

$$\max_{k \in I^-} \big|(\mathsf{D}_2\,\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k\big| \ \leq\ \varepsilon_{\mathrm{curv}}, \qquad \mathrm{TV}_{h;I}[\psi] := \sum_{k \in I^-} \big|\psi_{k+1} - \psi_k\big| \ \leq\ \varepsilon_{\mathrm{tv}},$$

where $I^- := \{k_a + 1, \dots, k_b - 1\}$.

Remark 7.439 (Audit properties, guards, and references)**.** (i) *Stability and ripple suppression.* By Lemma 7.415, $\big|\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_k)\big| \leq \|w\|_{\ell^1}\,\|\Lambda'_{\mathrm{law}}\|_\infty$, and the DTFT symbol $\widehat{\varsigma}(\xi) = \frac{i \sin \xi}{h}\widehat{W}(\xi)$ shows high–frequency attenuation for symmetric stencils ($w_{-j} = w_j$).

(ii) *Commutation and affine exactness.* D_0 commutes with $\mathsf{LP}_{\tau,h}$ and is exact on affine trends (Lemma 7.412 and Corollary 7.400); thus the guard is insensitive to linear drifts in v.

(iii) *Consistency with the continuum.* Under C^3 regularity and cell–average weights (Definition 7.398), $(\mathsf{D}_0\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k = \varsigma^{(\tau)}_{\mathrm{law}}(v_k) + \mathcal{O}(h^2)$ (Proposition 7.413); together with Proposition 7.432 this implies that, when the guards of Definition 7.438 hold on the forward tail $\{k \geq k_R\}$,

$$v_{k_R} = v_R + \mathcal{O}(h) \quad \text{and} \quad \widehat{\ell}_R = e^{v_{k_R}} = \ell_R\big(1 + \mathcal{O}(h)\big),$$

up to grid quantization in v (compare Corollary 7.436).

(iv) *Scaling and tolerance monotonicity.* The discrete estimator inherits the scaling covariance in v and physical invariance in ℓ, as well as tolerance monotonicity, from the continuum statements in Lemma 7.433 applied on the grid (set–inclusion arguments pass to the discrete admissible sets).

(v) *Boundary hygiene.* Using an eroded index set ensures the needed samples exist. If a full-support evaluation is preferred, admissible extensions (periodic/zero–padded/mirrored) preserve commutation of D_0 and $\mathsf{LP}_{\tau,h}$ on the extended grid (Proposition 7.404); state affine exactness only on the eroded set (Remark 7.405).

Intuition. $\widehat{\ell}_R$ is the grid–quantized *first–attainment* of the tolerance with a forward slope floor: once E_{law} is within $\varepsilon_{\mathrm{plat}}$ and $\psi_k \geq \varsigma_{\min}$ holds for all future indices, k_R is locked (guards in Definition 7.438 prevent false positives from local overshoots), consistent with the continuum ℓ_R and robust under smoothing and pipeline moves (Corollary 7.436 and Proposition 7.424).

Lemma 7.440 (Consistency and rate of the discrete estimator)**.** *Assume the hypotheses of Proposition 7.432 on an IR window $\mathcal{I}_{\mathrm{IR}}$ and that (i) $\Lambda_{\mathrm{law}} \in C^3$ on $\mathcal{I}_{\mathrm{IR}}$; (ii) the slope stencil D_0 and discrete low–pass $\mathsf{LP}_{\tau,h}$ are as in Definitions 7.406 and 7.409; (iii) the kernel satisfies eq. (7.538) with finite $m_2(W)$ and the cell–average weights Definition 7.398. Let $\widehat{\ell}_R$ be the discrete restoration length from Definition 7.437 and ℓ_R the continuum one from eq. (7.551). Then, as $h \to 0$ with τ, τ_E fixed,*

$$\boxed{\left|v_{k_R} - v_R\right| \;\le\; h \;+\; \frac{C}{\varsigma_{\min}}\Big(h^2 + \tau_E^2\Big), \qquad v_{k_R} = \ln \widehat{\ell}_R, \quad v_R = \ln \ell_R,} \tag{7.560}$$

where C depends on $m_2(W)$ and $\sup_{\mathcal{I}_{\mathrm{IR}}} |\Lambda''_{\mathrm{law}}|$, but not on h. Consequently,

$$\boxed{\left|\widehat{\ell}_R - \ell_R\right| \;\le\; \ell_R\Big(h \;+\; \frac{C}{\varsigma_{\min}}\Big(h^2 + \tau_E^2\Big)\Big)\,\Big(1 + \mathcal{O}(h)\Big),} \tag{7.561}$$

so $\widehat{\ell}_R \to \ell_R$ as $h \to 0$. If, instead of the grid index k_R, a de–quantized (linearly interpolated) crossing $\tilde{v}_R \in [v_{k_R-1}, v_{k_R}]$ is reported, then the leading h term in (7.560) is absent:

$$\left|\tilde{v}_R - v_R\right| \;\le\; \frac{C}{\varsigma_{\min}}\Big(h^2 + \tau_E^2\Big). \tag{7.562}$$

All bounds hold uniformly over admissible UV strips for the uniform estimator $\widehat{\ell}_R^{[\mathcal{U}]}$ (replace the per–slice sets by the intersections in Proposition 7.435).

Proof. Step 1 (discrete slope vs. robust slope). By Proposition 7.401 and Definition 7.398 and the second–order accuracy of D_0 (Definition 7.406), the composed estimator satisfies

$$\widehat{\psi}_k - \psi(v_k) = \Big(\mathsf{D}_0\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}}\Big)_k - \frac{d}{dv}\Big(\mathsf{LP}_{\tau}\Lambda_{\mathrm{law}}\Big)(v_k) = \mathcal{O}(h^2)$$

uniformly on compact subsets of $\mathcal{I}_{\mathrm{IR}}$; cf. Proposition 7.413 and Lemma 7.412 and the smoothness C^3 (the third derivative enters the truncation error).

Step 2 (mollified pointwise deficit). Write the continuum deficit $D(v) := 1 - (\mathsf{LP}_{\tau}\Lambda_{\mathrm{law}})(v)$ (cf. Lemma 7.395 and Definition 7.385). If an auxiliary measurement mollifier LP_{τ_E} is used (cf. Lemma 7.434), define $D^{(\tau_E)}(v) := 1 - (\mathsf{LP}_{\tau_E}\Lambda_{\mathrm{law}})(v)$. Then Lemma 7.434 yields $\|D^{(\tau_E)} - D\|_{L^\infty(\mathcal{I}_{\mathrm{IR}})} \le C_2\,\tau_E^2 + \mathcal{O}(\tau_E^4)$ with $C_2 = \frac{m_2(W)}{2}\sup_{\mathcal{I}_{\mathrm{IR}}} |\Lambda''_{\mathrm{law}}|$.

Step 3 (vertical error ⇒ horizontal shift). On $\mathcal{I}_{\mathrm{IR}}$, the slope guard of Definition 7.392 gives $\psi \ge \varsigma_{\min} > 0$; hence $D'(v) = -\psi(v) \le -\varsigma_{\min}$ and D is strictly decreasing (Lemma 7.423(3)). Let v_R be the first attainment for D and $v_R^{(\tau_E)}$ the first attainment for $D^{(\tau_E)}$ (both exist and are unique by Proposition 7.432). Then the mean–value estimate (as in Proposition 7.432) gives

$$\left|v_R^{(\tau_E)} - v_R\right| \le \frac{\|D^{(\tau_E)} - D\|_{L^\infty(\mathcal{I}_{\mathrm{IR}})}}{\varsigma_{\min}} \le \frac{C_2}{\varsigma_{\min}}\tau_E^2 + \mathcal{O}\Big(\frac{\tau_E^4}{\varsigma_{\min}}\Big).$$

Step 4 (grid quantization and discrete feasibility). By definition Definition 7.437, k_R is the *first index* at which the discrete feasibility holds. Since D is decreasing with floor

$\varsigma_{\min}$, the continuous crossing v_R must lie in $[v_{k_R-1}, v_{k_R}]$, whence the grid quantization error $|v_{k_R} - v_R| \le h$. To control additional bias from the discrete guards, use Step 1:

$$\widehat{\psi}_k \ge \psi(v_k) - Ch^2 \quad \text{uniformly in } k.$$

For h small enough that $Ch^2 \le \frac{1}{2}\varsigma_{\min}$, the discrete slope guard $\widehat{\psi}_k \ge \varsigma_{\min}$ for all $k \ge k_R$ follows from the continuum guard $\psi \ge \varsigma_{\min}$. Combining with Step 3 (applied to $D^{(\tau_E)}$ if relevant) yields

$$\left|v_{k_R} - v_R\right| \;\le\; h \;+\; \frac{C}{\varsigma_{\min}}\left(h^2 + \tau_E^2\right),$$

for some constant C independent of h, which is (7.560). If a linearly de–quantized crossing $\tilde{v}_R \in [v_{k_R-1}, v_{k_R}]$ is reported (solve the linear model with slope $\widehat{\psi}_{k_R}$), the h term drops, giving (7.562).

Step 5 (from v to ℓ and UV–uniformity). Since $\ell = e^v$, the map $v \mapsto \ell$ is Lipschitz on bounded v-ranges with factor ℓ, giving (7.561). Uniformity over UV strips follows by taking sup/inf in u and using the uniform guard stability in Proposition 7.424 together with the set–inclusion arguments of Proposition 7.435. □

Remark 7.441 (On the roles of h, τ, and τ_E)**.** The bound (7.560) separates: (i) a *quantization* term h intrinsic to grid first–attainment (removed by de–quantization); (ii) a *discrete/measurement bias* $\mathcal{O}(h^2/\varsigma_{\min})$ from D_0 and $\mathsf{LP}_{\tau,h}$ (Proposition 7.401 and Definition 7.406); (iii) an *auxiliary smoothing* bias $\mathcal{O}(\tau_E^2/\varsigma_{\min})$ controlled by Lemma 7.434. The parameter τ defines the *continuum* robust slope and is part of ℓ_R's definition (no extra τ^2 appears here). Scaling/tolerance monotonicity for the discrete estimator follows from Lemma 7.433.

Proposition 7.442 (No false positives under discrete guards)**.** *Let the discrete curvature/TV guards of Definition 7.438 hold on the forward tail $I = \{k_{\min} + m + 1, \dots\}$ of the audit grid $v_k = v_0 + k\,h$ (so all stencil samples exist). If k_R is defined by Definition 7.437 and eq. (7.559), then for all $j \ge k_R$,*

$$E_{\mathrm{law}}(v_j) \le \varepsilon_{\mathrm{plat}} \quad \textit{and} \quad \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_j) =: (\mathsf{D}_0\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_j \;\ge\; \varsigma_{\min}.$$

Hence transient local overshoots of either E_{law} or the discrete slope cannot produce a spurious (premature) index k_R.

Proof. Slope constraint on the forward tail. By Definition 7.437, the index k_R is the *first* grid point such that $\widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_j) \ge \varsigma_{\min}$ for *all* $j \ge k_R$. Thus the slope inequality for $j \ge k_R$ holds by definition (no guard needed). The TV part of Definition 7.438 provides an audit check:

$$\mathrm{TV}_{h;[k_R,\infty)}[\psi] = \sum_{j \ge k_R} \left|\psi_{j+1} - \psi_j\right| \le \varepsilon_{\mathrm{tv}} \quad \text{with} \quad \psi_j := \widehat{\varsigma}^{(\tau)}_{\mathrm{law}}(v_j),$$

ensuring bounded variability of the readout, consistent with Lemma 7.423 at the discrete level.

Persistence of the deficit/tolerance inequality. Introduce the discrete law–deficit

$$D_k := 1 - (\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k \qquad \text{(cf. the continuum } D(v) = 1 - (\mathsf{LP}_\tau\Lambda_{\mathrm{law}})(v) \text{ in Lemma 7.395).}$$

By the three–point identity $f_{k+1}-f_k = h\,(\mathsf{D}_0 f)_k + \frac{h^2}{2}\,(\mathsf{D}_2 f)_k$ (valid for any grid function f, with D_0 as in Definition 7.406 and $\mathsf{D}_2 f_k := (f_{k+1} - 2f_k + f_{k-1})/h^2$), applied to $f_k := (\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k$, one obtains

$$D_{k+1}-D_k = -\big(f_{k+1}-f_k\big) = -\,h\,(\mathsf{D}_0 f)_k - \frac{h^2}{2}\,(\mathsf{D}_2 f)_k = -\,h\,\psi_k - \frac{h^2}{2}\,(\mathsf{D}_2\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k. \tag{7.563}$$

The discrete curvature guard of Definition 7.438 states that $\max_{k\in I^-}\big|(\mathsf{D}_2\mathsf{LP}_{\tau,h}\Lambda_{\mathrm{law}})_k\big| \le \varepsilon_{\mathrm{curv}}$. Combining this with (7.563) and the forward–tail slope floor $\psi_k \ge \varsigma_{\min}$ for all $k \ge k_R$ (from Definition 7.437) gives, for $k \ge k_R$,

$$D_{k+1} - D_k \;\le\; -\,h\,\varsigma_{\min} \;+\; \frac{h^2}{2}\,\varepsilon_{\mathrm{curv}}. \tag{7.564}$$

Hence, provided the grid step obeys the mild CFL–type condition

$$h \;\le\; \frac{2\,\varsigma_{\min}}{\varepsilon_{\mathrm{curv}}}, \tag{7.565}$$

the right–hand side of (7.564) is nonpositive and D_k is nonincreasing for all $k \ge k_R$. At $k = k_R$ the acceptance criterion requires $E_{\mathrm{law}}(v_{k_R}) \le \varepsilon_{\mathrm{plat}}$ (Definition 7.437). Two cases then yield persistence:

• *Canonical (mollified) deficit:* $E_{\mathrm{law}} = D$. If the audit uses $E_{\mathrm{law}}(v_k) = D_k$ (the discrete analogue of the continuum deficit; cf. Lemma 7.395), then

$$D_j \;\le\; D_{k_R} \;\le\; \varepsilon_{\mathrm{plat}} \qquad \forall\, j \ge k_R,$$

by the monotonicity deduced from (7.564)–(7.565).

• *General E_{law} controlled by guards.* If E_{law} is a pointwise (or separately mollified) visibility, assume the standard audit control $|E_{\mathrm{law}}(v_k) - D_k| \le \delta_{\mathrm{aux}}$ with $\delta_{\mathrm{aux}} = \mathcal{O}(\tau_E^2)$ from Lemma 7.434 (or $\mathcal{O}(h^2)$ from Proposition 7.413 when comparing discrete–continuous), uniformly for $k \ge k_R$. Then

$$E_{\mathrm{law}}(v_j) \;\le\; D_j + \delta_{\mathrm{aux}} \;\le\; D_{k_R} + \delta_{\mathrm{aux}} \;\le\; \varepsilon_{\mathrm{plat}} + \delta_{\mathrm{aux}}, \qquad j \ge k_R.$$

If the acceptance threshold incorporates the bias margin (the usual practice in Step 2 audits; cf. Corollary 7.436), the inequality $E_{\mathrm{law}}(v_j) \le \varepsilon_{\mathrm{plat}}$ persists for all $j \ge k_R$. (Equivalently, choose $\varepsilon_{\mathrm{plat}}^{\mathrm{eff}} := \varepsilon_{\mathrm{plat}} - \delta_{\mathrm{aux}}$ in the decision rule.)

Minimality ("first attainment"). By Definition 7.437, k_R is the smallest index that satisfies both inequalities, with the slope floor required on the entire forward tail. Thus no smaller index can be admissible (some constraint fails), excluding premature triggers. □

Remark 7.443 (Relationship to continuum monotonicity)**.** The discrete inequality (7.564) is the grid counterpart of the continuum identity $D'(v) = -\psi(v)$ (cf. Definition 7.385 and Lemma 7.395), with the extra $\frac{h^2}{2}\,\mathsf{D}_2$ term controlled by the discrete curvature guard (Definition 7.438). Under (7.565), the sign of the forward difference matches the continuum sign, preventing false positives from local overshoots. Guard stability across gauges/presentations and pipeline moves follows from Proposition 7.424.

State–coherence guard (uniform in volume).

Definition 7.444 (Uniform state coherence)**.** All restoration statements are conditioned on *state–channel* coherence remaining within the plateau tolerance, *uniformly in the volume* V (cf. the initialization deficits in eq. (7.535) and the plateau criterion in Section 6.12.4):

$$\boxed{\sup_{V} \left| 1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; T^{\star}, V) \right| \;\le\; \varepsilon_{\mathrm{plat}} \qquad \text{for all} \;\; \ell \ge \ell_R.} \tag{7.566}$$

Here ℓ_R is the (law–channel) restoration length defined by eq. (7.551) (see also Proposition 7.432).

Intuition. The guard forbids QII–type volume–induced decoherence in the state channel; any certified restoration is genuinely QIII (law–channel phenomenon), not an artefact of drifting states.

Proposition 7.445 (Separation of QIII vs. QII under the state guard)**.** *Assume the law–channel restoration condition of eq. (7.551) (or its UV–uniform variant eq. (7.553)) holds on an IR window* $\mathcal{I}_{\mathrm{IR}}$ *and the state–coherence guard (7.566) is satisfied. Then the system is in QIII (law–asymmetric, state–symmetric) on* $\mathcal{I}_{\mathrm{IR}}$*. Conversely, if there exist* $V_n \to \infty$ *and* $\ell_n \ge \ell_R$ *such that* $\left|1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell_n; T^{\star}, V_n)\right| > \varepsilon_{\mathrm{plat}}$*, then QIII cannot be certified at those scales.*

Proof. Step 1 (law restoration on $\mathcal{I}_{\mathrm{IR}}$*).* By eq. (7.551) and Proposition 7.432, there exists $v_R = \ln \ell_R$ such that for all $v \in \mathcal{I}_{\mathrm{IR}} \cap [v_R, \infty)$ the law–channel deficit $D(v) := 1 - (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v)$ obeys $D(v) \le \varepsilon_{\mathrm{plat}}$, and the robust slope $\psi(v) := \varsigma^{(\tau)}_{\mathrm{law}}(v)$ satisfies $\psi(v) \ge \varsigma_{\min} > 0$ (cf. Definitions 7.385 and 7.392 and Lemma 7.423).

Step 2 (state symmetry uniformly in V*).* The guard (7.566) gives $\sup_V \left| 1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; T^{\star}, V) \right| \le \varepsilon_{\mathrm{plat}}$ for all $\ell \ge \ell_R$, hence state–channel symmetry within the same tolerance on the whole IR window. This uniformity is stable under admissible limits and smoothing operations used in the pipeline (see Section 6.12.4 and Proposition 7.383).

Step 3 (quadrant identification and safety). By construction (cf. Section 7.8 vs. Section 7.7), QIII is the regime with restored law–channel (Step 1) and state symmetry (Step 2). Gauge/p-resentation safety of these statements follows from Proposition 7.424 and identity–ledger compatibility Remark 7.426.

In **Step 4, we argue by contrapositive:** If there exist $V_n \to \infty$ and $\ell_n \ge \ell_R$ with $\left|1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ll_n; T^{\star}, V_n)\right| > \varepsilon_{\mathrm{plat}}$, then (7.566) fails on those scales, violating the state–symmetry requirement; QIII cannot be certified there (the behaviour is consistent with QII–type decoherence). □

7.8.4 RG Ledger: Breakings Become Irrelevant

Objective. We show that the explicit breaking operators introduced in eq. (7.522) flow to irrelevance toward the IR. Concretely, we identify an IR fixed point for the symmetry-preserving couplings, linearise the RG flow of the breaking couplings, diagonalise the stability matrix to obtain eigen–operators with exponents $y_{\tilde{B}} < 0$, and verify the measured running

$\varepsilon_{\tilde{B}}(\mu) \sim \mu^{y_{\tilde{B}}} \to 0$ as $\mu \downarrow$ (Wilsonian sense [389]; see also [91, 82, 447]). All quoted exponents are reported *after Nielsen projection* to ensure gauge–parameter independence within tolerance [117, 243].

Setup and linearised flow. Let $g^a(\mu)$ denote symmetry–preserving couplings and $\varepsilon_A(\mu)$ the small breaking couplings multiplying the renormalised operators $\{\hat{\mathcal{O}}_A\}$. Near an IR fixed point $g^a(\mu) \to g^a_\star$ we write the linearised RG for the breakings

$$\boxed{\mu \frac{\mathrm{d}\,\varepsilon_A}{\mathrm{d}\mu} = \sum_B Y_{AB}\,\varepsilon_B \;+\; \mathcal{O}(\varepsilon^2), \qquad Y_{AB} := \left.\frac{\partial\,\beta_{\varepsilon_A}}{\partial \varepsilon_B}\right|_{g=g_\star,\ \varepsilon=0}.} \tag{7.567}$$

Equivalently, if the renormalised operators mix as

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu}\,\hat{\mathcal{O}}_A \;=\; -\,\gamma_{AB}\,\hat{\mathcal{O}}_B, \qquad \gamma \;=\; Z^{-1}\,\mu \frac{\mathrm{d}Z}{\mathrm{d}\mu},$$

and the deformation is written with explicit engineering dimensions as

$$\delta S \;=\; \int \mathrm{d}^D x \,\sum_A \varepsilon_A(\mu)\,\mu^{\,D-d_A}\,\hat{\mathcal{O}}_A,$$

then the linearised matrix is

$$\boxed{Y_{AB} \;=\; \gamma_{BA} \;-\; (D-d_A)\,\delta_{AB}}.$$

In particular, if the $\mu^{\,D-d_A}$ factor has already been absorbed into the definition of the (dimensionless) couplings, the canonical piece drops and $Y = \gamma^{\top}$.

Definition 7.446 (Centered log–derivative estimator in RG units)**.** Let $t := \ln \mu$ and suppose $\{\mu_k\}$ is a grid monotone in the IR direction.

$$\boxed{\widehat{y}_{\tilde{B}}(\mu_k) := \frac{1}{2\,\Delta \ln \mu}\,\ln\!\left(\frac{|\widetilde{\varepsilon}_{\tilde{B}}(\mu_{k+1})|}{|\widetilde{\varepsilon}_{\tilde{B}}(\mu_{k-1})|}\right), \qquad \Delta \ln \mu := \ln(\mu_{k+1}) - \ln(\mu_{k-1}),} \tag{7.568}$$

Definition 7.447 (IR fixed point and breaking sector)**.** An *IR fixed point* for the symmetry–preserving sector is a point $g_\star$ with $\beta^a(g_\star) = 0$ such that the linearised stability matrix

$$S^a{}_b \;:=\; \left.\frac{\partial \beta^a}{\partial g^b}\right|_{g_\star}$$

has eigenvalues with nonnegative real parts (IR attraction in the preserving subspace). The *breaking sector* is the vector space spanned by the renormalised operators $\{\hat{\mathcal{O}}_A\}$ with coordinates ε_A, equipped with the linearised flow eq. (7.567).

Intuition. We freeze the symmetric couplings at their IR attractor $g_\star$ and study how tiny explicit breakings ε_A evolve under RG.

Definition 7.448 (Nielsen projection and projected exponents)**.** Let α denote gauge parameters and evaluate correlators *on shell* so that the Nielsen identity eq. (7.581) applies. The *Nielsen projector* $\mathcal{N}(\alpha)$ is a linear, idempotent map on the breaking–operator space V such that

$$\mathcal{N}^2 = \mathcal{N}, \qquad \operatorname{im}\mathcal{N} \cong H^0_{\mathrm{BRST}} \text{ (physical cohomology)}, \qquad \partial_\alpha\big(\mathcal{N}X\big) = 0 \ \text{ for all } X \in V$$

(within admissible tolerance, cf. [117, 243]). For any mixing/stability matrix Z, Y on V (cf. eq. (7.567)), define their *Nielsen–projected* versions by restriction to the physical subspace $W := \operatorname{im}\mathcal{N}$:

$$Z^{\mathcal{N}} := \mathcal{N}\, Z\, \mathcal{N}\big|_W, \qquad Y^{\mathcal{N}} := \mathcal{N}\, Y\, \mathcal{N}\big|_W.$$

The eigenvalues of $Y^{\mathcal{N}}$ are the *Nielsen–projected breaking exponents* $\{y_{\tilde B}\}$, and any associated (right) eigenvectors $\{\tilde v^{(\tilde B)}\} \subset W$ define the *eigen–operators*

$$\widetilde{\mathcal{O}}_{\tilde B} \;:=\; \tilde v^{(\tilde B)}_{A}\, \hat{\mathcal{O}}_A.$$

(Equivalently, choosing a dual left eigenbasis $\{\tilde w^{(\tilde B)}\}$ with $(\tilde w^{(\tilde B)})^{\top}\tilde v^{(\tilde B')} = \delta_{\tilde B\tilde B'}$ sets the associated eigen–couplings $\widetilde{\varepsilon}_{\tilde B} := (\tilde w^{(\tilde B)})^{\top}\varepsilon$, cf. Definition 7.454.)

Intuition. Project onto the on–shell BRST–physical subspace first; read exponents from $Y^{\mathcal{N}}$ there. This removes gauge artefacts (isospectral in α by Proposition 7.458, with the tolerance check in eq. (7.588)).

Definition 7.449 (Jordan nilpotent part, index, and chains)**.** Work on the physical subspace $W := \operatorname{im}\mathcal{N}$ with the Nielsen–projected operator $Y^{\mathcal{N}}$ (cf. Definition 7.448). For each eigenvalue $y_{\tilde B}$ of $Y^{\mathcal{N}}$, let the generalised eigenspace be

$$\mathcal{G}_{\tilde B} \;:=\; \ker\!\Big((Y^{\mathcal{N}} - y_{\tilde B}\mathbb{1}_{\mathcal{K}})^{p}\Big) \quad \text{for sufficiently large } p.$$

Choose a basis of $\mathcal{G}_{\tilde B}$ that brings $Y^{\mathcal{N}}$ to Jordan form

$$Y^{\mathcal{N}}\big|_{\mathcal{G}_{\tilde B}} \;=\; J_{\tilde B} \;:=\; \bigoplus_{j=1}^{n_{\tilde B}} \Big(y_{\tilde B}\mathbb{1}_{m_{\tilde B,j}} + \mathsf{N}_{\tilde B,j}\Big),$$

where each $\mathsf{N}_{\tilde B,j}$ is strictly upper–triangular with $(\mathsf{N}_{\tilde B,j})^{m_{\tilde B,j}} = 0$ and $(\mathsf{N}_{\tilde B,j})^{m_{\tilde B,j}-1} \neq 0$. The nilpotent part on $\mathcal{G}_{\tilde B}$ is

$$\mathsf{N}_{\tilde B} \;:=\; \bigoplus_{j=1}^{n_{\tilde B}} \mathsf{N}_{\tilde B,j}, \qquad \operatorname{ind}\mathsf{N}_{\tilde B} \;:=\; r_{\tilde B} \;:=\; \max_{1\le j\le n_{\tilde B}} m_{\tilde B,j}.$$

For each block j, a (right) Jordan chain of length $m_{\tilde B,j}$, $\{\tilde v^{(\tilde B,j)}_{[k]}\}_{k=0}^{m_{\tilde B,j}-1} \subset \mathcal{G}_{\tilde B}$, satisfies

$$(Y^{\mathcal{N}} - y_{\tilde B}\mathbb{1})\,\tilde v^{(\tilde B,j)}_{[0]} = 0, \qquad (Y^{\mathcal{N}} - y_{\tilde B}\mathbb{1})\,\tilde v^{(\tilde B,j)}_{[k]} = \tilde v^{(\tilde B,j)}_{[k-1]} \quad (k \ge 1).$$

(Optionally pick a biorthogonal left chain $\{\tilde w^{(\tilde B,j)}_{[k]}\}_{k=0}^{m_{\tilde B,j}-1} \subset \mathcal{G}^{*}_{\tilde B}$ with $(\tilde w^{(\tilde B,j)}_{[k]})^{\top}\tilde v^{(\tilde B',j')}_{[\ell]} = \delta_{\tilde B\tilde B'}\delta_{jj'}\delta_{k\ell}$.)

Notation. $\mathcal{N}$ denotes the Nielsen projector (onto W), whereas N denotes the nilpotent Jordan part(s) inside blocks of $Y^{\mathcal{N}}$.
Intuition. Each physical eigenspace $\mathcal{G}_{\tilde{B}}$ decomposes into Jordan blocks; the nilpotent index $r_{\tilde{B}}$ is the length of the longest chain for $y_{\tilde{B}}$. When $r_{\tilde{B}} = 1$ the sector is diagonalizable; if $r_{\tilde{B}} > 1$, solutions of $\mu \frac{\mathrm{d}}{\mathrm{d}\mu} \widetilde{\varepsilon} = Y^{\mathcal{N}} \widetilde{\varepsilon}$ acquire factors $\mu^{y_{\tilde{B}}} (\log \mu)^q$ with $0 \le q < r_{\tilde{B}}$, while (ir)relevance is still governed by $\operatorname{Re} y_{\tilde{B}} < 0$ on W.

Proposition 7.450 (Solution of the linearised flow and irrelevance criterion)**.** *Work on the physical subspace $W := \operatorname{im} \mathcal{N}$ and write $\varepsilon(\mu) \in W$ for the Nielsen–projected breaking–coupling vector. Assume $Y^{\mathcal{N}}$ admits a Jordan decomposition on W. For each eigenvalue $y_{\tilde{B}}$, let its Jordan blocks be indexed by $j = 1, \dots, n_{\tilde{B}}$ with sizes $m_{\tilde{B},j}$, and choose right/left Jordan chains $\{\tilde{v}^{(\tilde{B},j)}_{[k]}\}_{k=0}^{m_{\tilde{B},j}-1}$, $\{\tilde{w}^{(\tilde{B},j)}_{[k]}\}_{k=0}^{m_{\tilde{B},j}-1}$ satisfying $(\tilde{w}^{(\tilde{B},j)}_{[k]})^{\top} \tilde{v}^{(\tilde{B}',j')}_{[\ell]} = \delta_{\tilde{B}\tilde{B}'} \delta_{jj'} \delta_{k\ell}$. Then the solution of the linearised system*

$$\mu \frac{\mathrm{d}\varepsilon}{\mathrm{d}\mu} = Y^{\mathcal{N}} \varepsilon, \qquad \varepsilon(\mu_0) \text{ given},$$

is

$$\boxed{\varepsilon(\mu) = \sum_{\tilde{B}} \sum_{j=1}^{n_{\tilde{B}}} \left(\frac{\mu}{\mu_0}\right)^{y_{\tilde{B}}} \sum_{k=0}^{m_{\tilde{B},j}-1} \frac{\left(\ln \frac{\mu}{\mu_0}\right)^k}{k!} c_{\tilde{B},j,k}\, \tilde{v}^{(\tilde{B},j)}_{[k]}, \qquad c_{\tilde{B},j,k} := \left(\tilde{w}^{(\tilde{B},j)}_{[k]}\right)^{\top} \varepsilon(\mu_0).} \tag{7.569}$$

In particular, if $\operatorname{Re} y_{\tilde{B}} < 0$ for every projected breaking mode (all $\tilde{B}$), then each component of $\varepsilon(\mu)$ decays as $\mu \downarrow 0$ (the polynomial logarithmic factors do not change the limit), and the breakings are irrelevant *in the Wilsonian sense.*

Intuition. Solve the linear ODE in Jordan form: each eigenvalue contributes a power $(\mu/\mu_0)^{y_{\tilde{B}}}$ and each Jordan block adds at most a polynomial in $\log(\mu/\mu_0)$. Strictly negative $\operatorname{Re} y_{\tilde{B}}$ wins against any such polynomial, so all projected breaking components vanish toward the IR.

Proof. By the projected linearised RG eq. (7.567) and the Nielsen projection Definition 7.448, the breaking vector on $W := \operatorname{im} \mathcal{N}$ obeys

$$\mu \frac{\mathrm{d}\varepsilon}{\mathrm{d}\mu} = Y^{\mathcal{N}} \varepsilon \; + \; r(\varepsilon, \mu), \qquad r(\varepsilon, \mu) = \mathcal{O}(\|\varepsilon\|^2).$$

Set $t := \ln(\mu/\mu_0)$ so that $\frac{\mathrm{d}}{\mathrm{d}t} = \mu \frac{\mathrm{d}}{\mathrm{d}\mu}$, giving

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = Y^{\mathcal{N}} \varepsilon + r(\varepsilon, t).$$

Choose a similarity R that brings $Y^{\mathcal{N}}$ to Jordan form on W (cf. Definition 7.449):

$$R^{-1} Y^{\mathcal{N}} R = \bigoplus_{\tilde{B}} \bigoplus_{j=1}^{n_{\tilde{B}}} \left(y_{\tilde{B}} \mathbb{1}_{m_{\tilde{B},j}} + \mathsf{N}_{\tilde{B},j} \right), \qquad (\mathsf{N}_{\tilde{B},j})^{m_{\tilde{B},j}} = 0.$$

Write $\widetilde{\varepsilon} := R^{-1} \varepsilon$. Variation of constants yields

$$\widetilde{\varepsilon}(t) = \mathrm{e}^{(t-t_0)J}\, \widetilde{\varepsilon}(t_0) + \int_{t_0}^{t} \mathrm{e}^{(t-s)J}\, R^{-1} r\Big(R \widetilde{\varepsilon}(s), s\Big)\, \mathrm{d}s, \quad J = \bigoplus_{\tilde{B}} \bigoplus_{j=1}^{n_{\tilde{B}}} \left(y_{\tilde{B}} \mathbb{1}_{m_{\tilde{B},j}} + \mathsf{N}_{\tilde{B},j} \right).$$

For each block, $\mathrm{e}^{(t-t_0)J_{\tilde B,j}} = \mathrm{e}^{y_{\tilde B}(t-t_0)}\sum_{k=0}^{m_{\tilde B,j}-1}\frac{(t-t_0)^k}{k!}(\mathsf{N}_{\tilde B,j})^k$. Expanding the initial data in a (right/left) Jordan basis $\{\tilde v_{[k]}^{(\tilde B,j)}\}$, $\{\tilde w_{[k]}^{(\tilde B,j)}\}$ with $(\tilde w_{[k]}^{(\tilde B,j)})^\top \tilde v_{[\ell]}^{(\tilde B',j')} = \delta_{\tilde B\tilde B'}\delta_{jj'}\delta_{k\ell}$ (see Definition 7.449), we obtain for the *linear* evolution

$$\varepsilon_{\mathrm{lin}}(t) = \sum_{\tilde B}\sum_{j=1}^{n_{\tilde B}} \mathrm{e}^{y_{\tilde B}(t-t_0)} \sum_{k=0}^{m_{\tilde B,j}-1} \frac{(t-t_0)^k}{k!}\, c_{\tilde B,j,k}\, \tilde v_{[k]}^{(\tilde B,j)}, \qquad c_{\tilde B,j,k} := \big(\tilde w_{[k]}^{(\tilde B,j)}\big)^\top \varepsilon(\mu_0).$$

Returning to μ via $t - t_0 = \ln(\mu/\mu_0)$ reproduces the boxed expression eq. (7.569). For the remainder, note that $R^{\pm 1}$ are bounded on the finite-dimensional breaking space and $r(\varepsilon,t) = \mathcal{O}(\|\varepsilon\|^2)$; hence the integral term is $\mathcal{O}(\|\varepsilon\|^2)$ uniformly on compact t-intervals.

If $\mathrm{Re}\, y_{\tilde B} < 0$ for all projected modes, then for each fixed k,

$$\Big(\tfrac{\mu}{\mu_0}\Big)^{y_{\tilde B}}\Big(\ln\tfrac{\mu}{\mu_0}\Big)^k \;\longrightarrow\; 0 \quad \text{as } \mu \downarrow 0,$$

so every linear Jordan component vanishes. For sufficiently small $\|\varepsilon(\mu_0)\|$, a Grönwall estimate applied to $\frac{\mathrm{d}}{\mathrm{d}t}\|\varepsilon\| \le \|Y^{\mathcal{N}}\|\,\|\varepsilon\| + C\|\varepsilon\|^2$ shows that the quadratic remainder cannot overcome the linear decay, and thus $\varepsilon(\mu) \to 0$ componentwise. This proves the irrelevance claim in the Wilsonian sense. □

Intuition. After projecting with Definition 7.448, the flow on W is governed by $Y^{\mathcal{N}}$. Its Jordan structure from Definition 7.449 adds only finite polynomials in $\ln(\mu)$ atop the power $(\mu/\mu_0)^{y_{\tilde B}}$; strict negativity of $\mathrm{Re}\, y_{\tilde B}$ dominates these, and the $\mathcal{O}(\|\varepsilon\|^2)$ term remains subleading for small breakings, yielding eq. (7.569) and decay to zero.

Lemma 7.451 (Basis and scheme covariance)**.** *Let V be the breaking–operator space and $W := \mathrm{im}\,\mathcal{N} \subset V$ the on–shell BRST–physical subspace (cf. Definition 7.448). Under a nonsingular linear mixing $\hat{\mathcal{O}}_A \mapsto M_A{}^B\hat{\mathcal{O}}_B$ that preserves W and the corresponding coupling redefinition that leaves the breaking pairing invariant, the projected stability matrix transforms by similarity on W:*

$$Y^{\mathcal{N}} \;\longmapsto\; Y^{\mathcal{N}\prime} = M_W\, Y^{\mathcal{N}}\, M_W^{-1}, \qquad M_W := \mathcal{N}\, M\, \mathcal{N}\big|_W.$$

Hence the set of projected breaking exponents $\{y_{\tilde B}\}$ (cf. Definition 7.448) is invariant. Moreover, any smooth change of renormalisation scheme implemented by a finite (invertible) renormalisation $F(g,\alpha)$ that preserves W leaves $\{y_{\tilde B}\}$ unchanged at the IR fixed point $g_\star$ (cf. Definition 7.447).

Proof. **(A) Pure basis change in the breaking sector.** Let V^* denote the dual (couplings) and write the breaking deformation as the pairing $\langle \varepsilon, \mathcal{O}\rangle = \sum_A \varepsilon_A \hat{\mathcal{O}}_A$. A basis change $\mathcal{O} \mapsto \mathcal{O}' := M\mathcal{O}$ with $M \in \mathrm{GL}(V)$ induces the dual change $\varepsilon \mapsto \varepsilon' := M^{-T}\varepsilon$ so that $\langle \varepsilon', \mathcal{O}'\rangle = \langle \varepsilon, \mathcal{O}\rangle$. If the linearised RG for couplings reads (cf. eq. (7.567))

$$\mu\,\frac{\mathrm{d}\varepsilon}{\mathrm{d}\mu} = Y^*\,\varepsilon + \mathcal{O}(\varepsilon^2),$$

then

$$\mu\,\frac{\mathrm{d}\varepsilon'}{\mathrm{d}\mu} = M^{-T} Y^* M^T\,\varepsilon' + \mathcal{O}(\varepsilon'^2).$$

Passing to operators ($Y := (Y^*)^T$) gives $Y \mapsto MYM^{-1}$.

Restrict now to $W = \operatorname{im}\mathcal{N}$ (cf. Definition 7.448). By hypothesis $MW \subseteq W$, so $M_W := \mathcal{N}M\mathcal{N}\big|_W : W \to W$ is invertible.[11] The projected matrix $Y^{\mathcal{N}} := \mathcal{N}Y\mathcal{N}\big|_W$ therefore transforms by similarity:

$$Y^{\mathcal{N}} \;\longmapsto\; Y^{\mathcal{N}\prime} = \mathcal{N}(MYM^{-1})\mathcal{N}\big|_W = (\mathcal{N}M\mathcal{N})\,Y^{\mathcal{N}}\,(\mathcal{N}M^{-1}\mathcal{N}) = M_W\,Y^{\mathcal{N}}\,M_W^{-1}.$$

Similarity preserves spectra, hence $\{y_{\tilde{B}}\}$ is invariant under admissible basis changes.

(B) Finite renormalisation (scheme) change at the fixed point. Let $Z(g,\alpha,\mu)$ be the renormalisation matrix on V and define the anomalous–dimension matrix $\gamma := Z^{-1}\mu\,\frac{\mathrm{d}Z}{\mathrm{d}\mu}$; with canonical dimensions separated (see the discussion below eq. (7.567)), write $Y := d - \gamma$ in an operator basis. A smooth scheme change is implemented by a finite, invertible $F(g,\alpha)$:

$$Z \;\longmapsto\; Z' := F\,Z, \qquad \gamma' \;=\; Z'^{-1}\mu\frac{\mathrm{d}Z'}{\mathrm{d}\mu} \;=\; F^{-1}\gamma F \;+\; F^{-1}\left(\beta^a\frac{\partial F}{\partial g^a} + \frac{\partial F}{\partial\alpha}\,\mu\frac{\mathrm{d}\alpha}{\mathrm{d}\mu}\right).$$

Project onto W after going on shell. By the Nielsen identity (eq. (7.581)) and Definition 7.448, the explicit α–term vanishes in cohomology; if F preserves W let $F_W := \mathcal{N}F\mathcal{N}\big|_W$. At an IR fixed point $g_\star$ with $\beta(g_\star) = 0$ (cf. Definition 7.447) we have

$$\gamma_\star^{\mathcal{N}} \;\longmapsto\; \gamma_\star^{\mathcal{N}\prime} = F_W^{-1}\,\gamma_\star^{\mathcal{N}}\,F_W.$$

Assuming F_W mixes only operators within equal canonical-dimension blocks (so $[F_W, d] = 0$), it follows that

$$Y_\star^{\mathcal{N}} = d - \gamma_\star^{\mathcal{N}} \;\longmapsto\; Y_\star^{\mathcal{N}\prime} = F_W^{-1}(d - \gamma_\star^{\mathcal{N}})F_W = F_W^{-1}\,Y_\star^{\mathcal{N}}\,F_W,$$

i.e. a similarity on W. Thus the eigenvalues $\{y_{\tilde{B}}\}$ are scheme independent at the fixed point.

(C) Summary. Admissible basis changes act by similarity on W, and finite scheme changes reduce to similarity at the fixed point; in both cases the spectrum of $Y^{\mathcal{N}}$ (hence the projected exponents from Definition 7.448) is invariant. □

Intuition. Relabelling operators or changing scheme only *conjugates* the projected flow generator $Y^{\mathcal{N}}$ on W, so the physical exponents $y_{\tilde{B}}$ are untouched.

Definition 7.452 (Measured running and local exponent estimator)**.** Let $W := \operatorname{im}\mathcal{N}$ be the on–shell BRST–physical subspace (cf. Definition 7.448). For a projected eigen–operator $\hat{\tilde{\mathcal{O}}}_{\tilde{B}}$ with breaking exponent $y_{\tilde{B}}$ (from the spectrum of $Y^{\mathcal{N}}$; see Definition 7.448), define the *eigen–coupling component*

$$\widetilde{\varepsilon}_{\tilde{B},[0]}(\mu) \;:=\; \left(\tilde{w}_{[0]}^{(\tilde{B})}\right)^{\top}\varepsilon(\mu),$$

[11] If $M_W w = 0$ with $w \in W$, then $\mathcal{N}Mw = 0$. But $Mw \in W$ (preservation), hence $Mw \in W \cap \ker\mathcal{N} = \{0\}$, so $w = 0$ since M is invertible.

using the top element of a left Jordan chain on W (cf. Definition 7.449); in the diagonalizable case this is the usual left eigenvector projection. The *measured running* and its local estimator are then

$$\widetilde{\varepsilon}_{\tilde{B},[0]}(\mu) \;\sim\; \mu^{y_{\tilde{B}}} \times \Big[\text{polylog corrections from Jordan blocks}\Big], \quad \text{cf. eq. (7.569)}, \tag{7.570}$$

$$\widehat{y}_{\tilde{B}}(\mu) := \frac{\mathrm{d}}{\mathrm{d}\ln\mu}\,\ln\Big|\widetilde{\varepsilon}_{\tilde{B},[0]}(\mu)\Big|, \tag{7.571}$$

$$\text{or discretely} \quad \widehat{y}_{\tilde{B}}(\mu_i) := \frac{\ln\Big|\widetilde{\varepsilon}_{\tilde{B},[0]}(\mu_{i+1})\Big| - \ln\Big|\widetilde{\varepsilon}_{\tilde{B},[0]}(\mu_i)\Big|}{\ln\mu_{i+1} - \ln\mu_i}. \tag{7.572}$$

On any certified plateau (cf. Definition 6.297) the estimator is approximately scale–independent and reads off $y_{\tilde{B}}$ within tolerance. All observables entering $\widetilde{\varepsilon}_{\tilde{B},[0]}$ are understood with the Nielsen projection applied (cf. Definition 7.448).

Intuition. Take a log–derivative (or its discrete version) of the Nielsen–projected eigen–coupling along the RG flow eq. (7.567); by eq. (7.569) any Jordan–block polylog factors only modulate the slope transiently, so on a plateau (Definition 6.297) $\widehat{y}_{\tilde{B}}$ stabilises to $y_{\tilde{B}}$.

Proposition 7.453 (Convergence of the measured exponent)**.** *Under the assumptions of Proposition 7.450 and with μ restricted to the Step 3 certified IR half–space (mask $\mathcal{M}^{[\mathcal{U}]}$ of Proposition 7.427), the estimator in eq. (7.572) (see Definition 7.452) satisfies*

$$\widehat{y}_{\tilde{B}}(\mu) = y_{\tilde{B}} + \mathcal{O}\Big(\frac{1}{|\ln(\mu/\mu_0)|}\Big) \quad \text{as } \mu \downarrow 0,$$

and the discrete version converges to the same limit as the grid in $\ln\mu$ is refined. The estimate is gauge–parameter independent within the tolerance set by the Nielsen projection (cf. Definition 7.457 and Corollary 7.459).

Intuition. Using the Jordan expansion of the projected flow (Proposition 7.450 and Definition 7.449), each mode behaves like a power $\mu^{y_{\tilde{B}}}$ times a polynomial in $\ln\mu$, so the log–derivative peels off $y_{\tilde{B}}$ up to $1/\ln\mu$ corrections. Inside the Step 3 mask (Proposition 7.427) the nonlinear remainder is small and decays.

Proof. Let $t := \ln(\mu/\mu_0) \to -\infty$ as $\mu \downarrow 0$ and let $\widetilde{\varepsilon}_{\tilde{B}}$ denote the eigen–coupling component defined in Definition 7.454 (and used in Definition 7.452). By Proposition 7.450 together with the Jordan structure of Definition 7.449, we can write

$$\widetilde{\varepsilon}_{\tilde{B}}(\mu) = \mathrm{e}^{y_{\tilde{B}}t}\Big(P_{\tilde{B}}(t) + r_{\tilde{B}}(t)\Big), \tag{7.573}$$

where $P_{\tilde{B}}$ is a polynomial of degree at most $\operatorname{ind}\mathsf{N}_{\tilde{B}} - 1$ (degree 0 if $Y^{\mathcal{N}}$ is diagonalisable on the $y_{\tilde{B}}$ sector) and $r_{\tilde{B}}(t)$ collects the nonlinear $\mathcal{O}(\widetilde{\varepsilon}^2)$ remainder coming from the projected RG eq. (7.567).

Step 1 (control from the Step 3 mask). Inside $\mathcal{M}^{[\mathcal{U}]}$ (cf. Proposition 7.427) the breaking sector is small and decaying, so there exists $\delta > 0$ with

$$r_{\tilde{B}}(t) = \mathcal{O}(\mathrm{e}^{\delta t}), \qquad r'_{\tilde{B}}(t) = \mathcal{O}(\mathrm{e}^{\delta t}), \tag{7.574}$$

obtained by differentiating the projected flow on $W = \operatorname{im}\mathcal{N}$ (cf. Definition 7.457) and applying a Grönwall estimate to the $\mathcal{O}(\tilde{\varepsilon}^2)$ remainder.

Step 2 (log–derivative). Define $f_{\tilde{B}}(t) := \ln \widetilde{\varepsilon}_{\tilde{B}}(\mu)$. From eq. (7.573),

$$\frac{\mathrm{d}f_{\tilde{B}}}{\mathrm{d}t}(t) = y_{\tilde{B}} + \frac{P'_{\tilde{B}}(t) + r'_{\tilde{B}}(t)}{P_{\tilde{B}}(t) + r_{\tilde{B}}(t)}.$$

If $\deg P_{\tilde{B}} = m \geq 0$, then

$$\frac{P'_{\tilde{B}}(t)}{P_{\tilde{B}}(t)} = \frac{m}{t} + \mathcal{O}\Big(\frac{1}{t^2}\Big). \tag{7.575}$$

Combining eq. (7.575) with eq. (7.574) and the fact that $|P_{\tilde{B}}(t)| \gtrsim |t|^m$ for large $|t|$ (or $P_{\tilde{B}} \to a_0 \neq 0$ when $m = 0$), we get

$$\frac{\mathrm{d}f_{\tilde{B}}}{\mathrm{d}t}(t) = y_{\tilde{B}} + \mathcal{O}\Big(\frac{1}{|t|}\Big), \quad t \to -\infty.$$

Returning to μ (since $\frac{\mathrm{d}}{\mathrm{d}\ln\mu} = \frac{\mathrm{d}}{\mathrm{d}t}$) yields

$$\widehat{y}_{\tilde{B}}(\mu) = \frac{\mathrm{d}}{\mathrm{d}\ln\mu} \ln \widetilde{\varepsilon}_{\tilde{B}}(\mu) = y_{\tilde{B}} + \mathcal{O}\Big(\frac{1}{|\ln(\mu/\mu_0)|}\Big).$$

Step 3 (discrete estimator). For $t_i = \ln(\mu_i/\mu_0)$ with step $h_i := t_{i+1} - t_i$, the forward difference in eq. (7.572) can be written as

$$\widehat{y}_{\tilde{B}}(\mu_i) = \frac{f_{\tilde{B}}(t_{i+1}) - f_{\tilde{B}}(t_i)}{h_i} = \frac{\mathrm{d}f_{\tilde{B}}}{\mathrm{d}t}(t_i^*), \quad t_i^* \in [t_i, t_{i+1}],$$

so by Step 2 we have $\widehat{y}_{\tilde{B}}(\mu_i) = y_{\tilde{B}} + \mathcal{O}(1/|t_i^*|)$. If $h_i \to 0$ (grid refinement) while $t_i \to -\infty$, then $t_i^* \to -\infty$ and $\widehat{y}_{\tilde{B}}(\mu_i) \to y_{\tilde{B}}$. (A centred difference adds an $\mathcal{O}(h_i^2)$ truncation error; the forward difference adds $\mathcal{O}(h_i)$, both vanishing upon refinement.)

Step 4 (gauge–parameter independence). The measurement uses the Nielsen–projected eigen–coupling (cf. Definitions 7.452 and 7.457). The projected spectrum is gauge–independent by the isospectral similarity flow (Proposition 7.458 and Corollary 7.459); any residual dependence is bounded by the tolerance in eq. (7.588). This proves the claim. □

Intuition. After diagonalising the projected flow, each mode looks like $\mu^{y_{\tilde{B}}}$ times at most a polynomial in $\ln\mu$; the log–derivative peels off $y_{\tilde{B}}$ with corrections $\sim 1/\ln\mu$. Discretisation and gauge choices only add vanishing (or tolerance–bounded) effects once we are inside the Step 3 IR mask.

Diagonalisation and eigen–operators.

Definition 7.454 (Eigen–operators and eigen–couplings)**.** Work on the physical subspace $W := \operatorname{im}\mathcal{N}$ (cf. Definition 7.448) and let $Y^{\mathcal{N}} := \mathcal{N}\,Y\,\mathcal{N}\big|_W$ be the projected stability matrix from eq. (7.567). Choose R whose columns form a (generalised) right Jordan basis on W so that

$$R^{-1}Y^{\mathcal{N}}R \;=\; J \;=\; \operatorname{diag}(J_{\tilde{B}}), \qquad J_{\tilde{B}} = y_{\tilde{B}}\mathbb{1} + \mathsf{N}_{\tilde{B}}, \quad (\mathsf{N}_{\tilde{B}})^{m_{\tilde{B}}} = 0 \text{ (cf. } \textit{Definition } 7.449).$$

Define the *eigen–operators* and *eigen–couplings* by the dual change of basis

$$\boxed{\widetilde{\mathcal{O}}_{\tilde{B}} := \sum_{A} (R^{-1})_{\tilde{B}A}\, \hat{\mathcal{O}}_A, \qquad \widetilde{\varepsilon}_{\tilde{B}} := \sum_{A} R_{A\tilde{B}}\, \varepsilon_A,} \tag{7.576}$$

so that the breaking sector is expressed in the (generalised) eigenbasis of $Y^{\mathcal{N}}$. In the diagonalisable case one has $J = \mathrm{diag}(y_{\tilde{B}})$ and $\mathsf{N}_{\tilde{B}} = 0$.

Intuition. This is the Nielsen–projected change of basis aligning operators and couplings with RG eigendirections on W (Definition 7.448); when $Y^{\mathcal{N}}$ is diagonalisable, each mode runs independently at linear order (cf. eq. (7.567)).

Proposition 7.455 (Decoupled linear flow and solution)**.** *Assume $Y^{\mathcal{N}}$ (on $W = \mathrm{im}\,\mathcal{N}$) is diagonalisable over $\mathbb{C}$ with eigenvalues $\{y_{\tilde{B}}\}$ and adopt the eigenbasis of Definition 7.454. Then the linearised RG flow eq. (7.567) decouples componentwise:*

$$\boxed{\mu \frac{\mathrm{d}\,\widetilde{\varepsilon}_{\tilde{B}}}{\mathrm{d}\mu} = y_{\tilde{B}}\, \widetilde{\varepsilon}_{\tilde{B}} + \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \qquad \Rightarrow \quad \widetilde{\varepsilon}_{\tilde{B}}(\mu) = \widetilde{\varepsilon}_{\tilde{B}}(\mu_0) \left(\frac{\mu}{\mu_0}\right)^{y_{\tilde{B}}} \Big[1 + \mathcal{O}_I\Big(\sup_{\mu\in I} \|\widetilde{\varepsilon}(\mu)\|\Big)\Big],}$$

(7.577)

where I is any compact interval in $\ln \mu$ contained in the Step 3 certified IR mask (cf. Proposition 7.427). If $Y^{\mathcal{N}}$ has Jordan blocks, the linear evolution acquires only polynomial factors in $\ln(\mu/\mu_0)$, as stated in Proposition 7.450.

Intuition. After Nielsen projection (Definition 7.448) and diagonalisation, each projected mode follows a one–dimensional linear RG with exponent $y_{\tilde{B}}$; nonlinearity is subleading on the IR mask (Proposition 7.427). In the non–diagonalisable case, see the Jordan-form solution in Proposition 7.450.

Proof. **(1) Preliminaries and change of variables.** Write the projected breaking–sector RG (to quadratic order) as

$$\mu \frac{\mathrm{d}\varepsilon}{\mathrm{d}\mu} = Y^{\mathcal{N}} \varepsilon + \mathcal{R}(\varepsilon, \mu), \qquad \mathcal{R}(\varepsilon, \mu) = \mathcal{O}(\|\varepsilon\|^2), \tag{7.578}$$

with $Y^{\mathcal{N}}$ from eq. (7.567) and $\varepsilon \in W := \mathrm{im}\,\mathcal{N}$ (cf. Definition 7.448). Set $t := \ln(\mu/\mu_0)$ so that $\frac{\mathrm{d}}{\mathrm{d}t} = \mu \frac{\mathrm{d}}{\mathrm{d}\mu}$, giving

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = Y^{\mathcal{N}} \varepsilon + r(\varepsilon, t), \qquad r(\varepsilon, t) := \mathcal{R}(\varepsilon, \mu(t)). \tag{7.579}$$

Let R be as in Definition 7.454 with $R^{-1} Y^{\mathcal{N}} R = J = \mathrm{diag}(y_{\tilde{B}})$ (diagonalisable case). Define eigen–coordinates $\widetilde{\varepsilon} := R^{-1}\varepsilon$. Then

$$\frac{\mathrm{d}\widetilde{\varepsilon}}{\mathrm{d}t} = J\, \widetilde{\varepsilon} + \widetilde{r}(\widetilde{\varepsilon}, t), \qquad \widetilde{r}(\widetilde{\varepsilon}, t) := R^{-1} r(R\widetilde{\varepsilon}, t) = \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \tag{7.580}$$

since $R^{\pm 1}$ are bounded on the finite–dimensional space W.

(2) Variation of constants and decoupling. Duhamel's formula for eq. (7.580) reads

$$\widetilde{\varepsilon}(t) = \mathrm{e}^{(t-t_0)J}\,\widetilde{\varepsilon}(t_0) + \int_{t_0}^{t} \mathrm{e}^{(t-s)J}\,\widetilde{r}\big(\widetilde{\varepsilon}(s), s\big)\,\mathrm{d}s.$$

Because J is diagonal, the *linear* term decouples componentwise:

$$\big(\mathrm{e}^{(t-t_0)J}\,\widetilde{\varepsilon}(t_0)\big)_{\tilde{B}} = \mathrm{e}^{y_{\tilde{B}}(t-t_0)}\,\widetilde{\varepsilon}_{\tilde{B}}(t_0).$$

The integral couples components only through $\widetilde{r} = \mathcal{O}(\|\widetilde{\varepsilon}\|^2)$ and is higher order.

(3) Uniform control on the IR mask. Restrict to a compact interval $I = [t_-, t_+]$ contained in the Step 3 certified IR half–space (mask $\mathcal{M}^{[\mathcal{U}]}$, Proposition 7.427). Smallness of the breaking sector on I implies the bound

$$\Big\| \int_{t_0}^{t} \mathrm{e}^{(t-s)J}\,\widetilde{r}(\widetilde{\varepsilon}(s), s)\,\mathrm{d}s \Big\| \le K_I \left(\sup_{u\in I} \|\widetilde{\varepsilon}(u)\| \right)^2$$

for some finite K_I independent of $\widetilde{\varepsilon}$. Hence

$$\widetilde{\varepsilon}_{\tilde{B}}(t) = \mathrm{e}^{y_{\tilde{B}}(t-t_0)}\,\widetilde{\varepsilon}_{\tilde{B}}(t_0)\left[1 + \mathcal{O}_I\Big(\sup_{u\in I} \|\widetilde{\varepsilon}(u)\| \Big)\right].$$

(4) Conclusion. Returning to μ via $t = \ln(\mu/\mu_0)$ yields eq. (7.577). If $Y^{\mathcal{N}}$ is not diagonalisable, replace J by its Jordan form and recover the polynomial factors in $\ln(\mu/\mu_0)$ as in Proposition 7.450 and Definition 7.449. □

Corollary 7.456 (Irrelevance criterion)**.** *Work on the physical subspace $W := \operatorname{im}\mathcal{N}$ and let $\widetilde{\varepsilon}_{\tilde{B}}(\mu)$ be the eigen–couplings associated with the eigen–operators $\widetilde{\mathcal{O}}_{\tilde{B}}$ from Definition 7.454, built using the projected matrix $Y^{\mathcal{N}} := \mathcal{N}Y\mathcal{N}\big|_W$ (cf. Definition 7.448 and eq. (7.567)). If* $\operatorname{Re} y_{\tilde{B}} < 0$ *for all projected breaking modes, then $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \to 0$ as $\mu \downarrow 0$. Equivalently, each $\widetilde{\mathcal{O}}_{\tilde{B}}$ is* irrelevant *in the Wilsonian sense.*

Proof. Set $t := \ln(\mu/\mu_0) \le 0$. By Proposition 7.455 in the diagonalisable case (or Proposition 7.450 together with Definition 7.449 for general Jordan blocks), the projected RG flow in the eigenbasis on W satisfies

$$\frac{\mathrm{d}\,\widetilde{\varepsilon}_{\tilde{B}}}{\mathrm{d}t} = y_{\tilde{B}}\,\widetilde{\varepsilon}_{\tilde{B}} + \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \qquad \widetilde{\varepsilon}_{\tilde{B}}(t) = \mathrm{e}^{y_{\tilde{B}}(t-t_0)}\widetilde{\varepsilon}_{\tilde{B}}(t_0)\left[1 + \mathcal{O}_I\Big(\sup_{s\in[t,t_0]} \|\widetilde{\varepsilon}(s)\| \Big)\right],$$

uniformly on any compact interval $[t, t_0] \subset$ the Step 3 certified IR mask (cf. Proposition 7.427). Since $\operatorname{Re} y_{\tilde{B}} < 0$, we have $\mathrm{e}^{\operatorname{Re} y_{\tilde{B}}(t-t_0)} \to 0$ as $t \to -\infty$ (i.e. $\mu \downarrow 0$), and the remainder is subleading for sufficiently small initial data by the same control used in Proposition 7.455; hence $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \to 0$.

In the presence of Jordan blocks, Proposition 7.450 yields

$$\widetilde{\varepsilon}_{\tilde{B}}(t) = \mathrm{e}^{y_{\tilde{B}}(t-t_0)} \sum_{k=0}^{m_{\tilde{B}}-1} \frac{(t-t_0)^k}{k!}\, c_{\tilde{B},k} \;+\; \mathcal{O}(\|\widetilde{\varepsilon}\|^2),$$

so $\mathrm{e}^{\operatorname{Re} y_{\tilde{B}}(t-t_0)}(t-t_0)^k \to 0$ for each fixed k as $t \to -\infty$, again implying $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \to 0$. Thus every projected breaking mode decays toward the IR and is irrelevant. □

Remark (Nielsen projection, gauge/scheme consistency). All statements are made on $W = \operatorname{im}\mathcal{N}$ (cf. Definition 7.448). Using $Y^{\mathcal{N}} := \mathcal{N}Y\mathcal{N}\big|_W$ and (block-)Jordanising it as in Definitions 7.449 and 7.454 ensures that the exponents $y_{\tilde{B}}$ are gauge–parameter independent (isospectral similarity flow of Proposition 7.458, with tolerance as in eq. (7.588)) and basis/scheme covariant (Lemma 7.451).

Nielsen projection (gauge–parameter safety).

Definition 7.457 (Nielsen identity and on–shell/BRST projection)**.** Let α denote the (set of) gauge parameters (e.g. the R_ξ parameter ξ is one component). Gauge–parameter derivatives of the 1PI effective action satisfy the Nielsen identity

$$\boxed{\frac{\partial\Gamma[\phi;\alpha]}{\partial\alpha} + \int \mathrm{d}^D x\, \mathcal{C}_i(\phi,\alpha;x)\,\frac{\delta\Gamma[\phi;\alpha]}{\delta\phi_i(x)} = 0,} \tag{7.581}$$

so gauge–parameter dependence vanishes at stationary points $\delta\Gamma/\delta\phi = 0$ and for on–shell BRST–invariant observables (see [117, 243]). Let $\mathcal{N}(\alpha)$ denote the linear projector on the breaking–operator space V onto the BRST–physical cohomology, evaluated on shell and compatible with the Slavnov–Taylor identity (cf. eq. (7.16)):

$$\mathcal{N}^2 = \mathcal{N}, \qquad \operatorname{im}\mathcal{N} \cong H^0_{\mathrm{BRST}},$$
$$\partial_\alpha\big(\mathcal{N}X\big) = 0 \quad \text{for all physical } X,$$
(within admissible tolerance; cf. *eq.* (7.588)).

For any mixing/flow matrices Z, Y on V (cf. eq. (7.567)), define their Nielsen–projected versions on the physical subspace $W := \operatorname{im}\mathcal{N}$ by restriction:

$$Z^{\mathcal{N}}(\alpha) := \mathcal{N}(\alpha)\,Z(\alpha)\,\mathcal{N}(\alpha)\big|_W, \qquad Y^{\mathcal{N}}(\alpha) := \mathcal{N}(\alpha)\,Y(\alpha)\,\mathcal{N}(\alpha)\big|_W.$$

The eigenvalues $y_{\tilde{B}}(\alpha)$ of $Y^{\mathcal{N}}(\alpha)$ are the *Nielsen–projected breaking exponents*; associated right eigenvectors in W define the physical eigen–operators/eigen–couplings as in Definition 7.454. By the isospectral similarity flow, these exponents are gauge–parameter independent within tolerance (cf. Proposition 7.458 and Corollary 7.459).

Intuition. Project *after* going on shell and into BRST cohomology: $Y^{\mathcal{N}}$ then captures the physically meaningful mixing/flow (eq. (7.567)). The spectrum of $Y^{\mathcal{N}}$ is stable under gauge–parameter variations (within eq. (7.588)) by Proposition 7.458 and Corollary 7.459, and basis/scheme choices act by similarity (Lemma 7.451).

Proposition 7.458 (Similarity flow of the projected stability matrix)**.** *Under the Nielsen identity eq. (7.581) and evaluation on shell with BRST projection as in Definition 7.457, there exists a smooth matrix $K(\alpha)$ on the physical subspace $W := \operatorname{im}\mathcal{N}$ such that, for any gauge–parameter component α,*

$$\frac{\partial Y^{\mathcal{N}}}{\partial\alpha} = [\,K(\alpha),\, Y^{\mathcal{N}}(\alpha)\,].$$

Consequently,

$$Y^{\mathcal{N}}(\alpha) = S(\alpha,\alpha_0)\, Y^{\mathcal{N}}(\alpha_0)\, S(\alpha,\alpha_0)^{-1}, \qquad S(\alpha,\alpha_0) := \mathcal{P}\exp\Big(\int_{\alpha_0}^{\alpha} K(\zeta)\,\mathrm{d}\zeta\Big),$$

and the projected breaking spectrum $\{y_{\tilde{B}}(\alpha)\}$ *is independent of* α *(isospectrality).*

Proof. **Step 0 (Projector variation drops on W).** By the on–shell/BRST construction of Definition 7.457, $\partial_\alpha(\mathcal{N}X) = 0$ for any physical X (within the tolerance of eq. (7.588)). Hence, when differentiating projected objects like $Z^{\mathcal{N}} := \mathcal{N}Z\mathcal{N}|_W$ and $Y^{\mathcal{N}} := \mathcal{N}Y\mathcal{N}|_W$, the $\partial_\alpha\mathcal{N}$ terms vanish on W.

Step 1 (From Nielsen to an on–shell generator on operator space). The Nielsen identity eq. (7.581) implies that a gauge–parameter variation is a field redefinition generated by a local functional $\mathcal{C}_i$, so insertions of renormalised composite operators transform as

$$\partial_\alpha\Big[\mathcal{O}(\phi)\Big]^{\mathrm{R}} = [\,K_\alpha,\,\mathcal{O}^{\mathrm{R}}\,] + (\text{BRST exact}), \quad \text{see [117, 243]}.$$

Projecting to $W := \operatorname{im}\mathcal{N}$ on shell removes BRST–exact pieces (Definition 7.457), so there is a smooth matrix $K(\alpha)$ on W with

$$\partial_\alpha\mathcal{O}^{\mathrm{R}}_W = [\,K(\alpha),\,\mathcal{O}^{\mathrm{R}}_W\,], \qquad \mathcal{O}^{\mathrm{R}}_W := \mathcal{N}\,\mathcal{O}^{\mathrm{R}}\,\mathcal{N}\Big|_W. \tag{7.582}$$

Step 2 (Implications for the projected renormalisation matrix). Let $Z(\alpha,\mu)$ be the operator mixing matrix on the breaking sector (eq. (7.567)) and define $Z^{\mathcal{N}} := \mathcal{N}Z\mathcal{N}\big|_W$. Bare operators are α–independent, and $\mathcal{O}^{\mathrm{R}}_W = Z^{\mathcal{N}}\mathcal{O}^{bare}_W$; using eq. (7.582) and Step 0 gives

$$\partial_\alpha Z^{\mathcal{N}} = A\,Z^{\mathcal{N}} + Z^{\mathcal{N}}B, \qquad A := L_K, \quad B := -R_K, \tag{7.583}$$

i.e. $AX - XB = [K,X]$ for any matrix X on W (left/right actions by K).

Step 3 (Lax equation for $\gamma^{\mathcal{N}}$ and $Y^{\mathcal{N}}$). Define $\gamma^{\mathcal{N}} := Z^{\mathcal{N}-1}\,\mu\,\frac{\mathrm{d}Z^{\mathcal{N}}}{\mathrm{d}\mu}$ and separate canonical dimensions so that $Y^{\mathcal{N}} := d - \gamma^{\mathcal{N}}$ (cf. the conventions below eq. (7.567)). Differentiating $\gamma^{\mathcal{N}}$ w.r.t. α and using eq. (7.583) yields

$$\begin{aligned}\partial_\alpha\gamma^{\mathcal{N}} &= (\partial_\alpha Z^{\mathcal{N}-1})\,\mu\frac{\mathrm{d}Z^{\mathcal{N}}}{\mathrm{d}\mu} + Z^{\mathcal{N}-1}\,\mu\frac{\mathrm{d}}{\mathrm{d}\mu}(\partial_\alpha Z^{\mathcal{N}}) \\ &= [\,\gamma^{\mathcal{N}},\,B\,] \;+\; Z^{\mathcal{N}-1}\mu\frac{\mathrm{d}A}{\mathrm{d}\mu}Z^{\mathcal{N}} \;+\; \mu\,\frac{\mathrm{d}B}{\mathrm{d}\mu}.\end{aligned} \tag{7.584}$$

On shell, RG flow and gauge–parameter variations commute up to ad_K; differentiating eq. (7.583) w.r.t. μ at fixed bare theory gives

$$\mu\,\frac{\mathrm{d}A}{\mathrm{d}\mu} = [\,A,\,\gamma^{\mathcal{N}}\,], \qquad \mu\,\frac{\mathrm{d}B}{\mathrm{d}\mu} = [\,\gamma^{\mathcal{N}},\,B\,]. \tag{7.585}$$

Insert eq. (7.585) into eq. (7.584) and rewrite $Z^{\mathcal{N}-1}[A,\gamma^{\mathcal{N}}]Z^{\mathcal{N}} = [\,Z^{\mathcal{N}-1}AZ^{\mathcal{N}},\,\gamma^{\mathcal{N}}\,]$ to get

$$\partial_\alpha\gamma^{\mathcal{N}} = [\,\gamma^{\mathcal{N}},\,B - Z^{\mathcal{N}-1}AZ^{\mathcal{N}}\,].$$

Define

$$K(\alpha) := B(\alpha) - Z^{\mathcal{N}-1}(\alpha)\, A(\alpha)\, Z^{\mathcal{N}}(\alpha) \quad \text{on } W, \tag{7.586}$$

then

$$\partial_\alpha \gamma^{\mathcal{N}} = [\,\gamma^{\mathcal{N}},\, K(\alpha)\,]. \tag{7.587}$$

Since d is α–independent, we conclude

$$\partial_\alpha Y^{\mathcal{N}} = [\,K(\alpha),\, Y^{\mathcal{N}}(\alpha)\,],$$

i.e. a Lax equation in the gauge parameter.

Step 4 (Integration and isospectrality). The Lax equation integrates to the path–ordered similarity flow

$$Y^{\mathcal{N}}(\alpha) = S(\alpha,\alpha_0)\, Y^{\mathcal{N}}(\alpha_0)\, S(\alpha,\alpha_0)^{-1}, \qquad S(\alpha,\alpha_0) = \mathcal{P}\exp\Big(\int_{\alpha_0}^{\alpha} K(\zeta)\,\mathrm{d}\zeta\Big).$$

Similarity preserves spectra, hence the projected breaking exponents $y_{\tilde{B}}(\alpha)$ (eigenvalues of $Y^{\mathcal{N}}(\alpha)$) are independent of α. This is consistent with the gauge–independence statements collected in Corollary 7.459. □

Intuition. Changing the gauge parameter is (on shell) a field redefinition (eq. (7.581)); after the Nielsen projection (Definition 7.457) it acts by conjugation on the physical operator space W, giving a Lax equation for $Y^{\mathcal{N}}$. The path–ordered solution is a similarity transform, so the eigenvalues $y_{\tilde{B}}$ are invariant.

Corollary 7.459 (Gauge–parameter independence of projected exponents)**.** *Under the hypotheses of Proposition 7.458, the multiset of eigenvalues of $Y^{\mathcal{N}}(\alpha)$ (with algebraic multiplicities) is independent of the gauge parameter component α:*

$$\{y_{\tilde{B}}(\alpha)\}_{\tilde{B}} \;=\; \{y_{\tilde{B}}(\alpha_0)\}_{\tilde{B}} \qquad \textit{for all admissible } \alpha,$$

where admissibility is as in the on–shell/BRST setting of Definition 7.457. In practice (finite statistics/truncations), acceptance demands the gauge–tolerance audit

$$\boxed{\sup_{\alpha\in\Xi_{\mathrm{adm}}} \big|y_{\tilde{B}}(\alpha) - y_{\tilde{B}}(\alpha_0)\big| \;\le\; \varepsilon_{\mathrm{gauge}},} \tag{7.588}$$

with Ξ_{adm} the admissible gauge set and $\varepsilon_{\mathrm{gauge}}$ chosen below plateau tolerances (cf. the certification pipeline and plateau criterion in Definition 6.297).

Proof. By Proposition 7.458, on the physical subspace $W := \operatorname{im}\mathcal{N}$ one has

$$Y^{\mathcal{N}}(\alpha) = S(\alpha,\alpha_0)\, Y^{\mathcal{N}}(\alpha_0)\, S(\alpha,\alpha_0)^{-1},$$

with $S(\alpha,\alpha_0) = \mathcal{P}\exp\big(\int_{\alpha_0}^{\alpha} K(\zeta)\,\mathrm{d}\zeta\big)$ invertible on W. Therefore the characteristic polynomials coincide:

$$\begin{aligned}
\det\big(\lambda\mathbb{1} - Y^{\mathcal{N}}(\alpha)\big) &= \det\big(\lambda\mathbb{1} - SY^{\mathcal{N}}(\alpha_0)S^{-1}\big) \\
&= \det\big(S(\lambda\mathbb{1} - Y^{\mathcal{N}}(\alpha_0))S^{-1}\big) \\
&= \det\big(\lambda\mathbb{1} - Y^{\mathcal{N}}(\alpha_0)\big),
\end{aligned}$$

so the spectra (as multisets with algebraic multiplicities) are identical for all admissible α. Degenerate eigenspaces may rotate by $S(\alpha, \alpha_0)$, but eigenvalues—the projected exponents defined via Definitions 7.454 and 7.457—are unchanged. Inequality (7.588) records the practical tolerance used when validating gauge–independence numerically on certified plateaux (cf. Definition 6.297). □

Intuition. After the Nielsen projection (Definition 7.457), changing the gauge parameter acts by a similarity transform on $Y^{\mathcal{N}}$ (Proposition 7.458); similarity preserves eigenvalues, so the measured exponents are gauge–invariant up to audit tolerance (7.588).

Lemma 7.460 (Compatibility with basis/scheme changes)**.** *Let V be the breaking–operator space and $W := \operatorname{im}\mathcal{N} \subset V$ the on–shell BRST–physical subspace (cf. Definition 7.457). Let $M(\alpha) \in \mathrm{GL}(V)$ be an admissible (gauge–respecting) linear mixing of breaking operators that preserves W, and let the renormalisation scheme vary smoothly with α while preserving evaluation on shell and W. Then*

$$Y^{\mathcal{N}} \;\longmapsto\; \widetilde{Y}^{\mathcal{N}} = (\mathcal{N}M\mathcal{N})\, Y^{\mathcal{N}}\, (\mathcal{N}M^{-1}\mathcal{N})\Big|_W,$$

i.e. a similarity on W, so the multiset $\{y_{\tilde{B}}\}$ of projected breaking exponents is invariant (cf. Definition 7.454). Moreover, any finite (invertible) renormalisation $F(g, \alpha)$ that preserves W leaves $\{y_{\tilde{B}}\}$ unchanged at the IR fixed point $g_\star$ (cf. Definition 7.447).

Proof. **(A) Basis change (on W).** This is the Nielsen–projected version of Lemma 7.451. A basis change $\mathcal{O} \mapsto \mathcal{O}' := M\mathcal{O}$ induces $Y \mapsto MYM^{-1}$ at linear order (with dual couplings transformed to preserve the breaking pairing; cf. eq. (7.567)). Since $MW \subseteq W$, the restricted map $M_W := \mathcal{N}M\mathcal{N}\big|_W$ is invertible on W, and

$$Y^{\mathcal{N}} = \mathcal{N}Y\mathcal{N}\Big|_W \;\longmapsto\; \widetilde{Y}^{\mathcal{N}} = \mathcal{N}(MYM^{-1})\mathcal{N}\Big|_W = M_W\, Y^{\mathcal{N}}\, M_W^{-1},$$

a similarity on W. Therefore the spectrum $\{y_{\tilde{B}}\}$ is unchanged (see also Definition 7.454).

(B) Scheme change at the fixed point. Let $Z(g, \alpha, \mu)$ be the mixing matrix, $\gamma := Z^{-1}\mu\,\frac{\mathrm{d}Z}{\mathrm{d}\mu}$, and separate canonical dimensions so that $Y := d - \gamma$ (conventions below eq. (7.567)). A finite renormalisation $F(g, \alpha)$ produces $Z \mapsto Z' := FZ$ and

$$\gamma' \;=\; Z'^{-1}\mu\frac{\mathrm{d}Z'}{\mathrm{d}\mu} \;=\; F^{-1}\gamma F + F^{-1}\left(\beta^a\partial_{g^a}F + \partial_\alpha F\;\mu\frac{\mathrm{d}\alpha}{\mathrm{d}\mu}\right).$$

Projecting to W after going on shell (Nielsen identity, Definition 7.457 and eq. (7.581)) removes the explicit α–term in cohomology; if F preserves W define $F_W := \mathcal{N}F\mathcal{N}\big|_W$. At an IR fixed point $g_\star$ with $\beta(g_\star) = 0$ (cf. Definition 7.447),

$$\gamma_\star^{\mathcal{N}} \;\longmapsto\; \gamma_\star^{\mathcal{N}'} = F_W^{-1}\,\gamma_\star^{\mathcal{N}}\,F_W.$$

Assuming F_W mixes only operators within equal canonical–dimension blocks (so $[F_W, d] = 0$), we obtain

$$Y_\star^{\mathcal{N}} = d - \gamma_\star^{\mathcal{N}} \;\longmapsto\; Y_\star^{\mathcal{N}'} = F_W^{-1}(d - \gamma_\star^{\mathcal{N}})F_W = F_W^{-1}Y_\star^{\mathcal{N}}F_W,$$

a similarity on W. Hence the projected exponents are scheme–independent at the fixed point (see also Lemma 7.451). □

Remark. The present lemma is equivalent in content to Lemma 7.451 but stated explicitly after the Nielsen projection (Definition 7.457). Together with the similarity flow in the gauge parameter (Proposition 7.458) and the gauge–tolerance audit (7.588), it ensures that the projected exponents $\{y_{\tilde{B}}\}$ are invariant under admissible basis relabellings, scheme changes at $g_\star$, and gauge–parameter variations on the certified band.

IR window and consistency with the restoration mask.

Definition 7.461 (IR μ–window induced by the restoration mask)**.** Let $\mu = \kappa/\ell$ as in Definition 7.431 and write $v := \ln \ell$. Given any admitted IR ℓ–window (uniform in u)

$$\mathcal{I}_\ell := \{\ \ell \geq \ell^{\mathrm{IR}}_{\min}\ \} \qquad \text{within which the Step 3 guards hold for all } u \in \mathcal{U},\ \text{i.e.}$$
eqs. (7.542)*and* (7.548) (and the plateau/certification conditions of Definition 6.297),

define the corresponding μ–window by the order–reversing map (cf. $\mu = \kappa/\ell$)

$$\mathcal{I}_\mu := \{\ \mu \leq \mu^{\mathrm{IR}}_{\max}\ \}, \qquad \mu^{\mathrm{IR}}_{\max} := \kappa/\ell^{\mathrm{IR}}_{\min}.$$

In particular, the Step 3 certified mask $\mathcal{M}^{[\mathcal{U}]} = \{(u, v) : u \in \mathcal{U},\ v \geq \ln \ell_R^{[\mathcal{U}]}\}$ (see Proposition 7.427) induces the μ–half–line

$$\mathcal{I}_\mu^{[\mathcal{U}]} := \{\ \mu \leq \mu_R^{[\mathcal{U}]}\ \}, \qquad \mu_R^{[\mathcal{U}]} := \kappa/\ell_R^{[\mathcal{U}]}.$$

Proposition 7.462 (Consistency of the RG window with law restoration)**.** *On $\mathcal{I}_\mu^{[\mathcal{U}]}$ the law–channel guards of Step 3 remain enforced: along every admissible UV slice $u \in \mathcal{U}$, the law–deficit stays within tolerance (plateau/acceptance per Definition 6.297 and Proposition 7.427) and the certified slope satisfies $\varsigma^{(\tau)}_{\mathrm{law}}(\ell) > 0$ for the corresponding $\ell = \kappa/\mu$ (cf. eqs.* (7.542) *and* (7.548)*). In conjunction with the irrelevance ledger (Corollary 7.456), the breaking sector is small and decaying on $\mathcal{I}_\mu^{[\mathcal{U}]}$, and the hypotheses of Proposition 7.453 hold there.*

Proof. By Proposition 7.427, for every $u \in \mathcal{U}$ and every $v = \ln \ell \geq \ln \ell_R^{[\mathcal{U}]}$ one has the Step 3 plateau and slope constraints, together with the monotonicity/guard conditions eqs. (7.542) and (7.548) (within the certification pipeline Definition 6.297). The map $v = \ln \ell \mapsto \mu = \kappa/\ell$ is smooth and order–reversing, so the condition $\mu \leq \kappa/\ell_R^{[\mathcal{U}]}$ is equivalent to $v \geq \ln \ell_R^{[\mathcal{U}]}$. Therefore the same constraints transport to $\mathcal{I}_\mu^{[\mathcal{U}]}$, establishing the stated enforcement on the μ–half–line.

Since the Step 3 mask also bounds the law–deficit on certified plateaux (Proposition 7.427 and Definition 6.297), the breaking sector remains small there. Together with the negativity of the projected breaking exponents (irrelevance criterion Corollary 7.456, derived from the linearised Jordan solution Proposition 7.450), this implies decay of the projected breaking components on $\mathcal{I}_\mu^{[\mathcal{U}]}$. Consequently, the assumptions required for the estimator convergence Proposition 7.453 are satisfied on this window. □

Lemma 7.463 (Estimator invariances, locality, and accuracy)**.** *Let $t_k := \ln \mu_k$ and suppose $t_{k\pm1}$ exist. Then:*

Scale choice.
eq. (7.568) is invariant under the audit constant κ in $\mu = \kappa/\ell$ (cf. Definition 7.431).

Nielsen projection (gauge safety).
If data are taken on $W = \operatorname{im}\mathcal{N}$ (Definition 7.457), then $\widehat{y}_{\tilde{B}}$ is gauge–parameter independent within the tolerance eq. (7.588) (cf. Proposition 7.458 and Corollary 7.459).

Locality.
On a uniform grid in t with step h, eq. (7.568) equals the centered difference $\widehat{y}_{\tilde{B}}(t_k) = \frac{f_{\tilde{B}}(t_{k+1}) - f_{\tilde{B}}(t_{k-1})}{2h}$, where $f_{\tilde{B}}(t) := \ln|\widetilde{\varepsilon}_{\tilde{B}}(\mu(t))|$.

Normalization invariance.
Multiplying $\widetilde{\varepsilon}_{\tilde{B}}$ by any μ–independent constant (e.g. from re–normalising the eigenvectors in Definition 7.454) leaves eq. (7.568) unchanged.

Truncation error.
If $f_{\tilde{B}} \in C^3$ on an interval containing t_{k-1}, t_k, t_{k+1}, then

$$\widehat{y}_{\tilde{B}}(t_k) = f'_{\tilde{B}}(t_k) + \mathcal{O}(h^2),$$

with the constant depending on $\sup|f^{(3)}_{\tilde{B}}|$ on that interval.

Asymptotic accuracy on the IR window.
On the certified half–line $\mathcal{I}^{[\mathcal{U}]}_{\mu}$ (cf. Definition 7.461 and Proposition 7.462), if $t_k \to -\infty$ and $h \to 0$, then by Proposition 7.453

$$\widehat{y}_{\tilde{B}}(t_k) = y_{\tilde{B}} + \mathcal{O}\Big(\frac{1}{|t_k|}\Big) + \mathcal{O}(h^2).$$

Low–pass stability.
If LP_{τ_μ} satisfies eqs. (7.537) and (7.538) (zero–th and first moment conditions), then

$$\widehat{y}^{(\tau_\mu)}_{\tilde{B}}(t_k) = \widehat{y}_{\tilde{B}}(t_k) + \mathcal{O}(\tau_\mu^2) + \mathcal{O}(h^2),$$

so smoothing does not bias the estimate to leading order on plateaux.

Proof. **(a) Scale choice.** Replacing $\kappa \mapsto a\kappa$ shifts $t = \ln\mu$ by the constant $\ln a$, so $t_{k\pm1} \mapsto t_{k\pm1} + \ln a$. The centered difference cancels this shift exactly, leaving eq. (7.568) unchanged.

(b) Nielsen projection. On $W = \operatorname{im}\mathcal{N}$ (Definition 7.457), the projected flow generator $Y^{\mathcal{N}}$ obeys the similarity (Lax) equation in the gauge parameter (Proposition 7.458), implying gauge–independent projected exponents (Corollary 7.459). The measured quantity in eq. (7.568) is a ratio of $\widetilde{\varepsilon}_{\tilde{B}}$ at nearby μ; any residual gauge–dependence from finite statistics/truncations is bounded by eq. (7.588) on the certified band.

(c) Locality. On a uniform grid $t_{k\pm1} = t_k \pm h$,

$$\widehat{y}_{\tilde{B}}(t_k) = \frac{1}{2h}\Big(\ln|\widetilde{\varepsilon}_{\tilde{B}}(t_k + h)| - \ln|\widetilde{\varepsilon}_{\tilde{B}}(t_k - h)|\Big) = \frac{f_{\tilde{B}}(t_{k+1}) - f_{\tilde{B}}(t_{k-1})}{2h}.$$

(d) Normalization invariance. If $\widetilde{\varepsilon}_{\tilde{B}} \mapsto c\,\widetilde{\varepsilon}_{\tilde{B}}$ with $c > 0$ independent of μ, then the numerator and denominator inside the log in eq. (7.568) each pick up a factor c, which cancels.

(e) Truncation error. Taylor expand $f_{\tilde{B}}$ at t_k:

$$f_{\tilde{B}}(t_{k\pm1}) = f_{\tilde{B}}(t_k) \pm h f'_{\tilde{B}}(t_k) + \tfrac{h^2}{2} f''_{\tilde{B}}(t_k) \pm \tfrac{h^3}{6} f'''_{\tilde{B}}(\xi_\pm),$$

for some $\xi_\pm$ between t_k and $t_{k\pm1}$. Subtract and divide by $2h$:

$$\widehat{y}_{\tilde{B}}(t_k) = \frac{f_{\tilde{B}}(t_{k+1}) - f_{\tilde{B}}(t_{k-1})}{2h} = f'_{\tilde{B}}(t_k) + \tfrac{h^2}{6}\Big(f'''_{\tilde{B}}(\xi_+) - f'''_{\tilde{B}}(\xi_-)\Big) = f'_{\tilde{B}}(t_k) + \mathcal{O}(h^2).$$

(f) Asymptotic accuracy on the IR window. On $\mathcal{I}_\mu^{[\mathcal{U}]}$ (Definition 7.461 and Proposition 7.462), Proposition 7.453 gives $f'_{\tilde{B}}(t) = y_{\tilde{B}} + \mathcal{O}(1/|t|)$ as $t \to -\infty$. Combining with (e) yields $\widehat{y}_{\tilde{B}}(t_k) = y_{\tilde{B}} + \mathcal{O}(1/|t_k|) + \mathcal{O}(h^2)$.

(g) Low–pass stability. Let LP_{τ_μ} be a linear time–invariant operator in t with kernel K_{τ_μ} satisfying the moment conditions in eqs. (7.537) and (7.538): $\int K_{\tau_\mu} = 1$ and $\int t\, K_{\tau_\mu}(t)\,\mathrm{d}t = 0$. A standard moment expansion shows that for smooth inputs $\widehat{y}_{\tilde{B}}$,

$$\mathsf{LP}_{\tau_\mu}[\widehat{y}_{\tilde{B}}](t_k) = \widehat{y}_{\tilde{B}}(t_k) + \tfrac{m_2(K)}{2}\,\tau_\mu^2\,\partial_t^2 \widehat{y}_{\tilde{B}}(t_k) + \mathcal{O}(\tau_\mu^3) = \widehat{y}_{\tilde{B}}(t_k) + \mathcal{O}(\tau_\mu^2),$$

hence the claimed bias. Discretisation contributes the $\mathcal{O}(h^2)$ term from (e). Choosing τ_μ below plateau tolerances (cf. Definition 6.297) keeps the bias subleading. □

Remark 7.464 (Intuition for the centered estimator and the audit path)**.** The centered estimator eq. (7.568) is a numerical stand–in for the local slope $\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\ln|\widetilde{\varepsilon}_{\tilde{B}}|$, which equals the projected breaking exponent on plateaux. The key heuristics are:

(i) Why centered? On a certified plateau (Definition 6.297 and Propositions 7.427 and 7.462) the curve $f_{\tilde{B}}(t) := \ln|\widetilde{\varepsilon}_{\tilde{B}}(\mu(t))|$ is *almost linear* in $t = \ln\mu$. A centered difference approximates $f'_{\tilde{B}}(t_k)$ with $\mathcal{O}(h^2)$ bias (Lemma 7.463(e)), whereas a forward difference has only $\mathcal{O}(h)$ accuracy (Definition 7.452). Thus the centered form is less biased when the goal is to read off a constant slope.

(ii) Why use $|\cdot|$? Jordan blocks in the linearised solution (Proposition 7.450, Definition 7.449) add only *polynomial* factors in t, and possible phases from complex data do not affect the magnitude. Taking $\ln|\cdot|$ isolates the dominant power law, so the estimator tracks $y_{\tilde{B}}$ up to the $\mathcal{O}(1/|t|)$ corrections proved in Proposition 7.453.

(iii) Why it is scale–robust. Changing the audit constant in $\mu = \kappa/\ell$ (cf. Definition 7.431) shifts $t = \ln\mu$ by a constant; the centered difference cancels this shift exactly (Lemma 7.463(a)). Similarly, rescaling eigenvectors only multiplies $\widetilde{\varepsilon}_{\tilde{B}}$ by a μ–independent constant, which cancels inside the logarithmic ratio (Lemma 7.463(d)).

(iv) Why it is gauge–safe. After the Nielsen projection (Definition 7.457), changes in the gauge parameter act by a similarity transform on the projected flow generator (Proposition 7.458), hence leave the spectrum $y_{\tilde{B}}$ invariant (Corollary 7.459). The estimator therefore converges to a gauge–independent limit on the IR window (Definition 7.461 and Proposition 7.462), up to the audit tolerance (7.588) (Lemma 7.463(b)).

(v) Why smoothing helps (and when). On real data, high–frequency jitter in t contaminates differences. A low–pass with moment conditions eqs. (7.537) and (7.538) preserves constants and linear trends, so it attenuates noise without biasing the plateau slope to

leading order (Lemma 7.463(g)). Choosing the smoothing scale below the plateau tolerances (Definition 6.297) keeps the bias subleading.

In short: on the Step 3 IR window the projected eigen–coupling behaves like $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \sim \mu^{y_{\tilde{B}}}$ up to polylogarithmic and higher–order corrections (Proposition 7.450 and Corollary 7.456); the centered, gauge–safe estimator reads off the constant slope $y_{\tilde{B}}$ with controllable $\mathcal{O}(h^2)$ and $\mathcal{O}(1/|t|)$ errors (Proposition 7.453, Lemma 7.463).

Proposition 7.465 (Consistency, rates, and mollified variant)**.** *Work on the IR window $\mathcal{I}_\mu^{[\mathcal{U}]}$ of Definition 7.461 and let $\widehat{y}_{\tilde{B}}$ be the centered estimator of Definition 7.446. Assume the hypotheses of Propositions 7.450 and 7.453 and that the Step 3 guards (plateau/acceptance and monotonicity/curvature) hold on the window (Definition 6.297, Proposition 7.427, and eq. (7.548)). On a uniform t–grid with step h ($t = \ln \mu$) one has*

$$\widehat{y}_{\tilde{B}}(\mu_k) = y_{\tilde{B}} + \mathcal{O}\Big(\tfrac{1}{|\ln(\mu_k/\mu_0)|}\Big) + \mathcal{O}(h^2),$$

and for the mollified estimator $\widehat{y}_{\tilde{B}}^{(\tau_\mu)} := \mathsf{LP}_{\tau_\mu}[\widehat{y}_{\tilde{B}}]$ with a low–pass satisfying the moment conditions eqs. (7.537) and (7.538),

$$\widehat{y}_{\tilde{B}}^{(\tau_\mu)}(\mu_k) = y_{\tilde{B}} + \mathcal{O}\Big(\tfrac{1}{|\ln(\mu_k/\mu_0)|}\Big) + \mathcal{O}(h^2) + \mathcal{O}(\tau_\mu^2).$$

Implicit constants are uniform on compact subintervals of the IR window and are controlled by the curvature/TV guards in eq. (7.548). In particular, $\widehat{y}_{\tilde{B}}(\mu_k) \to y_{\tilde{B}}$ as $k \to \infty$ (i.e. $\mu_k \downarrow 0$) and $h, \tau_\mu \to 0$.

Proof. Write $t_k := \ln \mu_k$ and $f_{\tilde{B}}(t) := \ln|\widetilde{\varepsilon}_{\tilde{B}}(\mu(t))|$ with $\widetilde{\varepsilon}_{\tilde{B}}$ the Nielsen–projected eigen–coupling (Definitions 7.454 and 7.457). On the IR window $\mathcal{I}_\mu^{[\mathcal{U}]}$ we have, by Proposition 7.462, small and decaying breakings and the Step 3 plateau/guard conditions (Definition 6.297, Proposition 7.427, and eq. (7.548)).

Step 1 (continuum bias). By Proposition 7.453,

$$f'_{\tilde{B}}(t) = \frac{\mathrm{d}}{\mathrm{d}t} \ln|\widetilde{\varepsilon}_{\tilde{B}}(\mu(t))| = y_{\tilde{B}} + \mathcal{O}\Big(\tfrac{1}{|t|}\Big) \qquad (t \to -\infty),$$

uniformly on the window thanks to the guards (which bound derivatives and variations).

Step 2 (discretisation error of the centered difference). On a uniform grid with step h, Lemma 7.463(c,e) gives

$$\widehat{y}_{\tilde{B}}(t_k) = \frac{f_{\tilde{B}}(t_{k+1}) - f_{\tilde{B}}(t_{k-1})}{2h} = f'_{\tilde{B}}(t_k) + \mathcal{O}(h^2),$$

with the constant controlled by $\sup_{[t_{k-1},t_{k+1}]} |f'''_{\tilde{B}}|$, which is finite on the window by the curvature/TV guard eq. (7.548). Combining with Step 1 yields

$$\widehat{y}_{\tilde{B}}(t_k) = y_{\tilde{B}} + \mathcal{O}\Big(\tfrac{1}{|t_k|}\Big) + \mathcal{O}(h^2).$$

Step 3 (mollification bias). If $\widehat{y}_{\tilde{B}}^{(\tau_\mu)} = \mathsf{LP}_{\tau_\mu}[\widehat{y}_{\tilde{B}}]$ with the low–pass satisfying the zero–th and first moment conditions eqs. (7.537) and (7.538), then a standard moment expansion gives $\widehat{y}_{\tilde{B}}^{(\tau_\mu)}(t_k) = \widehat{y}_{\tilde{B}}(t_k) + \mathcal{O}(\tau_\mu^2)$; see Lemma 7.463(g). This adds to the error from Step 2.

Step 4 (uniformity and convergence). All $\mathcal{O}(\cdot)$ terms above are uniform on compact subintervals of the IR window because the guards keep $f_{\tilde{B}}$ and its derivatives bounded and because of the smallness/decay ensured by Proposition 7.462. Therefore,

$$\widehat{y}_{\tilde{B}}(\mu_k) \to y_{\tilde{B}} \quad \text{as} \quad k \to \infty \ (\mu_k \downarrow 0), \quad h \to 0,$$

and, with smoothing, also $\tau_\mu \to 0$.

Optional invariances. The estimator is invariant under the audit constant in $\mu = \kappa/\ell$ and under μ–independent re–normalisations of eigenvectors by Lemma 7.463(a,d); gauge safety follows from Definition 7.457, Proposition 7.458, and Corollary 7.459. □

Definition 7.466 (Step 4 acceptance: irrelevance and gauge safety)**.** Work on the physical subspace $W := \operatorname{im}\mathcal{N}$ and on the IR window $\mathcal{I}_\mu^{[\mathcal{U}]}$ induced by the Step 3 mask (cf. Definition 7.461 and Proposition 7.462). The RG ledger for explicit breakings is *accepted* if:

1. **Irrelevance.** For every projected breaking eigendirection $\tilde{B}$ that is excited,

$$\operatorname{Re} y_{\tilde{B}} \ < \ 0 \quad \text{(eigenvalues of } Y^{\mathcal{N}}\text{; cf. Definition 7.454 and Corollary 7.456).}$$

Moreover, the combined (estimator + gauge) band for $y_{\tilde{B}}$ over $\mathcal{I}_\mu^{[\mathcal{U}]}$ does not cross 0: with $\widehat{y}_{\tilde{B}}$ as in Definition 7.446 and the tolerance audit (7.588),

$$0 \ \notin \ \Big[\inf_{\mu \in \mathcal{I}_\mu^{[\mathcal{U}]}} \widehat{y}_{\tilde{B}}(\mu) \ - \ \varepsilon_{\text{gauge}} \ , \quad \sup_{\mu \in \mathcal{I}_\mu^{[\mathcal{U}]}} \widehat{y}_{\tilde{B}}(\mu) \ + \ \varepsilon_{\text{gauge}} \Big].$$

2. **Flow suppression on the window.** For all such $\tilde{B}$,

$$\left|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\right| \ \le \ \varepsilon_{\text{plat}} \qquad \text{for all} \ \ \mu \le \mu_R^{[\mathcal{U}]} = \kappa/\ell_R^{[\mathcal{U}]},$$

with $(\ell_R^{[\mathcal{U}]}, \mu_R^{[\mathcal{U}]})$ from Proposition 7.427 and Definition 7.461 and $\varepsilon_{\text{plat}}$ the plateau tolerance from the certification pipeline (cf. Definition 6.297). This is consistent with the linear decay implied by $\operatorname{Re} y_{\tilde{B}} < 0$ (cf. Proposition 7.450 and Corollary 7.456).

3. **Gauge safety.** Exponents are computed from the Nielsen–projected matrix $Y^{\mathcal{N}}$ (Definition 7.457), and satisfy

$$\boxed{\sup_{\xi \in \Xi_{\text{adm}}} \left| y_{\tilde{B}}(\xi) - y_{\tilde{B}}(\xi_0) \right| \ \le \ \varepsilon_{\text{gauge}},} \tag{7.589}$$

i.e. the gauge–tolerance audit (7.588) holds on $\mathcal{I}_\mu^{[\mathcal{U}]}$ (Proposition 7.458 and Corollary 7.459).

Proposition 7.467 (Soundness and robustness of Step 4 acceptance)**.** *If the criteria of Definition 7.466 hold on the IR window $\mathcal{I}_\mu^{[\mathcal{U}]}$ of Definition 7.461, then:*

(i) Every excited projected mode is RG–irrelevant in the Wilsonian sense: $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \to 0$ as $\mu \downarrow 0$.

(ii) The Step 3 law–channel restoration is consistent with the measured running on $\mathcal{I}_\mu^{[\mathcal{U}]}$; in particular the hypotheses of Proposition 7.453 are satisfied on this window.

(iii) The quoted exponents $\{y_{\tilde{B}}\}$ are gauge–parameter independent up to the audit tolerance $\varepsilon_{\text{gauge}}$ and invariant under admissible basis/scheme changes (Corollary 7.459 and Lemma 7.451).

Proof. All statements are made on the physical subspace $W := \operatorname{im}\mathcal{N}$ after Nielsen projection (Definition 7.457). Let $Y^{\mathcal{N}}$ be the projected stability matrix (eq. (7.567)).

(1) Irrelevance. By Item 1 of Definition 7.466, $\operatorname{Re} y_{\tilde{B}} < 0$ for every excited eigendirection and the combined (estimator+gauge) bands over $\mathcal{I}_\mu^{[\mathcal{U}]}$ do not cross 0. Hence, by the linear Jordan solution and irrelevance criterion (Proposition 7.450, Definition 7.449, and Corollary 7.456), each projected eigen–coupling satisfies

$$\widetilde{\varepsilon}_{\tilde{B}}(\mu) = \left(\tfrac{\mu}{\mu_0}\right)^{y_{\tilde{B}}} \Big[\operatorname{polylog}(\ln \tfrac{\mu}{\mu_0})\Big]\,[1+o(1)] \quad \longrightarrow \quad 0 \qquad (\mu \downarrow 0),$$

since the polynomial in $\ln(\mu/\mu_0)$ cannot overcome the negative real part of $y_{\tilde{B}}$. Because $\mathcal{I}_\mu^{[\mathcal{U}]} = \{\mu \le \mu_R^{[\mathcal{U}]}\}$ is a half–line (Definition 7.461 and Proposition 7.462), this decay holds along the entire IR direction.

(2) Consistency with Step 3 and applicability of Proposition 7.453. By Proposition 7.462, the Step 3 guards (plateaux and monotonicity/curvature, cf. Definition 6.297, Proposition 7.427, and eq. (7.548)) hold on $\mathcal{I}_\mu^{[\mathcal{U}]}$. Consequently the breaking sector is small and decaying there, and the continuum running of each eigen–coupling obeys the asymptotic form used in Proposition 7.453. Item 2 of Definition 7.466 (flow suppression $|\widetilde{\varepsilon}_{\tilde{B}}(\mu)| \le \varepsilon_{\text{plat}}$ for $\mu \le \mu_R^{[\mathcal{U}]}$) is consistent with this decay and guarantees that nonlinear remainders in the RG equation remain subleading on the window (cf. the remainder control in the proofs of Propositions 7.450 and 7.455). Hence the estimator consistency and rate statements of Proposition 7.453 (and, discretely, Proposition 7.465) apply.

(3) Gauge, basis, and scheme robustness. Gauge–parameter variations act by a similarity (Lax) flow on $Y^{\mathcal{N}}$,

$$\partial_\alpha Y^{\mathcal{N}} = [K(\alpha), Y^{\mathcal{N}}], \qquad Y^{\mathcal{N}}(\alpha) = S(\alpha,\alpha_0)\, Y^{\mathcal{N}}(\alpha_0)\, S(\alpha,\alpha_0)^{-1},$$

by Proposition 7.458; hence the spectrum $\{y_{\tilde{B}}\}$ is gauge–independent (Corollary 7.459), and the audit bound (7.588) (= (7.589)) in Definition 7.466 records finite–precision tolerance. Admissible basis changes and fixed–point scheme changes act by similarity on W (Lemma 7.451; Nielsen–projected version in Lemma 7.460), so the multiset of exponents is invariant. Therefore the quoted $\{y_{\tilde{B}}\}$ are robust under the allowed gauge/basis/scheme variations.

Putting (1)–(3) together establishes the claimed soundness and robustness of the Step 4 acceptance. □

Remarks. (i) Item 2 of Definition 7.466 (flow suppression) also ensures numerical stability for the centered estimator Definition 7.446; together with Proposition 7.465 it guarantees that discretisation and mollification errors remain below the plateau tolerances on $\mathcal{I}_\mu^{[\mathcal{U}]}$. (ii) If some $y_{\tilde{B}}$ are nearly degenerate, eigenvectors may rotate along the audit path, but similarity invariance preserves the spectrum and the measured exponents (cf. Corollary 7.459 and Lemma 7.451).

Outputs for Step 4. All deliverables are produced on the on–shell BRST–physical subspace $W := \operatorname{im}\mathcal{N}$ (Nielsen projection; cf. Definition 7.457). First, we present the *projected stability data at the fixed point*: the matrix $Y^{\mathcal{N}}(g_\star)$ at the IR fixed point $g_\star$ (Definition 7.447), its spectrum of projected exponents $\{y_{\tilde{B}}\}$, and the change of basis R that brings $Y^{\mathcal{N}}$ to eigen/Jordan form on W (Definition 7.454); when present, nontrivial Jordan structure is documented via block sizes and nilpotent indices (Definition 7.449).

Next, we report *measured runnings and slope fits*. For each projected mode we plot $\mu \mapsto \widetilde{\varepsilon}_{\tilde{B}}(\mu)$ on the IR window $\mathcal{I}_\mu^{[\mathcal{U}]}$ induced by the Step 3 restoration mask (Definition 7.461), fit slopes using the centered estimator eq. (7.568) (optionally its mollified variant satisfying eqs. (7.537) and (7.538)), and overlay confidence bands consistent with Propositions 7.453 and 7.465.

We then provide a brief *robustness summary*: we record the spread of the extracted $\{y_{\tilde{B}}\}$ across admissible gauges (checked against the audit bound eq. (7.589), equivalent to eq. (7.588) by Corollary 7.459) and across admissible estimator controls (grid step h, smoothing scale τ_μ), citing the rate guarantees of Proposition 7.465.

Finally, we include a *consistency note with the restoration mask and Step 2 slope*: we verify that the Step 4 IR window lies entirely inside the Step 3 certified region (Proposition 7.462) and respects law–channel restoration and slope positivity, i.e. $\varsigma_{\mathrm{law}}^{(\tau)}(\ell) > 0$ together with the monotonicity/curvature guards eqs. (7.542) and (7.548) along the ℓ–preimage $\mathcal{I}_\ell$ (cf. Definitions 6.297 and 7.461 and Proposition 7.427). For reproducibility, we record $(\kappa,\ \mathcal{N},\ Z^{\mathcal{N}},\ Y^{\mathcal{N}})$, the chosen R, the window endpoints $(\ell_R^{[\mathcal{U}]}, \mu_R^{[\mathcal{U}]})$, and the estimator settings (grid h, smoothing τ_μ) alongside code stencils and seeds.

Negative Nielsen–projected exponents $y_{\tilde{B}}$ (eigenvalues of $Y^{\mathcal{N}}$) certify that explicit symmetry breakings are RG–irrelevant (Corollary 7.456), and the estimator plots/bands on $\mathcal{I}_\mu^{[\mathcal{U}]}$ substantiate this with controlled rates (Propositions 7.453 and 7.465). Together with the Step 3 restoration mask and positive IR slope (Proposition 7.427 and eq. (7.542)), this closes the Step 4 ledger and prepares the Ward/Slavnov–Taylor/Nielsen closure in subsequent steps [389, 91, 117, 243].

Conclusion for Step 4. Step 4 established irrelevance of explicit breakings on the *physical* operator space by working after the Nielsen projection $W := \operatorname{im}\mathcal{N}$ (cf. Definition 7.457). On W the projected stability matrix $Y^{\mathcal{N}}$ governs the linearised RG of the breaking sector (cf. eq. (7.567)). Its spectral/Jordan data (Definition 7.449) yield the projected exponents $y_{\tilde{B}}$, and the Jordan-form solution shows that each eigen–coupling runs as a power of μ multiplied by at most a finite polynomial in $\ln\mu$ (Proposition 7.450). The criterion $\operatorname{Re} y_{\tilde{B}} < 0$ therefore guarantees $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \to 0$ toward the IR, i.e. Wilsonian irrelevance (Corollary 7.456).

We then *measured and certified* these exponents on the IR window induced by the Step 3 restoration mask (Definition 7.461 and Proposition 7.462). Using the centered log–derivative estimator (Definition 7.446, eq. eq. (7.568))—optionally mollified under moment constraints—we obtained controlled convergence to $y_{\tilde{B}}$ with explicit rates: $\widehat{y}_{\tilde{B}} = y_{\tilde{B}} + \mathcal{O}(1/|\ln\mu|) + \mathcal{O}(h^2)$ (and $+\mathcal{O}(\tau_\mu^2)$ if smoothed), as formalised in Propositions 7.453 and 7.465. The Step 3 guards ensure the smallness/decay required for these bounds across the entire window (Proposition 7.462).

Robustness was demonstrated along three axes. First, *gauge safety*: by the Nielsen identity

the projected generator $Y^{\mathcal{N}}$ evolves by a similarity (Lax) flow in the gauge parameter, so its spectrum is invariant (Proposition 7.458 and Corollary 7.459), with a practical audit band (7.588). Second, *basis/scheme covariance*: admissible operator relabellings and fixed–point scheme changes act by similarity on W, leaving $\{y_{\tilde{B}}\}$ unchanged (Lemmas 7.451 and 7.460). Third, *flow suppression* on the certified window matches the irrelevance prediction and stabilises estimation (Item 2 in Definition 7.466).

Finally, Step 4 delivered a reproducible audit packet: $Y^{\mathcal{N}}(g_\star)$ and its spectral/Jordan data, estimator plots with confidence bands on $\mathcal{I}_\mu^{[\mathcal{U}]}$, gauge/instrument robustness tables, and a consistency report with the Step 3 mask. With these pieces, the acceptance test of Definition 7.466 implies the soundness/robustness guarantees in Proposition 7.467. In short, Step 4 does not merely assert but *certifies* that the explicit breakings are RG–irrelevant on the physical subspace, closing the QIII ledger and preparing the Ward/Slavnov–Taylor/Nielsen closure in the subsequent steps.

7.8.5 Ward/ST/Nielsen Closure (Band–Projected)

Objective. We certify that global Ward structures are *restored* in the IR while the gauge/BRST sector remains exact on shell. Concretely, we (i) define a band–projected Ward–residual norm $\mathcal{W}(\ell)$ (below), (ii) demand a *strictly negative* logarithmic slope on the Step 3 IR window (cf. eq. (7.542)),

$$\partial_{\ln \ell}\, \mathcal{W}(\ell) \;\le\; -c \;<\; 0 \qquad \text{for all } \ell \in \mathcal{I}_\ell,$$

and (iii) verify restoration at the Step 3 length (cf. eq. (7.551)):

$$\mathcal{W}\big(\ell_R\big) \;\le\; \varepsilon_{\mathrm{plat}}.$$

In parallel, the Slavnov–Taylor (ST) identity holds on shell at all ℓ, and all quoted IR poles/residues have *zero gauge–parameter slope* by the Nielsen identity (cf. eq. (7.581); see also [117, 243, 442]).

Band–projected Ward residual.

Definition 7.468 (Band–limited 1PI functional and Ward residual)**.** Fix the instrumentation used in eq. (7.522): a UV projector $P_x(\lambda_{\mathrm{UV}})$ and an IR kernel $K_{\mathrm{IR}}^{(\ell)}$, applied consistently to fields and sources, and evaluate on shell. Let $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$ denote the resulting *band–limited* 1PI effective action, and let G be a global symmetry group with generators T^a (representation on fields understood). Write the associated Ward operators $W^a[\Gamma]$ (which vanish identically when the symmetry is exact; see, e.g., [117, 447]).

Define the admitted momentum band and the band–projected Ward operator by

$$\boxed{\begin{aligned} \mathfrak{B}(\lambda_{\mathrm{UV}},\ell) &:= \left\{ p \in \mathbb{R}^d \;\middle|\; \begin{array}{l} P_x(\lambda_{\mathrm{UV}}) \text{ and } K_{\mathrm{IR}}^{(\ell)} \text{ admit external kinematics} \\ \text{with total momentum } p \end{array} \right\}, \\ \mathcal{W}^a(p;\ell) &:= \Big(W^a[\Gamma^{(\lambda_{\mathrm{UV}},\ell)}]\Big)\Big|_p , \end{aligned}} \tag{7.590}$$

where the restriction $|_p$ means evaluation at external kinematics compatible with the band (and on–shell conditions). Let $\mathcal{R}(p;\ell)$ be a *co–channel reference response* (e.g. the appropriate band–limited two–point kernel) such that $\|\mathcal{R}(p;\ell)\|_{\mathrm{op}} > 0$ on $\mathfrak{B}$. The *dimensionless Ward residual* is

$$\boxed{\mathcal{W}(\ell) := \sup_{a} \sup_{p\in\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)} \frac{\left\|\mathcal{W}^{a}(p;\ell)\right\|_{\mathrm{op}}}{\left\|\mathcal{R}(p;\ell)\right\|_{\mathrm{op}}}.} \tag{7.591}$$

Intuition. We quantify the (band–limited) failure of the Ward identities by comparing the Ward operator to a co–channel response, yielding a scale–free number $\mathcal{W}(\ell)$. Restricting to the same band used to define $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$ keeps the metric consistent with the instrumentation and with the Step 3 IR window; on–shell evaluation ensures gauge/BRST artefacts are excluded (Nielsen and ST protection, cf. eq. (7.581)).

Lemma 7.469 (Well–posedness and invariances for the band–projected residual)**.** *Let* $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ *and* $\mathcal{W}(\ell)$ *be as in eqs.* (7.590) *and* (7.591)*. Assume, for each fixed* $(\lambda_{\mathrm{UV}},\ell)$*:*

(i) $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ *is compact;*

(ii) $p \mapsto \mathcal{W}^{a}(p;\ell)$ *and* $p \mapsto \mathcal{R}(p;\ell)$ *are continuous (as operator–valued maps);*

(iii) $\|\mathcal{R}(p;\ell)\|_{\mathrm{op}} > 0$ *for all* $p \in \mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$*;*

(iv) *the Ward–generator index set is compact: either a* finite *set of generators* $\{T^{a}\}$*, or (equivalently) the supremum over* a *is taken over the unit sphere of a finite–dimensional Lie algebra with a fixed norm.*

Then $\mathcal{W}(\ell)$ *is finite and the supremum is attained.*

Moreover:

(A) *(*Unitary field re–bases*) If the external field multiplet in the audited channel is re–expressed by a unitary change of basis* U *(with respect to the inner product that induces* $\|\cdot\|_{\mathrm{op}}$*), then both* $\mathcal{W}^{a}$ *and* $\mathcal{R}$ *transform by conjugation, the operator norm is unitarily invariant, and* $\mathcal{W}(\ell)$ *is unchanged.*

(B) *(*Uniform leg–rescalings in the channel*) If each external leg in the audited channel is rescaled by a positive scalar* s *(i.e.* $\phi \mapsto s\,\phi$ *for those species only), then* n*–point kernels in that channel acquire the common factor* s^{n}*; hence the numerator and denominator in eq.* (7.591) *are multiplied by the same factor, and* $\mathcal{W}(\ell)$ *is unchanged.*

(C) *(*Reference normalisation*) Replacing* $\mathcal{R}$ *by* $c\,\mathcal{R}$ *with a* constant $c > 0$ *rescales* $\mathcal{W}(\ell)$ *by* $1/c$*. The* log–slope *criterion* $\partial_{\ln\ell}\mathcal{W} \le -c_{0} < 0$ *and any comparison of slopes are invariant under such constant renormalisations. (If* c *depended on* ℓ*, the slope would shift by* $-\partial_{\ln\ell}\ln c(\ell)$*, so admissible choices must be* ℓ*–independent.)*

Proof. **Well–posedness.** Fix $(\lambda_{\mathrm{UV}},\ell)$. For each generator label a, define

$$F_{a}(p;\ell) := \frac{\|\mathcal{W}^{a}(p;\ell)\|_{\mathrm{op}}}{\|\mathcal{R}(p;\ell)\|_{\mathrm{op}}} \qquad (p \in \mathfrak{B}(\lambda_{\mathrm{UV}},\ell)).$$

By (ii)–(iii), both numerator and denominator are continuous in p and the denominator is strictly positive on $\mathfrak{B}(\lambda_{\mathrm{UV}}, \ell)$; hence $F_a(\,\cdot\,;\ell)$ is continuous on the compact set $\mathfrak{B}(\lambda_{\mathrm{UV}}, \ell)$ and attains a finite maximum there (extreme–value theorem).

If the set of a is finite, then $\mathcal{W}(\ell) = \max_a \max_{p\in\mathfrak{B}} F_a(p;\ell)$ is the maximum of finitely many attained maxima and is therefore finite and attained. If instead we take the supremum over the unit sphere in a finite–dimensional Lie algebra (assumption (iv)), the map

$$(p, \hat{a}) \;\longmapsto\; F_{\hat{a}}(p;\ell)$$

is continuous on the compact product $\mathfrak{B}(\lambda_{\mathrm{UV}}, \ell) \times S$ (with S the unit sphere), so the joint maximum exists and is finite; in particular, the supremum over a is attained.

(A) Unitary field re–bases. Let U be unitary with respect to the inner product that induces $\|\cdot\|_{\mathrm{op}}$. In the audited channel, tensors/kernels transform by conjugation (or congruence) with U—the precise side (left/right) depends on slot convention but is identical for numerator and denominator, cf. the "same channel" prescription in Definition 7.468. Because the operator norm is unitarily invariant,

$$\|\mathcal{W}^a\|_{\mathrm{op}} \mapsto \|U^{-1}\mathcal{W}^a U\|_{\mathrm{op}} = \|\mathcal{W}^a\|_{\mathrm{op}}, \qquad \|\mathcal{R}\|_{\mathrm{op}} \mapsto \|U^{-1}\mathcal{R}U\|_{\mathrm{op}} = \|\mathcal{R}\|_{\mathrm{op}},$$

so each ratio F_a and thus $\mathcal{W}(\ell)$ are unchanged.

(B) Uniform leg–rescalings in the channel. Let $\phi \mapsto s\,\phi$ with $s > 0$ for all external legs in the audited channel; then an n–point amputated kernel in that channel scales as s^n. By Definition 7.468, both $\mathcal{W}^a$ and the co–channel reference $\mathcal{R}$ are chosen with the same external–leg structure (same n), hence

$$\|\mathcal{W}^a\|_{\mathrm{op}} \mapsto s^n\|\mathcal{W}^a\|_{\mathrm{op}}, \qquad \|\mathcal{R}\|_{\mathrm{op}} \mapsto s^n\|\mathcal{R}\|_{\mathrm{op}},$$

and F_a (hence $\mathcal{W}$) is invariant.

(C) Reference normalisation. If $\mathcal{R} \mapsto c\,\mathcal{R}$ with a constant $c > 0$, then $F_a \mapsto F_a/c$ and $\mathcal{W}(\ell) \mapsto \mathcal{W}(\ell)/c$. Thus the absolute level depends on the chosen normalisation of the reference kernel, but the *logarithmic slope* $\partial_{\ln\ell} \ln \mathcal{W}$ (and the strict negativity condition of the Step 5 objective) is unaffected by any *constant* choice of c. If c depended on ℓ, the slope would shift by the additive term $-\partial_{\ln\ell} \ln c(\ell)$; hence admissible normalisations must be ℓ–independent for the slope test to be meaningful. In practice we fix $\mathcal{R}$ once and for all on the Step 3 window (cf. Proposition 7.462) to avoid this ambiguity.

These statements use only the band–limited setup and same–channel normalisation in Definition 7.468 and do not rely on additional structure. □

Proposition 7.470 (Vanishing for exact symmetry; leading response to explicit breakings)**.** *Let $\mathcal{W}(\ell)$ be the band–projected Ward residual of Definition 7.468.*

(Exact symmetry). *If the global symmetry generated by T^a is exact for the band–limited 1PI functional $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$ (on shell), then*

$$\mathcal{W}^a(\cdot;\ell) \equiv 0 \qquad \textit{and hence} \qquad \mathcal{W}(\ell) = 0.$$

(Small explicit breakings). *If explicit breaking couplings $\varepsilon_A(\mu)$ multiply renormalised operators $\hat{\mathcal{O}}_A$ as in eq. (7.522), with $\mu = \kappa/\ell$ (cf. Definition 7.461), then for sufficiently small ε one has the linear expansion (on shell and within the admitted band)*

$$\mathcal{W}^a(p;\ell) = \sum_A \varepsilon_A(\kappa/\ell)\, \mathcal{K}^a{}_A(p;\ell) + \mathcal{O}\Big(\|\varepsilon\|^2\Big). \tag{7.592}$$

for some band–limited kernels $\mathcal{K}^a_A$ depending on the channel and instrumentation $(P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$. Consequently, there exists a finite constant $C(\lambda_{\mathrm{UV}},\ell) > 0$ (uniform on the band $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$) such that

$$\mathcal{W}(\ell) \;\le\; C(\lambda_{\mathrm{UV}},\ell) \sum_{\tilde{B}} \Big|\widetilde{\varepsilon}_{\tilde{B}}(\kappa/\ell)\Big| \;+\; \mathcal{O}(\|\varepsilon\|^2), \tag{7.593}$$

where $\widetilde{\varepsilon}_{\tilde{B}}$ are the Nielsen–projected eigen–couplings (Definitions 7.454 and 7.457).

Proof. **Exact symmetry.** If the symmetry generated by T^a is exact for $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$ (on shell), then the Ward operator vanishes identically: $W^a[\Gamma^{(\lambda_{\mathrm{UV}},\ell)}] \equiv 0$ (e.g. [117, 447]). Therefore $\mathcal{W}^a(p;\ell) = 0$ for all $p \in \mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$, and by eq. (7.591) the residual $\mathcal{W}(\ell) = 0$.

Linear response to explicit breakings. Consider the band–limited functional with small explicit breakings,

$$\Gamma^{(\lambda_{\mathrm{UV}},\ell)}[\phi;\varepsilon] = \Gamma_0^{(\lambda_{\mathrm{UV}},\ell)}[\phi] + \sum_A \varepsilon_A(\kappa/\ell)\, \mathcal{I}_A^{(\lambda_{\mathrm{UV}},\ell)}[\phi] \;+\; \mathcal{O}(\|\varepsilon\|^2),$$

where $\Gamma_0^{(\lambda_{\mathrm{UV}},\ell)}$ is the symmetric ($\varepsilon = 0$) functional, and $\mathcal{I}_A^{(\lambda_{\mathrm{UV}},\ell)}$ denotes the band–limited, renormalised insertion of $\hat{\mathcal{O}}_A$ (consistent with $P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}}$; cf. Definition 7.468). The Ward operator is linear in Γ, so expanding at the symmetric point and evaluating on shell yields the Gateaux derivative

$$W^a[\Gamma^{(\lambda_{\mathrm{UV}},\ell)}] = W^a[\Gamma_0^{(\lambda_{\mathrm{UV}},\ell)}] + \sum_A \varepsilon_A(\kappa/\ell) \Big(\mathrm{D}_{\mathcal{I}_A} W^a\Big)\Big[\Gamma_0^{(\lambda_{\mathrm{UV}},\ell)}\Big] \;+\; \mathcal{O}(\|\varepsilon\|^2).$$

Since the symmetry is exact at $\varepsilon = 0$, the first term vanishes; define the band–limited kernels (on shell)

$$\mathcal{K}^a_A(p;\ell) \;:=\; \Big(\mathrm{D}_{\mathcal{I}_A} W^a\Big)\Big[\Gamma_0^{(\lambda_{\mathrm{UV}},\ell)}\Big]\Big|_p,$$

to obtain eq. (7.592) after restricting to $p \in \mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ (eq. (7.590)). By the assumptions in Lemma 7.469, the remainder is $\mathcal{O}(\|\varepsilon\|^2)$ uniformly on the compact band.

From linear response to a band–uniform bound. Taking operator norms and using eq. (7.591) plus the triangle inequality,

$$\begin{aligned}
\mathcal{W}(\ell) &= \sup_a \sup_{p\in\mathfrak{B}} \frac{\big\|\sum_A \varepsilon_A\, \mathcal{K}^a_A(p;\ell)\big\|_{\mathrm{op}}}{\|\mathcal{R}(p;\ell)\|_{\mathrm{op}}} + \mathcal{O}(\|\varepsilon\|^2) \\
&\le \sum_A |\varepsilon_A(\kappa/\ell)| \underbrace{\sup_a \sup_{p\in\mathfrak{B}} \frac{\|\mathcal{K}^a_A(p;\ell)\|_{\mathrm{op}}}{\|\mathcal{R}(p;\ell)\|_{\mathrm{op}}}}_{=:C_A(\lambda_{\mathrm{UV}},\ell)} + \mathcal{O}(\|\varepsilon\|^2).
\end{aligned}$$

Set $C(\lambda_{\mathrm{UV}},\ell) := \sum_A C_A(\lambda_{\mathrm{UV}},\ell)$ to get $\mathcal{W}(\ell) \le C(\lambda_{\mathrm{UV}},\ell)\sum_A |\varepsilon_A(\kappa/\ell)| + \mathcal{O}(\|\varepsilon\|^2)$.

Passing to Nielsen–projected eigen–couplings. Let R be the change of basis that (block-)Jordanises the *projected* stability matrix on the physical subspace $W := \operatorname{im}\mathcal{N}$ (cf. Definitions 7.454 and 7.457): $\widetilde{\varepsilon} := R^{-1}\varepsilon$ with components $\widetilde{\varepsilon}_{\tilde{B}}$. In a finite–dimensional space all norms are equivalent, and the linear map R^{-1} is bounded; hence there exists a finite $M_R > 0$ (depending only on R) such that

$$\sum_A |\varepsilon_A| \;\le\; M_R \sum_{\tilde{B}} |\widetilde{\varepsilon}_{\tilde{B}}|.$$

Combining with the previous bound yields eq. (7.593) with the redefined constant $C(\lambda_{\mathrm{UV}},\ell) \leftarrow M_R\, C(\lambda_{\mathrm{UV}},\ell)$. Basis/scheme covariance of this step follows from Lemmas 7.451 and 7.460, and the on–shell construction ensures gauge–parameter safety within the tolerance ledger (eq. (7.581) and Corollary 7.459).

This proves both the vanishing in the symmetric case and the linear–response bound in the explicitly broken case, uniformly on the admitted band $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$. □

Comments. (i) The constant $C(\lambda_{\mathrm{UV}},\ell)$ is finite under the compactness/continuity assumptions of Lemma 7.469 and depends only on the instrumentation and the chosen co–channel reference $\mathcal{R}$. (ii) On the Step 4 IR window (Definition 7.461 and Proposition 7.462) the eigen–couplings $\widetilde{\varepsilon}_{\tilde{B}}(\kappa/\ell)$ decay (Step 4: Corollary 7.456), so eq. (7.593) implies $\mathcal{W}(\ell) \downarrow 0$, anticipating the Step 5 restoration test.

Corollary 7.471 (IR decay of the band–projected Ward residual under irrelevance)**.** *Fix the instrumentation* $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ *and work on the IR ray* $\mu = \kappa/\ell \downarrow 0$ *(cf. Definition 7.461). If all* excited *projected breaking exponents satisfy* $\operatorname{Re} y_{\tilde{B}} < 0$ *(as certified in Step 4), then*

$$\mathcal{W}(\ell) \;=\; \mathcal{O}\Big(\sum_{\tilde{B}} \mu^{\operatorname{Re} y_{\tilde{B}}}\, \mathrm{poly}\big(\ln\mu\big)\Big) \;\xrightarrow[\mu\to 0]{}\; 0,$$

with logarithmic factors present only when Jordan blocks occur (cf. Definition 7.449 and Proposition 7.450). Equivalently, letting $y_\star := \max_{\tilde{B}} \operatorname{Re} y_{\tilde{B}} < 0$*, one has* $\mathcal{W}(\ell) = \mathcal{O}\big(\mu^{\operatorname{Re} y_\star}\,\mathrm{poly}(\ln\mu)\big) \to 0$.

Proof. Start from the band–uniform linear–response bound of Proposition 7.470:

$$\mathcal{W}(\ell) \;\le\; C(\lambda_{\mathrm{UV}},\ell) \sum_{\tilde{B}} \big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big| \;+\; \mathcal{O}\big(\|\varepsilon(\mu)\|^2\big), \qquad \mu = \kappa/\ell, \tag{7.594}$$

where the constant $C(\lambda_{\mathrm{UV}},\ell)$ depends only on the instrumentation and the co–channel reference (Definition 7.468). By the Step 4 linear solution on the physical subspace (Definition 7.457 and Proposition 7.450), each projected eigen–coupling has the asymptotics

$$\widetilde{\varepsilon}_{\tilde{B}}(\mu) = \mu^{y_{\tilde{B}}}\Big[\mathrm{poly}\big(\ln\mu\big)\Big]\,[1 + o(1)] \qquad (\mu \downarrow 0),$$

with the polynomial factor absent when the corresponding Jordan block is trivial (Definition 7.449). Taking absolute values yields

$$\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big| = \mu^{\operatorname{Re} y_{\tilde{B}}}\,\mathrm{poly}\big(\ln\mu\big)\,[1 + o(1)].$$

Uniformity of the prefactor. Along the Step 3 IR window (half–line in ℓ, cf. Definition 7.461 and Proposition 7.462), the admitted band $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ stays inside a fixed compact region of momentum space and varies continuously with ℓ; $\mathcal{R}$ and the kernels $\mathcal{K}_A^a$ are continuous on band (assumptions of Lemma 7.469). Hence

$$C_\star \;:=\; \sup_{\ell\ge\ell_R}\; C(\lambda_{\mathrm{UV}},\ell) \;<\; \infty,$$

so $C(\lambda_{\mathrm{UV}},\ell)\le C_\star$ for all ℓ in the IR window.[12]

Quadratic remainder. By norm equivalence in finite dimension and the change of basis to the eigen–coordinates (Definition 7.454), there exists $M>0$ with $\|\varepsilon(\mu)\|\le M\sum_{\tilde B}|\widetilde{\varepsilon}_{\tilde B}(\mu)|$. Thus the remainder in (7.594) satisfies

$$\mathcal{O}\Big(\|\varepsilon(\mu)\|^2\Big)=\mathcal{O}\Big(\Big[\sum_{\tilde B}|\widetilde{\varepsilon}_{\tilde B}(\mu)|\Big]^2\Big)=\mathcal{O}\Big(\sum_{\tilde B}\mu^{\,2\,\mathrm{Re}\,y_{\tilde B}}\,\mathrm{poly}\Big(\ln\mu\Big)\Big),$$

which is $o\Big(\sum_{\tilde B}\mu^{\,\mathrm{Re}\,y_{\tilde B}}\,\mathrm{poly}(\ln\mu)\Big)$ as $\mu\downarrow 0$ because all $\mathrm{Re}\,y_{\tilde B}<0$.

Putting these estimates into (7.594) gives

$$\mathcal{W}(\ell)\;\le\; C_\star\sum_{\tilde B}\mu^{\,\mathrm{Re}\,y_{\tilde B}}\,\mathrm{poly}\Big(\ln\mu\Big)\,[1+o(1)],$$

which proves the claimed big–$\mathcal{O}$ bound and the limit $\mathcal{W}(\ell)\to 0$ as $\mu\downarrow 0$. The alternative form with $y_\star=\max_{\tilde B}\mathrm{Re}\,y_{\tilde B}$ follows by bounding the sum by a constant multiple of the dominant term. □

Definition 7.472 (UV–uniform Ward residual)**.** Let $\mathcal{U}=[u_{\min},u_{\max}]$ be an admissible UV strip (cf. Definition 7.430) and write $u=\ln\lambda_{\mathrm{UV}}$. For fixed ℓ, define

$$\mathcal{W}^{[\mathcal{U}]}(\ell):=\sup_{u\in\mathcal{U}}\;\sup_{p\in\mathfrak{B}(\mathrm{e}^u,\ell)}\;\frac{\big\|\mathcal{W}^a(p;\ell;u)\big\|_{\mathrm{op}}}{\big\|\mathcal{R}(p;\ell;u)\big\|_{\mathrm{op}}}\qquad(\text{sup over } a \text{ understood}),$$

with the dependence on u made explicit through the band $\mathfrak{B}(\mathrm{e}^u,\ell)$ and the band–limited objects $\mathcal{W}^a(\cdot;\ell;u)$, $\mathcal{R}(\cdot;\ell;u)$ (cf. Definition 7.468). Then, by definition,

$$\mathcal{W}^{[\mathcal{U}]}(\ell)=\sup_{u\in\mathcal{U}}\mathcal{W}(\ell;u),$$

and, under the assumptions of Lemma 7.469 uniformly in $u\in\mathcal{U}$, $\mathcal{W}^{[\mathcal{U}]}(\ell)$ is finite and inherits the invariances stated there.

Lemma 7.473 (Gauge–parameter safety via on–shell Nielsen projection)**.** *Assume gauge fixing and evaluate correlators* on shell. *Replace all insertions by their Nielsen–projected counterparts on $W=\mathrm{im}\,\mathcal{N}$ (cf. Definition 7.457). Then the band–projected residuals computed from the projected data $(Y^{\mathcal{N}},\Gamma^{(\lambda_{\mathrm{UV}},\ell)}|_W)$ are independent of the gauge parameter within the tolerance eq. (7.588) on any Step 3 IR window (cf. Definition 7.461 and Proposition 7.462).*

[12] If one does not assume global uniformity, the argument below still goes through whenever $C(\lambda_{\mathrm{UV}},\ell)$ has at most polylogarithmic growth in ℓ; the decay from $\mu^{\mathrm{Re}\,y_{\tilde B}}$ dominates. In our instrumentation, boundedness holds.

Proof. **1) On–shell gauge flow (Nielsen).** By the Nielsen identity (eq. (7.581)) and projection to the physical subspace $W = \operatorname{im}\mathcal{N}$ (Definition 7.457), gauge–parameter variation acts by an adjoint flow on composite operator multiplets: for a smooth gauge parameter ξ,

$$\partial_\xi X^{\mathcal{N}}(\xi) = \big[K(\xi),\, X^{\mathcal{N}}(\xi)\big] \quad \text{on } W,$$

for any renormalised insertion X (Ward operator or co–channel reference), with a bounded generator $K(\xi)$ (Proposition 7.458). The solution is the path–ordered similarity $X^{\mathcal{N}}(\xi) = S(\xi,\xi_0)^{-1} X^{\mathcal{N}}(\xi_0) S(\xi,\xi_0)$.

2) Effect on the residual at fixed (u,ℓ,p). Fix (u,ℓ) and an admissible $p \in \mathfrak{B}(\mathrm{e}^u,\ell)$. Denote $N(\xi) := \mathcal{W}^a(p;\ell;u,\xi)^{\mathcal{N}}$ and $D(\xi) := \mathcal{R}(p;\ell;u,\xi)^{\mathcal{N}}$. Then $N(\xi) = S^{-1}N_0 S$ and $D(\xi) = S^{-1}D_0 S$, where the subscript 0 refers to ξ_0. Consider the *dimensionless* map

$$\Phi(\xi) \;:=\; D(\xi)^{-1} N(\xi).$$

Differentiating and using $\partial_\xi D = [K,D]$, $\partial_\xi N = [K,N]$ gives

$$\partial_\xi \Phi = [K,\Phi], \qquad \Phi(\xi) = S(\xi,\xi_0)^{-1}\,\Phi(\xi_0)\,S(\xi,\xi_0).$$

Hence Φ is conjugate along the gauge flow.

3) Norm control and tolerance. Let $\|\cdot\|_{\mathrm{op}}$ be any operator norm subordinate to a fixed (gauge–independent) inner product on the co–channel space. Then

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\,\|\Phi(\xi)\|_{\mathrm{op}} \;=\; \lim_{h\to 0}\frac{\|(\mathrm{I}+h\,\mathrm{ad}_K)\Phi\|_{\mathrm{op}} - \|\Phi\|_{\mathrm{op}}}{h} \;\le\; 2\,\|K(\xi)\|_{\mathrm{op}}\,\|\Phi(\xi)\|_{\mathrm{op}},$$

by submultiplicativity and $\|\,[K,\Phi]\,\| \le \|K\|\,\|\Phi\| + \|\Phi\|\,\|K\|$. Grönwall then yields

$$\|\Phi(\xi)\|_{\mathrm{op}} \;\le\; \exp\!\Big(2\int_{\xi_0}^{\xi}\!\|K(\zeta)\|_{\mathrm{op}}\mathrm{d}\zeta\Big)\,\|\Phi(\xi_0)\|_{\mathrm{op}}.$$

Taking the supremum over $p \in \mathfrak{B}(\mathrm{e}^u,\ell)$ and a, and then over $u \in \mathcal{U}$, one obtains the same bound for $\mathcal{W}(\ell;u,\xi)$ and $\mathcal{W}^{[\mathcal{U}]}(\ell;\xi)$. On the admissible gauge set Ξ_{adm}, the integral of $\|K\|$ is finite; Step 5's gauge audit demands that the resulting variation stays below the tolerance:

$$\sup_{\xi\in\Xi_{\mathrm{adm}}}\Big|\mathcal{W}^{[\mathcal{U}]}(\ell;\xi) - \mathcal{W}^{[\mathcal{U}]}(\ell;\xi_0)\Big| \;\le\; \varepsilon_{\mathrm{gauge}},$$

in the same spirit as eq. (7.588). In particular, if the subordinate norm is chosen from a co–channel Gram metric that is itself protected on shell (via ST/Nielsen), the generator K is skew with respect to that metric and the exponential factor is 1, giving exact invariance; otherwise, invariance holds up to the stated tolerance.

4) Conclusion. Because the ratio that defines $\mathcal{W}$ can be written as $\|\Phi(\xi)\|_{\mathrm{op}}$ and Φ evolves by conjugation, the band–projected residual is independent of the gauge parameter within the audit tolerance on the IR window. This extends to the UV–uniform version $\mathcal{W}^{[\mathcal{U}]}$ by the supremum construction in Definition 7.472. □

Notes.

- In Definition 7.472 we stated equality $\mathcal{W}^{[\mathcal{U}]}(\ell) = \sup_{u\in\mathcal{U}} \mathcal{W}(\ell;u)$ (not just $\geq$), since $\mathcal{W}(\ell;u)$ is itself the supremum over p and a for fixed u.
- Uniform well–posedness of $\mathcal{W}^{[\mathcal{U}]}$ follows by applying Lemma 7.469 uniformly in $u\in\mathcal{U}$ (compactness of $\mathcal{U}$, continuity in u and p, and a uniform lower bound on $|\mathcal{R}|_{\mathrm{op}}$ over the union band).

Proposition 7.474 (Monotone trend under the Step 3 slope guard)**.** *Assume the Step 3 guard* $\varsigma^{(\tau)}_{\mathrm{law}}(\ell) > 0$ *and the curvature/TV constraints of eq. (7.548) on an IR window* $\ell \geq \ell_R$ *(cf. eq. (7.551)). Then there exist* $\ell_\star \geq \ell_R$ *and* $c > 0$ *such that for all* $\ell \geq \ell_\star$*,*

$$\frac{\mathrm{d}}{\mathrm{d}\ell}\mathcal{W}(\ell) \;\leq\; -\frac{c}{\ell}\mathcal{W}(\ell) \;+\; \mathcal{O}\Big(\|\varepsilon(\kappa/\ell)\|^2\Big), \tag{7.595}$$

and hence $\mathcal{W}(\ell)$ *is eventually decreasing (up to quadratic remainders) along the IR ray* $\mu = \kappa/\ell \downarrow 0$*.*

Proof. **Setup and uniform controls.** Fix the instrumentation $(P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}})$ and work on the Step 3 IR window $\ell \geq \ell_R$ (cf. Definition 7.461 and Proposition 7.462). By Proposition 7.470, the band–projected Ward residual obeys the band–uniform bound

$$\mathcal{W}(\ell) \;\leq\; C(\lambda_{\mathrm{UV}},\ell)\sum_{\tilde{B}}\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big| \;+\; \mathcal{O}\Big(\|\varepsilon(\mu)\|^2\Big), \qquad \mu = \kappa/\ell, \tag{7.596}$$

with $C(\lambda_{\mathrm{UV}},\ell)$ finite by Lemma 7.469. The curvature/TV guard eq. (7.548) and the smooth dependence of the band/data on ℓ (Definition 7.468) imply that $C(\lambda_{\mathrm{UV}},\ell)$ is bounded and Lipschitz in $t = \ln\ell$ on compact subwindows: there exists $C_\star, L_\star > 0$ with

$$0 < C(\lambda_{\mathrm{UV}},\ell) \leq C_\star, \qquad \left|\frac{\mathrm{d}}{\mathrm{d}\ln\ell}C(\lambda_{\mathrm{UV}},\ell)\right| \leq L_\star \quad (\ell \geq \ell_R). \tag{7.597}$$

Slope guard for the breaking sector. Let $t := \ln\mu = -\ln\ell$. Inside the Step 3 certified region the law–channel guard $\varsigma^{(\tau)}_{\mathrm{law}}(\ell) > 0$ together with Proposition 7.462 ensures that the breaking sector is small and decaying, and the local (logarithmic) slopes of the projected eigen–couplings are strictly negative beyond some $\ell_\star \geq \ell_R$: there exists $c_0 > 0$ such that for all $\ell \geq \ell_\star$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\ln\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu(t))\big| \;\leq\; -c_0 \qquad \text{for every excited mode } \tilde{B}, \tag{7.598}$$

up to errors of order $\mathcal{O}(\|\widetilde{\varepsilon}\|)$ that can be absorbed into c_0 for sufficiently small breakings (see Propositions 7.453 and 7.465). Since $\frac{\mathrm{d}}{\mathrm{d}\ell} = -\frac{1}{\ell}\frac{\mathrm{d}}{\mathrm{d}t}$, (7.598) gives

$$\frac{\mathrm{d}}{\mathrm{d}\ell}\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big| \;\leq\; -\frac{c_0}{\ell}\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big| \;+\; \mathcal{O}\Big(\frac{1}{\ell}\,\|\widetilde{\varepsilon}(\mu)\|^2\Big). \tag{7.599}$$

From eigen–couplings to $\mathcal{W}$. Differentiate (7.596) w.r.t. ℓ and use (7.597)–(7.599):

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}\ell}\mathcal{W}(\ell) &\leq \frac{\mathrm{d}C}{\mathrm{d}\ell}\sum_{\tilde{B}}|\widetilde{\varepsilon}_{\tilde{B}}| \;+\; C(\lambda_{\mathrm{UV}},\ell)\sum_{\tilde{B}}\frac{\mathrm{d}}{\mathrm{d}\ell}|\widetilde{\varepsilon}_{\tilde{B}}| \;+\; \mathcal{O}\Big(\|\varepsilon\|\,\|\varepsilon\|'_\ell\Big)\\ &\leq \frac{L_\star}{\ell}\sum_{\tilde{B}}|\widetilde{\varepsilon}_{\tilde{B}}| \;-\; \frac{c_0}{\ell}\,C(\lambda_{\mathrm{UV}},\ell)\sum_{\tilde{B}}|\widetilde{\varepsilon}_{\tilde{B}}| \;+\; \mathcal{O}\Big(\frac{1}{\ell}\,\|\widetilde{\varepsilon}\|^2\Big) \;+\; \mathcal{O}\Big(\|\varepsilon\|^2\Big).\end{aligned}$$

Using $\sum_{\tilde{B}} |\widetilde{\varepsilon}_{\tilde{B}}| \;\geq\; \frac{1}{C_\star}\,\mathcal{W}(\ell) \;-\; \mathcal{O}(\|\varepsilon\|^2)$ (which follows from (7.596) and $C \leq C_\star$) and absorbing the $\mathcal{O}(\|\varepsilon\|^2)$ pieces, we obtain

$$\frac{\mathrm{d}}{\mathrm{d}\ell}\,\mathcal{W}(\ell) \;\leq\; -\,\frac{1}{\ell}\left(\frac{c_0\,C(\lambda_{\mathrm{UV}},\ell)}{C_\star} - \frac{L_\star}{C_\star}\right)\mathcal{W}(\ell) \;+\; \mathcal{O}\Big(\|\varepsilon\|^2\Big).$$

Define $c := \frac{c_0\,\underline{C} - L_\star}{C_\star}$, where $\underline{C} := \inf_{\ell\geq\ell_\star} C(\lambda_{\mathrm{UV}},\ell) > 0$; for sufficiently large $\ell_\star$ (still within the Step 3 window) we may assume $c > 0$, yielding (7.595).

Eventual monotonicity. The differential inequality (7.595) implies that, for $\ell \geq \ell_\star$,

$$\frac{\mathrm{d}}{\mathrm{d}\ell}\Big(\ell^{\,c}\,\mathcal{W}(\ell)\Big) \;\leq\; \ell^{\,c}\,\mathcal{O}\Big(\|\varepsilon\|^2\Big),$$

so $\ell^{\,c}\mathcal{W}(\ell)$ is eventually nonincreasing up to a small quadratic correction; in particular $\mathcal{W}(\ell)$ is eventually decreasing along the IR ray once the breaking sector is sufficiently small (Proposition 7.462). □

Remarks.

- The slope input (7.598) is the continuum version of the estimator statement in Propositions 7.453 and 7.465, guaranteed on the Step 3 window by the law–channel guard $\varsigma^{(\tau)}_{\mathrm{law}}(\ell) > 0$ and the monotonicity/curvature controls eq. (7.548).
- The instrumentation factor $C(\lambda_{\mathrm{UV}},\ell)$ is band–uniformly bounded and slowly varying by Lemma 7.469 (uniform in ℓ on the window) and the smooth dependence of the band–limited kernels on ℓ (Definition 7.468); the curvature/TV guard ensures the Lipschitz control in (7.597).
- If desired, the inequality can be written in $t = \ln\ell$ form as $\frac{\mathrm{d}}{\mathrm{d}t}\ln\mathcal{W} \leq -c + \mathcal{O}(|\varepsilon|^2)$, equivalent to (7.595).

ST identity on shell (all scales).

Definition 7.475 (Band–limiting map and BRST covariance)**.** Let $\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}$ denote the linear band–limiting map that implements the fixed instrumentation of eq. (7.522) on fields, sources, antifields, and composite insertions:

$$\Gamma^{(\lambda_{\mathrm{UV}},\ell)} \;:=\; \mathscr{B}_{\lambda_{\mathrm{UV}},\ell}\,[\,\Gamma\,], \qquad \mathscr{B}_{\lambda_{\mathrm{UV}},\ell} := \Big(P_x(\lambda_{\mathrm{UV}}), K^{(\ell)}_{\mathrm{IR}}\Big) \;\text{ acting consistently on all entries.}$$

Assume $\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}$ is linear, continuous, commutes with ordinary functional derivatives, and is BRST–covariant in the sense that for the BRST differential ζ (a graded derivation) one has

$$\zeta\,\mathscr{B}_{\lambda_{\mathrm{UV}},\ell} \;=\; \mathscr{B}_{\lambda_{\mathrm{UV}},\ell}\,\zeta. \tag{7.600}$$

Equivalently, for the Slavnov–Taylor functional $\mathcal{S}(\cdot)$ one has

$$\mathcal{S}\Big(\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}[X]\Big) = \mathscr{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\mathcal{S}(X)\Big] \;+\; (\text{EOM terms}),$$

where the "EOM terms" are proportional to Euler–Lagrange derivatives and vanish on shell.[13]

Proposition 7.476 (On–shell Slavnov–Taylor identity at all bands)**.** *Assume:*

(i) anomaly freedom for the gauge symmetry ($H^{1,d}(\zeta\,|\,d) = 0$ at ghost number 1);

(ii) the gauge fixing is BRST–exact;

(iii) the explicit breaking operators selected in Step 1 are BRST–closed (ghost number 0) and lie in the physical cohomology after Nielsen projection (Definition 7.457);

(iv) the band–limiting map $\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}$ satisfies BRST covariance eq. (7.600) (Definition 7.475).

Then for every $(\lambda_{\mathrm{UV}}, \ell)$ one has the on–shell ST identity

$$\boxed{\mathcal{S}\Big(\Gamma^{(\lambda_{\mathrm{UV}},\ell)}\Big) \;=\; 0 \qquad \text{whenever} \qquad \frac{\delta\Gamma^{(\lambda_{\mathrm{UV}},\ell)}}{\delta\phi} \;=\; 0\,.} \tag{7.601}$$

Consequently, any nonzero Ward residual $\mathcal{W}(\ell)$ of eq. (7.591) reflects controlled global *symmetry breaking only (no gauge anomaly) within the band–limited description.*

Proof. **Unbanded ST identity (on shell).** By (i) and algebraic renormalisation (Quantum Action Principle), the renormalised Γ obeys $\mathcal{S}(\Gamma) = 0$ modulo EOM–exact terms to all orders [117, 243, 442]; hence exactly on shell: $\mathcal{S}(\Gamma) = 0$ when $\delta\Gamma/\delta\phi = 0$. Assumption (ii) keeps BRST invariance intact, and (iii) ensures the Step 1 breaking insertions are BRST–closed in the physical cohomology, so they do not generate gauge–sector breaking.

Push through the band–limiting map. With $\Gamma^{(\lambda_{\mathrm{UV}},\ell)} = \mathscr{B}_{\lambda_{\mathrm{UV}},\ell}[\Gamma]$ and eq. (7.600),

$$\mathcal{S}\Big(\Gamma^{(\lambda_{\mathrm{UV}},\ell)}\Big) = \mathcal{S}\Big(\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}[\Gamma]\Big) = \mathscr{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\mathcal{S}(\Gamma)\Big] \;+\; (\text{EOM terms}).$$

The first term vanishes on the unbanded shell. Since $\mathscr{B}$ commutes with functional derivatives (Definition 7.475), $\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\delta\Gamma/\delta\phi\Big] = \delta\Gamma^{(\lambda_{\mathrm{UV}},\ell)}/\delta\phi$, so the EOM remainder vanishes precisely on the *band–limited* shell, yielding eq. (7.601).

Implication for $\mathcal{W}$. Because eq. (7.601) holds at all bands, any nonzero $\mathcal{W}(\ell)$ (Definition 7.468) originates from global Ward breaking in the audited channel, not from a gauge anomaly. This is consistent with the Step 4 analysis of projected eigen–couplings and irrelevance (Proposition 7.450 and Corollary 7.456). □

Corollary 7.477 (Gauge safety of band–projected Ward diagnostics)**.** *Evaluate correlators on shell and restrict all operator insertions to the Nielsen–projected physical subspace $W = \operatorname{im}\mathcal{N}$ (cf. Definition 7.457). Then the band–projected Ward residual $\mathcal{W}(\ell)$ of Definition 7.468 is insensitive to gauge–parameter choices up to the tolerance eq. (7.588); in particular,*

$$\sup_{\xi\in\mathcal{X}_{\mathrm{adm}}} \Big|\mathcal{W}(\ell;\xi) - \mathcal{W}(\ell;\xi_0)\Big| \;\le\; \varepsilon_{\mathrm{gauge}},$$

where $\mathcal{X}_{\mathrm{adm}}$ denotes the admissible set of gauge parameters used in the gauge audit. Moreover, any nonzero signal $\mathcal{W}(\ell) > 0$ cannot be attributed to a gauge anomaly.

[13] This follows from linearity of $\mathscr{B}$ and its commutation with functional derivatives; in the antifield/BRST setup the possible departures are EOM–exact by the Quantum Action Principle and algebraic renormalisation [117, 243]. Moreover, since $\mathscr{B}$ acts slotwise on sources/antifields and preserves ghost number, it is compatible with the BRST grading.

Proof. **(A) Gauge–parameter insensitivity on W.** By the Nielsen identity eq. (7.581) and the projection to the on–shell BRST–physical subspace (Definition 7.457), the dependence on a gauge parameter ξ acts on W by conjugation (Lax form) with a smooth generator $K(\xi)$; see Proposition 7.458. For fixed $(\lambda_{\mathrm{UV}}, \ell)$ and admissible external $p \in \mathfrak{B}(\lambda_{\mathrm{UV}}, \ell)$, write

$$N(\xi) := \Big(\mathcal{W}^a(p;\ell)\Big)^{\mathcal{N}}, \qquad D(\xi) := \Big(\mathcal{R}(p;\ell)\Big)^{\mathcal{N}},$$

and consider the dimensionless co–channel ratio $\Phi(\xi) := D(\xi)^{-1}N(\xi)$. By the Nielsen/Lax flow on W, $\partial_\xi \Phi = [K(\xi), \Phi(\xi)]$, hence $\Phi(\xi) = S(\xi,\xi_0)^{-1}\Phi(\xi_0)S(\xi,\xi_0)$ with $S = \mathcal{P}\exp\int K$ (cf. Proposition 7.458). Subordinate operator norms are stable under conjugation up to the tolerance used in the gauge audit eq. (7.588); taking the supremum over a and $p \in \mathfrak{B}$ (and, if used, over u in a UV strip as in Definition 7.472) preserves this bound. This gives the stated gauge–parameter insensitivity for $\mathcal{W}(\ell)$; compare also Lemma 7.473.

(B) Excluding gauge anomalies. By Proposition 7.476 the Slavnov–Taylor identity holds *on shell* at every band $(\lambda_{\mathrm{UV}}, \ell)$, provided the anomaly cohomology is trivial and the band–limiting map is BRST–covariant (Definition 7.475). Therefore gauge symmetry is exact on shell at all scales in the band–limited description, and any nonzero Ward residual $\mathcal{W}(\ell)$ computed as in Definition 7.468 cannot originate from a gauge anomaly. Combining this with the linear–response structure of the Ward operator in the presence of explicit *global* breakings (Proposition 7.470) shows that $\mathcal{W}(\ell) > 0$ reflects only controlled global Ward breaking in the audited channel.

The two claims together establish the corollary. □

IR decay and plateau tolerance for Ward residuals.

Definition 7.478 (IR decay and plateau acceptance for $\mathcal{W}$)**.** Let $\mathcal{I}_{\mathrm{IR}} \subset \mathbb{R}$ be the Step 3 IR window in $v := \ln \ell$ where the guards of eqs. (7.542) and (7.548) hold, and let ℓ_R be the (uniform) restoration length (cf. Definitions 7.430 and 7.461 and eq. (7.551)). We *accept* the Ward–residual trend if there exists a constant $c > 0$ such that

$$\boxed{\frac{\partial\, \mathcal{W}(\ell)}{\partial \ln \ell} \;\le\; -c \;<\; 0 \quad \text{for all} \quad \ell \text{ with } \ln \ell \in \mathcal{I}_{\mathrm{IR}}, \qquad \mathcal{W}(\ell_R) \;\le\; \varepsilon_{\mathrm{plat}}.} \tag{7.602}$$

The constant c is chosen commensurate with the curvature/TV guards of eq. (7.548) so that transient ripples cannot fake monotone decay.

Operational note. In practice we estimate the derivative in eq. (7.602) by a centered finite difference in $v = \ln \ell$, optionally preceded by a low–pass in v satisfying eqs. (7.537) and (7.538); acceptance requires the estimated slope to lie below $-c$ across the window, together with the plateau bound at ℓ_R.

Lemma 7.479 (Log–slope decay implied by irrelevance)**.** *Assume fixed instrumentation $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ and the linear–response bound Proposition 7.470 on a Step 3 IR window (cf. Definition 7.461 and Proposition 7.462):*

$$\mathcal{W}(\ell) \;\le\; C(\lambda_{\mathrm{UV}}, \ell) \sum_{\tilde{B}} \big|\widetilde{\varepsilon}_{\tilde{B}}(\kappa/\ell)\big| \;+\; \mathcal{O}\Big(\|\varepsilon\|^2\Big).$$

If all projected breaking exponents satisfy $\operatorname{Re} y_{\tilde{B}} < 0$*, then on any compact subwindow of the Step 3 mask*

$$\frac{\partial}{\partial \ln \ell}\,\mathcal{W}(\ell) \;\le\; \Big(\frac{\partial}{\partial \ln \ell}\ln C(\lambda_{\mathrm{UV}},\ell)\Big)\,\mathcal{W}(\ell) - \gamma_\star\,\mathcal{W}(\ell) + \mathcal{O}\big(\|\varepsilon\|^2\big), \qquad \gamma_\star := \min_{\tilde{B}} \big|\operatorname{Re} y_{\tilde{B}}\big| > 0. \tag{7.603}$$

In particular, if C *is band–uniformly slowly varying so that* $\sup_{\ln\ell\in\mathcal{I}_{\mathrm{IR}}} \big|\partial_{\ln\ell}\ln C\big| \le \eta < \gamma_\star$*, then*

$$\frac{\partial}{\partial \ln \ell}\,\mathcal{W}(\ell) \;\le\; -\,(\gamma_\star - \eta)\,\mathcal{W}(\ell) \;+\; \mathcal{O}\big(\|\varepsilon\|^2\big),$$

so $\mathcal{W}$ *has a strictly negative log–slope up to quadratic remainders.*

Proof. Write $\mu = \kappa/\ell$ so that $\partial_{\ln\ell} = -\,\partial_{\ln\mu}$. Let $S(\ell) := \sum_{\tilde{B}} \big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big|$. From Proposition 7.470,

$$\mathcal{W}(\ell) \;\le\; C(\lambda_{\mathrm{UV}},\ell)\,S(\ell) \;+\; \mathcal{O}\big(\|\varepsilon\|^2\big). \tag{7.604}$$

Differentiate (7.604) w.r.t. $\ln\ell$:

$$\frac{\partial \mathcal{W}}{\partial \ln \ell} \;\le\; \Big(\frac{\partial \ln C}{\partial \ln \ell}\Big)\,\mathcal{W} \;+\; C(\lambda_{\mathrm{UV}},\ell)\,\frac{\partial S}{\partial \ln \ell} \;+\; \mathcal{O}\big(\|\varepsilon\|\,\partial_{\ln\ell}\|\varepsilon\|\big).$$

In the projected eigen–basis (Definitions 7.454 and 7.457), the linearised flow (Propositions 7.450 and 7.455) gives

$$\frac{\partial}{\partial \ln \mu}\,|\widetilde{\varepsilon}_{\tilde{B}}| = \operatorname{Re} y_{\tilde{B}}\,|\widetilde{\varepsilon}_{\tilde{B}}| \;+\; \mathcal{O}\big(\|\widetilde{\varepsilon}\|^2\big),$$

hence

$$\frac{\partial S}{\partial \ln \ell} = -\sum_{\tilde{B}} \operatorname{Re} y_{\tilde{B}}\,|\widetilde{\varepsilon}_{\tilde{B}}| \;+\; \mathcal{O}\big(\|\widetilde{\varepsilon}\|^2\big) \;\le\; -\,\gamma_\star\,S(\ell) \;+\; \mathcal{O}\big(\|\widetilde{\varepsilon}\|^2\big).$$

Plugging back and using (7.604) to replace $S(\ell)$ by $\mathcal{W}(\ell)/C(\lambda_{\mathrm{UV}},\ell)$ yields (7.603). If $\big|\partial_{\ln\ell}\ln C\big| \le \eta < \gamma_\star$ on the window, the strict negativity follows. □

Proposition 7.480 (Sufficient conditions for the acceptance inequality)**.** *Let the assumptions of Lemma 7.479 hold on a compact IR window* $\mathcal{I}_{\mathrm{IR}} = [v_1, v_2] \subset \{\ln\ell \ge \ln\ell_R\}$*, and suppose* $\mathcal{W}$ *is continuous with a positive lower bound on that window:* $\inf_{v\in\mathcal{I}_{\mathrm{IR}}} \mathcal{W}(e^v) \ge W_{\min} > 0$*. Then the acceptance condition eq. (7.602) holds with any*

$$0 \;<\; c \;\le\; \gamma_\star\,W_{\min}\,.$$

Proof. From Lemma 7.479, $\frac{\partial}{\partial\ln\ell}\mathcal{W} \le -\gamma_\star\mathcal{W} + \mathcal{O}(\|\varepsilon\|^2)$. Inside the Step 3 mask the quadratic remainder is dominated by the linear term; in particular, shrinking the window if necessary we may absorb it into the coefficient to get $\frac{\partial}{\partial\ln\ell}\mathcal{W} \le -\frac{\gamma_\star}{2}\mathcal{W}$. By the positivity lower bound, $-\frac{\gamma_\star}{2}\mathcal{W} \le -\frac{\gamma_\star}{2}W_{\min}$, which implies eq. (7.602) with $c \le \frac{\gamma_\star}{2}W_{\min}$. The plateau condition is inherited from Step 3, which enforces $\mathcal{W}(\ell_R) \le \varepsilon_{\mathrm{plat}}$ by construction of the mask and the choice of reference channel. □

Remark 7.481 (Robust (scale–free) alternative)**.** The proportional inequality of Lemma 7.479 yields an equivalent, scale–free acceptance in terms of the *log–slope*:

$$\frac{\partial}{\partial \ln \ell}\,\ln\Big(\mathcal{W}(\ell)\Big) \;\le\; -\gamma \;<\; 0 \quad \text{on } \mathcal{I}_{\mathrm{IR}},$$

which implies exponential decay of $\mathcal{W}$ in $\ln \ell$. This weaker (and more natural) requirement is automatically satisfied under Step 4 irrelevance; the stricter linear floor eq. (7.602) may be adopted as a conservative operational check on finite windows by estimating a uniform slope floor via the robust trend statistics used in Step 3.

Nielsen protection: zero gauge–parameter slope (poles/residues).

Definition 7.482 (Band–limited physical two–point kernel, poles and residues)**.** Fix $(\lambda_{\mathrm{UV}}, \ell)$ and a gauge parameter $\xi \in \Xi_{\mathrm{adm}}$. Let $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$ be the band–limited 1PI functional (cf. Definition 7.468) and define the *Nielsen–projected* 1PI two–point kernel on the physical subspace $W = \operatorname{im}\mathcal{N}(\xi)$ (evaluated on shell; cf. Definition 7.457) by

$$\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi) \;:=\; \mathcal{N}(\xi)\,\Gamma_2^{(\lambda_{\mathrm{UV}},\ell)}(p^2)\,\mathcal{N}(\xi)\Big|_W.$$

A *physical pole* in channel α is a real $m_\alpha^2(\ell;\xi)$ with

$$\det \Gamma_2^{\mathcal{N}}(p^2;\ell,\xi)\Big|_{p^2=m_\alpha^2} = 0,$$

assumed simple ($\partial_{p^2} \det \Gamma_2^{\mathcal{N}} \neq 0$ at $p^2 = m_\alpha^2$). The corresponding residue $Z_\alpha(\ell;\xi) > 0$ is defined by the Laurent expansion of the projected propagator $D^{\mathcal{N}}(p^2;\ell,\xi) := \Big(\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi)\Big)^{-1}$:

$$D^{\mathcal{N}}(p^2;\ell,\xi) = \frac{Z_\alpha(\ell;\xi)\,P_\alpha(\ell;\xi)}{p^2 - m_\alpha^2(\ell;\xi)} \;+\; \text{regular},$$

where $P_\alpha(\ell;\xi)$ is the rank–one spectral projector on W.

All p^2 are taken in the admitted band $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ of Definition 7.468.

Lemma 7.483 (Nielsen similarity flow for $\Gamma_2^{\mathcal{N}}$)**.** *Under the hypotheses of Definition 7.457 (evaluation on shell), there exists a smooth generator $K(\xi)$ on $W = \operatorname{im}\mathcal{N}(\xi)$ such that*

$$\partial_\xi \Gamma_2^{\mathcal{N}}(p^2;\ell,\xi) = \Big[\,K(\xi),\,\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi)\,\Big] \quad \textit{for all } p^2 \in \mathfrak{B}(\lambda_{\mathrm{UV}},\ell). \tag{7.605}$$

Equivalently, with $S(\xi,\xi_0) := \mathcal{P}\exp\Big(\int_{\xi_0}^{\xi} K(\zeta)\,\mathrm{d}\zeta\Big)$,

$$\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi) = S(\xi,\xi_0)\,\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi_0)\,S(\xi,\xi_0)^{-1}. \tag{7.606}$$

Proof. By the Nielsen identity (eq. (7.581)) and projection to the BRST–physical subspace (Definition 7.457), the ξ–variation of any renormalised operator multiplet on W is an adjoint action generated by a smooth $K(\xi)$; cf. the Lax equation and similarity flow in Proposition 7.458. The 1PI two–point kernel is a bilinear form on the field/operator multiplet; therefore its ξ–variation is also given by the adjoint action $[K(\xi),\cdot]$ on W, which yields eq. (7.605). Path–ordered integration gives eq. (7.606). □

Corollary 7.484 (Zero gauge–parameter slope of pole locations and residues)**.** *Under the assumptions of Lemma 7.483, the physical pole positions and residues of* $\Gamma_2^{\mathcal{N}}$ *are gauge–parameter independent (within the tolerance ledger eq. (7.588)): for each channel* α *and fixed* $(\lambda_{\mathrm{UV}}, \ell)$*,*

$$\partial_\xi m_\alpha^2(\ell;\xi) = 0,$$
$$\partial_\xi Z_\alpha(\ell;\xi) = 0,$$

and the corresponding spectral projectors transform by similarity, $P_\alpha(\ell;\xi) = S(\xi,\xi_0)\, P_\alpha(\ell;\xi_0)\, S(\xi,\xi_0)^{-1}$.

Proof. By eq. (7.606), $\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi) = S\,\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi_0)\,S^{-1}$ with $S = S(\xi,\xi_0)$. Taking determinants,

$$\det \Gamma_2^{\mathcal{N}}(p^2;\ell,\xi) = \det\Big(S\,\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi_0)\,S^{-1}\Big) = \det \Gamma_2^{\mathcal{N}}(p^2;\ell,\xi_0),$$

so the zero set in p^2 is independent of ξ. For a simple zero $p^2 = m_\alpha^2$ (definition above), the implicit function theorem gives $\partial_\xi m_\alpha^2 = 0$.

For residues, invert eq. (7.606) to obtain the propagator similarity,

$$D^{\mathcal{N}}(p^2;\ell,\xi) = \Big(\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi)\Big)^{-1} = S(\xi,\xi_0)\, D^{\mathcal{N}}(p^2;\ell,\xi_0)\, S(\xi,\xi_0)^{-1}.$$

Near a simple pole $p^2 \approx m_\alpha^2$ one has $D^{\mathcal{N}}(p^2;\ell,\xi_0) = \dfrac{Z_\alpha(\ell;\xi_0)\,P_\alpha(\ell;\xi_0)}{p^2 - m_\alpha^2} + \text{regular}$. Conjugating,

$$D^{\mathcal{N}}(p^2;\ell,\xi) = \frac{Z_\alpha(\ell;\xi_0)\, SP_\alpha(\ell;\xi_0)S^{-1}}{p^2 - m_\alpha^2} + \text{regular},$$

which is precisely the Laurent form with the *same* scalar residue and the conjugated projector. Hence $Z_\alpha(\ell;\xi) = Z_\alpha(\ell;\xi_0)$ and $P_\alpha(\ell;\xi) = SP_\alpha(\ell;\xi_0)S^{-1}$. If one implements the numerical audit with subordinate operator norms, any residual ξ–variation is bounded by the tolerance in eq. (7.588); see also the general gauge–safety statements Corollary 7.459 and Lemma 7.473. □

Proposition 7.485 (Gauge–parameter independence of pole positions and residues)**.** *On any IR window* $\ln \ell \in \mathcal{I}_{\mathrm{IR}}$ *inside the Step 3 mask (cf. Definition 7.461 and Proposition 7.462), all physical pole positions and residues of the Nielsen–projected two–point kernel* $\Gamma_2^{\mathcal{N}}$ *(cf. Definition 7.482) are independent of the gauge parameter* ξ*:*

$$\boxed{\partial_\xi m_\alpha^2(\ell;\xi) = 0, \qquad \partial_\xi Z_\alpha(\ell;\xi) = 0, \qquad \forall\, \xi \in \mathcal{X}_{\mathrm{adm}}.} \tag{7.607}$$

Here $\mathcal{X}_{\mathrm{adm}}$ *denotes the admissible set of gauge parameters specified by the gauge audit eq. (7.588). In practice we require the tolerance check* $\sup_{\xi\in\mathcal{X}_{\mathrm{adm}}} \big|\partial_\xi m_\alpha^2\big|,\ \sup_{\xi\in\mathcal{X}_{\mathrm{adm}}} \big|\partial_\xi Z_\alpha\big| \le \varepsilon_{\mathrm{gauge}}$ *with* $\varepsilon_{\mathrm{gauge}} < \varepsilon_{\mathrm{plat}}$ *(cf. eq. (7.588)).*

Proof. Fix $(\lambda_{\mathrm{UV}}, \ell)$ and work on the physical subspace $W = \operatorname{im}\mathcal{N}$ evaluated on shell (Definition 7.457). By the Nielsen similarity flow for two–point kernels (Lemma 7.483), there exists a smooth $K(\xi)$ such that

$$\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi) = S(\xi,\xi_0)\,\Gamma_2^{\mathcal{N}}(p^2;\ell,\xi_0)\,S(\xi,\xi_0)^{-1}, \quad S(\xi,\xi_0) := \mathcal{P}\exp\Big(\int_{\xi_0}^{\xi} K(\zeta)\,\mathrm{d}\zeta\Big).$$

Pole positions. Let $F(p^2,\xi) := \det \Gamma_2^{\mathcal{N}}(p^2;\ell,\xi)$. Determinants are invariant under similarity, hence $F(p^2,\xi) = F(p^2,\xi_0)$ for all p^2 in the admitted band $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ (Definition 7.468). Therefore $\partial_\xi F(p^2,\xi) = 0$ pointwise in p^2. If $m_\alpha^2(\ell;\xi)$ is a *simple* physical pole (definition in Definition 7.482), then $F\big(m_\alpha^2(\ell;\xi),\xi\big) = 0$ with $\partial_{p^2} F \neq 0$ at $p^2 = m_\alpha^2$. Differentiating the identity $F(m_\alpha^2(\xi),\xi) = 0$ and using $\partial_\xi F \equiv 0$ gives

$$0 = \partial_\xi F(m_\alpha^2,\xi) = \partial_{p^2} F(m_\alpha^2,\xi)\,\partial_\xi m_\alpha^2(\xi),$$

hence $\partial_\xi m_\alpha^2(\ell;\xi) = 0$.

Residues. Write $A(p^2,\xi) := \Gamma_2^{\mathcal{N}}(p^2;\ell,\xi)$ and $D(p^2,\xi) := A(p^2,\xi)^{-1}$. Near a simple pole $p^2 = m_\alpha^2$ one has the Laurent form

$$D(p^2,\xi) = \frac{Z_\alpha(\ell;\xi)\,P_\alpha(\ell;\xi)}{p^2 - m_\alpha^2(\ell;\xi)} + \text{regular},$$

with rank–one spectral projector P_α on W (Definition 7.482). From similarity,

$$D(p^2,\xi) = S(\xi,\xi_0)\,D(p^2,\xi_0)\,S(\xi,\xi_0)^{-1}.$$

Since m_α^2 is already ξ–independent, conjugating the Laurent expansion at ξ_0 yields

$$D(p^2,\xi) = \frac{Z_\alpha(\ell;\xi_0)\,SP_\alpha(\ell;\xi_0)S^{-1}}{p^2 - m_\alpha^2} + \text{regular}.$$

Thus the scalar residue is unchanged, $Z_\alpha(\ell;\xi) = Z_\alpha(\ell;\xi_0)$, while the projector transforms by similarity, $P_\alpha(\ell;\xi) = SP_\alpha(\ell;\xi_0)S^{-1}$. Equivalently, using left/right eigenvectors $A(m_\alpha^2,\xi)v_\alpha = 0$, $w_\alpha^\top A(m_\alpha^2,\xi) = 0$ with $w_\alpha^\top v_\alpha = 1$, one has

$$Z_\alpha(\ell;\xi) = \Big(w_\alpha^\top\,\partial_{p^2} A(m_\alpha^2,\xi)\,v_\alpha\Big)^{-1},$$

and under similarity $v_\alpha \mapsto S^{-1}v_\alpha$, $w_\alpha^\top \mapsto w_\alpha^\top S$ and $\partial_{p^2}A \mapsto S^{-1}(\partial_{p^2}A)S$, leaving the scalar $w_\alpha^\top \partial_{p^2}A\,v_\alpha$ invariant.

Tolerance statement. On Step 3 IR windows the band–limited kernels vary smoothly and are uniformly bounded (Lemma 7.469 and Proposition 7.462), so any finite–statistics or truncation–induced residual ξ–dependence is controlled by the audit bound eq. (7.588), yielding the practical check stated.

This proves (7.607). □

Remark 7.486 (Degenerate multiplets)**.** If several physical modes share the same pole (mass degeneracy), Lemma 7.483 implies a *block* similarity within the degenerate subspace. The pole position is ξ–independent and the spectral projector onto the multiplet is conjugated as a block. Individual residues may rotate within the multiplet; choosing a smooth basis (e.g. by good quantum numbers) renders each residue gauge–independent.

Reporting. Evaluate (7.607) throughout the IR window $\ln\ell \in \mathcal{I}_{\mathrm{IR}}$ at or beyond ℓ_R and report the resulting bands together with the law–channel slope $\varsigma_{\mathrm{law}}^{(\tau)}$ from Step 2 (cf. eq. (7.542)).

Discrete estimators (audit path).

Definition 7.487 (Centered discrete estimators and optional smoothing)**.** Let $v_k := \ln \ell_k$ be a uniform grid with step $h > 0$ (cf. the centered–difference pattern used for Step 4 in Definition 7.446), and let $\{\xi_r\}_r$ be a *uniform* grid of gauge parameters with spacing $\Delta\xi > 0$ inside $\mathcal{X}_{\mathrm{adm}}$. Define the centered finite–difference estimators

$$\boxed{\widehat{\partial_v \mathcal{W}}(v_k) := \frac{\mathcal{W}(v_{k+1}) - \mathcal{W}(v_{k-1})}{2h}, \qquad \widehat{\partial_\xi m_\alpha^2}(\ell_k;\xi_r) := \frac{m_\alpha^2(\ell_k;\xi_{r+1}) - m_\alpha^2(\ell_k;\xi_{r-1})}{2\Delta\xi},} \tag{7.608}$$

and analogously for $Z_\alpha(\ell;\xi)$, with $\mathcal{W}$ defined in Definition 7.468 and (m_α^2, Z_α) in Definition 7.482. When numerical ripples are present, apply a low–pass LP_τ in v or in ξ whose kernel satisfies the moment conditions of eqs. (7.537) and (7.538); such filters preserve first derivatives up to an $\mathcal{O}(\tau^2)$ bias.

Lemma 7.488 (Consistency, rate, and smoothing bias)**.** *Assume $\mathcal{W} \in C^3$ in v on the Step 3 IR window (cf. Definition 7.461 and Proposition 7.462) and $m_\alpha^2, Z_\alpha \in C^3$ in ξ on $\mathcal{X}_{\mathrm{adm}}$. Then the centered estimators in (7.608) satisfy*

$$\widehat{\partial_v \mathcal{W}}(v_k) = \partial_v \mathcal{W}(v_k) + \mathcal{O}(h^2), \qquad \widehat{\partial_\xi m_\alpha^2}(\ell_k;\xi_r) = \partial_\xi m_\alpha^2(\ell_k;\xi_r) + \mathcal{O}\big((\Delta\xi)^2\big),$$

with $\Delta\xi := \xi_{r+1} - \xi_r = \xi_r - \xi_{r-1}$; the same holds for Z_α. After applying LP_τ (satisfying eqs. (7.537) and (7.538)), the additional bias is $\mathcal{O}(\tau^2)$. Implicit constants are uniform on compact subwindows thanks to the curvature/TV guards eq. (7.548).

Proof. **(A) Centered differences in v.** Let $f(v) := \mathcal{W}(v)$ and expand at v_k:

$$f(v_{k\pm1}) = f(v_k) \pm h f'(v_k) + \frac{h^2}{2} f''(v_k) \pm \frac{h^3}{6} f^{(3)}(\zeta_\pm),$$

for some $\zeta_\pm$ between v_k and $v_{k\pm1}$. Subtract and divide by $2h$:

$$\widehat{\partial_v \mathcal{W}}(v_k) = \frac{f(v_{k+1}) - f(v_{k-1})}{2h} = f'(v_k) + \frac{h^2}{6}\,\frac{f^{(3)}(\zeta_+) - f^{(3)}(\zeta_-)}{2} = \partial_v \mathcal{W}(v_k) + \mathcal{O}(h^2).$$

On the Step 3 window, the curvature/TV guard eq. (7.548) bounds $f^{(3)}$, giving a uniform $\mathcal{O}(h^2)$.

(B) Centered differences in ξ. Fix ℓ_k and set $g(\xi) := m_\alpha^2(\ell_k;\xi)$ (the same argument applies to Z_α). With $\Delta\xi := \xi_{r+1} - \xi_r = \xi_r - \xi_{r-1}$,

$$g(\xi_{r\pm1}) = g(\xi_r) \pm \Delta\xi\, g'(\xi_r) + \frac{(\Delta\xi)^2}{2} g''(\xi_r) \pm \frac{(\Delta\xi)^3}{6} g^{(3)}(\eta_\pm),$$

so

$$\widehat{\partial_\xi m_\alpha^2}(\ell_k;\xi_r) = \frac{g(\xi_{r+1}) - g(\xi_{r-1})}{2\Delta\xi} = g'(\xi_r) + \mathcal{O}\big((\Delta\xi)^2\big) = \partial_\xi m_\alpha^2(\ell_k;\xi_r) + \mathcal{O}\big((\Delta\xi)^2\big).$$

Smoothness (C^3) on $\mathcal{X}_{\mathrm{adm}}$ yields uniform constants on compact subsets; the admissible set is where the gauge audit eq. (7.588) is performed.

(C) Smoothing bias. Let LP_τ be the convolution/averaging operator in v (or in ξ) with kernel K_τ satisfying the moment conditions of eqs. (7.537) and (7.538): $\int K_\tau = 1$ and $\int t\,K_\tau(t)\,dt = 0$. For a C^2 function h, the standard moment expansion gives

$$(\mathsf{LP}_\tau h)(x) = h(x) + \frac{\mu_2(K)}{2}\,\tau^2 h''(x) + \mathcal{O}(\tau^3),$$

so, applied either to $\mathcal{W}$ in v or to m_α^2, Z_α in ξ, the induced bias on first derivatives is $\mathcal{O}(\tau^2)$ (the $\mathcal{O}(\tau^3)$ term is uniform on compact sets under eq. (7.548)). Combining with (A,B) yields the stated $\mathcal{O}(h^2) + \mathcal{O}((\Delta\xi)^2) + \mathcal{O}(\tau^2)$ rates. □

Corollary 7.489 (Estimator outcome under Nielsen protection)**.** *Assume the hypotheses of Definition 7.487 and Lemma 7.488 and the zero gauge–slope statement Proposition 7.485. Then, for every grid point $v_k = \ln \ell_k$ in the Step 3 IR window (cf. Definition 7.461 and Proposition 7.462) and every $\xi_r \in \mathcal{X}_{\mathrm{adm}}$, the centered estimators (optionally with the low–pass LP_τ of eqs. (7.537) and (7.538)) satisfy*

$$\widehat{\partial_\xi m_\alpha^2}(\ell_k;\xi_r) = 0 + \mathcal{O}\Big((\Delta\xi)^2 + \tau^2\Big), \qquad \widehat{\partial_\xi Z_\alpha}(\ell_k;\xi_r) = 0 + \mathcal{O}\Big((\Delta\xi)^2 + \tau^2\Big),$$

uniformly on compact subwindows of the Step 3 mask. In numerical audits, these errors are required to fall below the tolerance in eq. (7.588).

Proof. By Proposition 7.485 one has, on $W = \operatorname{im}\mathcal{N}$ and throughout the Step 3 IR window,

$$\partial_\xi m_\alpha^2(\ell;\xi) = 0, \qquad \partial_\xi Z_\alpha(\ell;\xi) = 0 \quad \text{for all } \xi \in \mathcal{X}_{\mathrm{adm}}.$$

Fix ℓ_k and define $g(\xi) := m_\alpha^2(\ell_k;\xi)$ and $h(\xi) := Z_\alpha(\ell_k;\xi)$. The regularity assumptions of Lemma 7.488 give $g, h \in C^3(\mathcal{X}_{\mathrm{adm}})$. For the centered finite–difference estimator on the uniform ξ–grid (spacing $\Delta\xi$) introduced in Definition 7.487,

$$\widehat{\partial_\xi g}(\xi_r) = \frac{g(\xi_{r+1}) - g(\xi_{r-1})}{2\Delta\xi} = \partial_\xi g(\xi_r) + \mathcal{O}\Big((\Delta\xi)^2\Big),$$

and the same holds for h, with implicit constants uniform on compact subsets of the window by Lemma 7.488 (the curvature/TV guard eq. (7.548) ensures the needed uniform bounds).

Since $\partial_\xi g \equiv 0$ and $\partial_\xi h \equiv 0$ by Proposition 7.485, the unsmoothed estimators obey

$$\widehat{\partial_\xi m_\alpha^2}(\ell_k;\xi_r) = \mathcal{O}\Big((\Delta\xi)^2\Big), \qquad \widehat{\partial_\xi Z_\alpha}(\ell_k;\xi_r) = \mathcal{O}\Big((\Delta\xi)^2\Big).$$

If, as permitted in Definition 7.487, one applies the low–pass operator LP_τ in ξ with kernel satisfying eqs. (7.537) and (7.538), the moment expansion yields an additional $\mathcal{O}(\tau^2)$ bias on first derivatives (see Lemma 7.488). Combining the finite–difference error with the smoothing bias gives the stated $\mathcal{O}\Big((\Delta\xi)^2 + \tau^2\Big)$ rates for both m_α^2 and Z_α.

Uniformity on compact subwindows of the Step 3 mask follows from the window consistency Proposition 7.462 together with the curvature/TV guard eq. (7.548). Finally, the audit requirement in eq. (7.588) enforces that these numerical errors lie below the prescribed gauge–tolerance threshold. □

Acceptance criteria (identity ledger). On the certified IR window $\mathcal{I}_{\mathrm{IR}}$ (cf. Definition 7.461 and Proposition 7.462), we *accept* the identity ledger when three checks jointly pass. First, **ST exactness**: the on–shell Slavnov–Taylor identity holds at all probed scales, exactly as in eq. (7.601),

$$\boxed{\mathcal{S}\big(\Gamma^{(\lambda_{\mathrm{UV}},\ell)}\big) = 0 \quad \text{upon} \quad \frac{\delta\Gamma^{(\lambda_{\mathrm{UV}},\ell)}}{\delta\phi} = 0.} \tag{7.609}$$

Second, **Ward restoration**: the band–projected residual decays with strictly negative logarithmic slope across the window and is within plateau tolerance at the restoration length (cf. Definition 7.478),

$$\boxed{\widehat{\partial_v \mathcal{W}}(v_k) \;\le\; -\,c \;<\; 0 \quad \forall\, v_k \in \mathcal{I}_{\mathrm{IR}}, \qquad \mathcal{W}(\ell_R) \;\le\; \varepsilon_{\mathrm{plat}},} \tag{7.610}$$

with c chosen commensurate with the curvature/TV guards of eq. (7.548), and where $\widehat{\partial_v \mathcal{W}}$ is the centered estimator of Definition 7.487. Third, **Gauge–parameter independence**: every quoted IR pole and residue is flat in ξ to within the audit tolerance (cf. Proposition 7.485),

$$\boxed{\Big|\widehat{\partial_\xi m_\alpha^2}(\ell_k;\xi_r)\Big| \;\le\; \varepsilon_{\mathrm{gauge}}, \qquad \Big|\widehat{\partial_\xi Z_\alpha}(\ell_k;\xi_r)\Big| \;\le\; \varepsilon_{\mathrm{gauge}},} \tag{7.611}$$

for all ℓ_k with $v_k \in \mathcal{I}_{\mathrm{IR}}$ and all $\xi_r \in \Xi_{\mathrm{adm}}$, where the discrete derivatives are those of Definition 7.487 and the continuum statement is eq. (7.607).

Outputs for Step 5. To document acceptance and enable replication, report (i) a plot of $v \mapsto \mathcal{W}(e^v)$ over $\mathcal{I}_{\mathrm{IR}}$ with the fitted (optionally smoothed) slope, explicitly showing $\widehat{\partial_v \mathcal{W}} \le -c$ and a marker at $v = \ln \ell_R$; (ii) compact tables of the discrete gauge–slopes $\widehat{\partial_\xi m_\alpha^2}$ and $\widehat{\partial_\xi Z_\alpha}$ evaluated at/beyond ℓ_R across Ξ_{adm}, including uncertainty bands reflecting $(h, \Delta\xi, \tau)$ from Definition 7.487; and (iii) a short cross–reference ledger confirming that (a) the Step 2 law–channel slope is positive on the same window (eq. (7.542)), (b) the Step 4 projected breaking exponents satisfy $\mathrm{Re}\, y_{\tilde{B}} < 0$ (Proposition 7.450 and Corollary 7.456), and (c) the restoration length ℓ_R is that certified in Step 3 (Definition 7.430 and eq. (7.551)). Together with the on–shell ST identity at all bands (Proposition 7.476), these artefacts close the Step 5 identity ledger.

7.8.6 Spectral Reconvergence to Symmetric Multiplets

Objective. On the IR plateau (the window $\mathcal{I}_{\mathrm{IR}}$ of eq. (7.542) with $v = \ln \ell \ge \ln \ell_R$ from eq. (7.551)), we demonstrate *multiplet reconvergence*: for each representation ρ of the emergent symmetry G with components $a = 1, \dots, d_\rho$, the mass and residue splittings close,

$$\frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)} \longrightarrow 0, \qquad \frac{\delta Z_\rho(\ell)}{\overline{Z_\rho}(\ell)} \longrightarrow 0 \quad \text{as} \quad v \in \mathcal{I}_{\mathrm{IR}},\ v \uparrow,$$

consistent with Kato continuity under the ℓ–flow [115] and the RG irrelevance of explicit breakings (Step 7.8.4; [389, 91, 82]).

Band–projected 2–point sector and pole data.

Definition 7.490 (Band–projected two–point sector and pole data)**.** Fix $(\lambda_{\mathrm{UV}}, \ell)$ and admitted momenta $p \in \mathfrak{B}(\lambda_{\mathrm{UV}}, \ell)$ (cf. Definition 7.468). Let $\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}$ be the band–limiting map of Definition 7.475 and let $\mathcal{N}$ be the Nielsen projector of Definition 7.457 with $W = \operatorname{im}\mathcal{N}$. The band– and Nielsen–projected 1PI two–point kernel is

$$\Gamma_2^{\mathcal{N}}(p^2; \lambda_{\mathrm{UV}}, \ell) \;:=\; \Big(\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}\big[\Gamma^{(2)}(p^2)\big] \Big)^{\mathcal{N}}\Big|_W .$$

Physical poles and residues are those of $\Gamma_2^{\mathcal{N}}$ as in Definition 7.482: simple poles $p^2 = m_\alpha^2(\ell)$ are simple zeros of $\det \Gamma_2^{\mathcal{N}}(p^2; \lambda_{\mathrm{UV}}, \ell)$ with $\partial_{p^2} \det \Gamma_2^{\mathcal{N}} \neq 0$, and their scalar residues are

$$\boxed{\; Z_\alpha(\ell) \;=\; \Big(w_\alpha^\top \, \partial_{p^2} \Gamma_2^{\mathcal{N}}\big(m_\alpha^2; \lambda_{\mathrm{UV}}, \ell\big)\, v_\alpha \Big)^{-1}, \;} \tag{7.612}$$

where v_α, w_α are right/left null vectors of $\Gamma_2^{\mathcal{N}}$ at $p^2 = m_\alpha^2$ on W normalized by $w_\alpha^\top v_\alpha = 1$. This spectral characterisation and the use of residues at simple poles follow standard QFT practice [91, 82], while continuity of the pole data under parameter flows is governed by Kato perturbation theory [115]. Gauge–parameter insensitivity on shell (within the admitted audit tolerance) is ensured by the ST/BRST framework and algebraic renormalisation [117, 243, 442] together with Propositions 7.476 and 7.485 and Corollary 7.477.

Intuition (outside the environment): we band-limit with $\mathscr{B}_{\lambda_{\mathrm{UV}},\ell}$, project to the BRST-physical/Nielsen subspace W, then read off pole positions and residues from $\Gamma_2^{\mathcal{N}}$. The cited sources cover (i) pole/residue practice in QFT [91, 82], (ii) continuity of simple poles under smooth parameter flows [115], and (iii) on-shell gauge safety via ST/BRST and algebraic renormalisation [117, 243, 442].

Multiplet identification and dispersion measures.

Definition 7.491 (IR multiplets and dispersion)**.** Let ρ be an irrep of the emergent symmetry G acting on the physical subspace $W = \operatorname{im}\mathcal{N}$ (cf. Definition 7.457). Assume that for ℓ in the IR window $\mathcal{I}_{\mathrm{IR}}$ (cf. eqs. (7.542) and (7.551)) there exists a smooth projector $P^\rho(\ell)$ on W whose range collects the d_ρ physical modes that reconverge to the ρ–multiplet as explicit breakings become irrelevant (Step 7.8.4). Let $\mathcal{I}_\rho(\ell)$ be the index set of poles of $\Gamma_2^{\mathcal{N}}$ (cf. Definitions 7.482 and 7.490) associated with $P^\rho(\ell)$. Define the *multiplet means* and *max–deviation dispersions* by

$$\overline{m_\rho^2}(\ell) := \frac{1}{d_\rho} \sum_{i \in \mathcal{I}_\rho(\ell)} m_i^2(\ell), \qquad \delta m_\rho^2(\ell) := \max_{i \in \mathcal{I}_\rho(\ell)} \Big| m_i^2(\ell) - \overline{m_\rho^2}(\ell) \Big|,$$

and analogously for residues $\overline{Z_\rho}(\ell)$ and $\delta Z_\rho(\ell)$.

$P^\rho(\ell)$ tracks a spectral cluster of the band– and Nielsen–projected kernel $\Gamma_2^{\mathcal{N}}(p^2; \lambda_{\mathrm{UV}}, \ell)$ (Definition 7.490); $\mathcal{I}_\rho(\ell)$ labels the corresponding simple poles $p^2 = m_i^2(\ell)$ in that cluster, and the dispersion measures summarize intra-multiplet splittings using already-defined pole data [91, 82].

Lemma 7.492 (Kato continuity and smooth tracking)**.** *Assume that $v \mapsto \Gamma_2^{\mathcal{N}}(p^2;\lambda_{\mathrm{UV}},e^v)$ is C^1 jointly in (p^2,v) on the admitted band $\mathfrak{B}(\lambda_{\mathrm{UV}},\ell)$ (cf. Definition 7.468) and that, within a given cluster selected by $P^\rho(e^v)$, all poles remain simple and separated from the rest of the spectrum (no accidental crossings beyond symmetry). Then there exist C^1 functions $m_i^2(v)$ and $Z_i(v)$ for $i\in\mathcal{I}_\rho(e^v)$, and the maps $\ell\mapsto \overline{m_\rho^2}(\ell),\delta m_\rho^2(\ell)$ (and likewise for residues) are continuous on the IR window $\mathcal{I}_{\mathrm{IR}}$.*

Proof. Set $A(p^2,v):=\Gamma_2^{\mathcal{N}}(p^2;\lambda_{\mathrm{UV}},e^v)$ and $F(p^2,v):=\det A(p^2,v)$. By hypothesis, A is C^1 in (p^2,v) on the admitted band, hence so is F.

(i) *Smooth pole tracking.* Let $p^2=m_i^2(v_0)$ be a simple zero of $F(\cdot,v_0)$ in the cluster selected by $P^\rho(e^{v_0})$, so $\partial_{p^2}F(m_i^2(v_0),v_0)\neq 0$ (simplicity; cf. Definition 7.482). The Implicit Function Theorem yields a neighborhood U of v_0 and a unique C^1 function $m_i^2(v)$ on U with $F(m_i^2(v),v)=0$ and $m_i^2(v_0)$ as given. Repeating for each simple pole in the finite cluster and using the separation (no crossings beyond symmetry) provides C^1 labels $m_i^2(v)$ for all $i\in\mathcal{I}_\rho(e^v)$ across the window. This is a standard application of Kato's perturbation framework for isolated finite-dimensional spectral clusters [115, Chs. II–IV].

(ii) *Residue regularity.* At a simple pole $p^2=m_i^2(v)$, the inverse $D(p^2,v):=A(p^2,v)^{-1}$ admits the Laurent form

$$D(p^2,v) \;=\; \frac{Z_i(v)\,P_i(v)}{p^2-m_i^2(v)}+\text{regular},$$

where $P_i(v)=v_i(v)\,w_i(v)^\top$ is the rank-one spectral projector on W with $A(m_i^2(v),v)\,v_i(v)=0$, $w_i(v)^\top A(m_i^2(v),v)=0$, $w_i^\top v_i=1$, and

$$Z_i(v) \;=\; \Big(w_i(v)^\top\,\partial_{p^2}A\Big(m_i^2(v),v\Big)\,v_i(v)\Big)^{-1} \quad \text{(cf. Definition 7.490)}.$$

By simplicity and C^1 dependence of A, one may choose $v_i(\cdot),w_i(\cdot)$ C^1 in v (locally uniquely up to smooth rephasing), see [115, Thm. II-1.8, Sec. II-5]. Since $\partial_{p^2}A$ is C^1 and the denominator above never vanishes at a simple pole, $Z_i(v)$ is C^1.

(iii) *Continuity of multiplet averages and max–deviations.* By construction, $P^\rho(e^v)$ is smooth and selects a fixed-rank cluster, so the index set $\mathcal{I}_\rho(e^v)$ varies without changing cardinality. Finite sums and averages of continuous functions $m_i^2(e^v)$ are continuous, hence $\overline{m_\rho^2}(\ell)$ is continuous. The map $x\mapsto \max_j x_j$ is continuous on $\mathbb{R}^{d_\rho}$, so $\delta m_\rho^2(\ell)=\max_{i\in\mathcal{I}_\rho(\ell)}|m_i^2(\ell)-\overline{m_\rho^2}(\ell)|$ is continuous; the same argument applies to residues.

Putting (i)–(iii) together gives the claim. □

Proposition 7.493 (Linear response of splittings to explicit breakings)**.** *Work on the physical subspace $W=\operatorname{im}\mathcal{N}$ and within a fixed IR window $\mathcal{I}_{\mathrm{IR}}$. For the ρ–block selected by $P^\rho(\ell)$ (cf. Definition 7.491) of the band– and Nielsen–projected kernel $\Gamma_2^{\mathcal{N}}$ (cf. Definition 7.490), assume the explicit breaking couplings $\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)$ are sufficiently small. Then one can decompose, for p^2 near the common symmetric pole $m_{\rho,\mathrm{sym}}^2(\ell)$,*

$$\Gamma_\rho^{(2)}(p^2;\ell)=\Big[\Gamma_\rho^{(2)}\Big]_{\mathrm{sym}}(p^2;\ell)\,\mathbf{1}_{d_\rho}\;+\;\sum_{\tilde B}\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\,\Delta_\rho^{(\tilde B)}(p^2;\ell)\;+\;\mathcal{O}(\|\widetilde{\varepsilon}\|^2),$$

where $\big[\Gamma^{(2)}_\rho\big]_{\mathrm{sym}} := \frac{1}{d_\rho}\mathrm{Tr}\,\Gamma^{(2)}_\rho$ *and each* $\Delta^{(\tilde B)}_\rho$ *is traceless on the* ρ*–block (Schur/Wigner–Eckart form; the trace part has been absorbed into the symmetric piece). Consequently, the intra–multiplet mass and residue splittings obey*

$$\delta m^2_\rho(\ell) \;\le\; C_\rho(\ell)\sum_{\tilde B}\big|\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\big| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \qquad \delta Z_\rho(\ell) \;\le\; C'_\rho(\ell)\sum_{\tilde B}\big|\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\big| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \tag{7.613}$$

with $\delta m^2_\rho, \delta Z_\rho$ *as in Definition 7.491.*

Proof. Let $A_\rho(p^2;\ell) := P^\rho(\ell)\,\Gamma^{\mathcal{N}}_2(p^2;\lambda_{\mathrm{UV}},\ell)\,P^\rho(\ell)\big|_{\mathrm{ran}\,P^\rho}$ denote the $d_\rho\times d_\rho$ block (cf. Definition 7.490). Decompose A_ρ into its scalar part and traceless part on the block:

$$A_\rho(p^2;\ell) = a_\rho(p^2;\ell)\,\mathbf{1}_{d_\rho} + \sum_{\tilde B}\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\,\Delta^{(\tilde B)}_\rho(p^2;\ell) + \mathcal{O}(\|\widetilde{\varepsilon}\|^2),$$

where $a_\rho := \frac{1}{d_\rho}\mathrm{Tr}\,A_\rho$ and $\mathrm{Tr}\,\Delta^{(\tilde B)}_\rho \equiv 0$. Representation theory (Schur's lemma / Wigner–Eckart) justifies that in the symmetric limit the block is proportional to the identity, while explicit breakings furnish traceless tensor structures within the block [91, 82]. Let $m^2_{\rho,\mathrm{sym}}(\ell)$ solve $a_\rho\big(m^2_{\rho,\mathrm{sym}}(\ell);\ell\big)=0$; by Definition 7.482, simple poles in the block are then the zeros of the d_ρ eigenvalue branches of A_ρ near $m^2_{\rho,\mathrm{sym}}(\ell)$.

(i) Linearized pole shifts. Evaluate at $p^2 = m^2_{\rho,\mathrm{sym}}(\ell)$ and set

$$\mu_\rho(\ell) := \frac{1}{d_\rho}\,\mathrm{Tr}\,\partial_{p^2}A_\rho\big(m^2_{\rho,\mathrm{sym}}(\ell);\ell\big), \qquad \delta A_\rho := \sum_{\tilde B}\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\,\Delta^{(\tilde B)}_\rho\big(m^2_{\rho,\mathrm{sym}}(\ell);\ell\big).$$

By simplicity of poles within the cluster (cf. Definition 7.482 and Lemma 7.492) and C^1 regularity, Kato/implicit–function theory gives, for each component i,

$$m^2_i(\ell) - m^2_{\rho,\mathrm{sym}}(\ell) \;=\; -\frac{\theta_i(\ell)}{\mu_\rho(\ell)} \;+\; \mathcal{O}(\|\widetilde{\varepsilon}\|^2),$$

where $\theta_i(\ell)$ are the eigenvalues of the traceless perturbation δA_ρ on the ρ–block (degenerate perturbation theory in a finite cluster) [115, Chs. II–IV]. Hence, using $|\theta_i|\le\|\delta A_\rho\|$,

$$\begin{aligned}\delta m^2_\rho(\ell) &= \max_i\big|m^2_i - m^2_{\rho,\mathrm{sym}}\big| \\ &\le\; \frac{\|\delta A_\rho\|}{|\mu_\rho(\ell)|} + \mathcal{O}(\|\widetilde{\varepsilon}\|^2) \\ &\le\; \Big\|\big(\partial_{p^2}A_\rho\big)^{-1}\big(m^2_{\rho,\mathrm{sym}};\ell\big)\Big\|\sum_{\tilde B}\big|\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\big|\,\big\|\Delta^{(\tilde B)}_\rho\big\| \\ &\qquad + \mathcal{O}(\|\widetilde{\varepsilon}\|^2),\end{aligned}$$

which yields (7.613) for δm^2_ρ upon absorbing blockwise norms into $C_\rho(\ell)$.

(ii) Linearized residue shifts. Write $D_\rho(p^2;\ell) := A_\rho(p^2;\ell)^{-1}$ and recall that, at a simple pole $p^2 = m^2_i(\ell)$,

$$Z_i(\ell) = \Big(w_i^{\top}\,\partial_{p^2}A_\rho\big(m^2_i(\ell);\ell\big)\,v_i\Big)^{-1} \quad\text{with}\quad A_\rho(m^2_i)v_i = 0,\;\; w_i^{\top}A_\rho(m^2_i) = 0,\;\; w_i^{\top}v_i = 1$$

(cf. Definition 7.490). Differentiate this formula with respect to the breaking amplitudes $\widetilde{\varepsilon}_{\tilde{B}}$ at the symmetric point, using the first–order variations of m_i^2, v_i, w_i, and A_ρ from (i) (Kato's eigenvector perturbation within a simple cluster) [115, Thm. II-1.8, Sec. II-5]. The result is

$$Z_i(\ell) - Z_{\rho,\mathrm{sym}}(\ell) \;=\; -\,Z_{\rho,\mathrm{sym}}(\ell)^2 \left(w_{i,\mathrm{sym}}^{\top}\, \partial_{p^2} \delta A_\rho\, v_{i,\mathrm{sym}} \right) \;+\; \mathcal{O}(\|\widetilde{\varepsilon}\|^2),$$

up to additional linear terms proportional to $\partial_{p^2}^2 A_\rho$ times the already–bounded mass shift from (i). Taking maxima over i and using operator–norm bounds gives

$$\delta Z_\rho(\ell) \;\le\; C'_\rho(\ell) \sum_{\tilde{B}} \left| \widetilde{\varepsilon}_{\tilde{B}}(\kappa/\ell) \right| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2),$$

with $C'_\rho(\ell)$ depending on $\|Z_{\rho,\mathrm{sym}}(\ell)\|$, $\|\partial_{p^2} \Delta_\rho^{(\tilde{B})}\|$, and $\|\partial_{p^2}^2 A_\rho\|$ evaluated at $p^2 = m^2_{\rho,\mathrm{sym}}(\ell)$.

Both bounds use only blockwise linear algebra and standard degenerate perturbation theory for isolated finite clusters, together with the spectral/residue conventions of Definitions 7.482 and 7.490 and smooth tracking from Lemma 7.492; see [115] for the perturbation framework and [91, 82] for the two–point/pole–residue practice. This establishes (7.613). □

Theorem 7.494 (Multiplet reconvergence on the IR plateau)**.** *Work on the Step 3 IR window with $\varsigma_{\mathrm{law}}^{(\tau)}(\ell) > 0$ and curvature/TV guards (cf. eqs. (7.542), (7.548) and (7.551) and Proposition 7.462). Assume Step 4 irrelevance:* $\mathrm{Re}\, y_{\tilde{B}} < 0$ *for all excited projected breakings (cf. Proposition 7.450 and Corollary 7.456). Suppose further that the multiplet mean satisfies either*

$$(A)\;\; \overline{m_\rho^2}(\ell) \;\ge\; m^2_{\rho,\min} > 0 \qquad \text{or} \qquad (B)\;\; \overline{m_\rho^2}(\ell) \;\asymp\; \ell^{-\alpha} \;\; \text{on the window with} \;\; \alpha < \gamma_\star,$$

where $\gamma_\star := \min_{\tilde{B}} |\,\mathrm{Re}\, y_{\tilde{B}}| > 0$ and $\mu = \kappa/\ell$. Then, as $v = \ln \ell \uparrow$ within $\mathcal{I}_{\mathrm{IR}}$ (equivalently $\mu \downarrow 0$),

$$\boxed{\frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)} \;\longrightarrow\; 0, \qquad \frac{\delta Z_\rho(\ell)}{\overline{Z_\rho}(\ell)} \;\longrightarrow\; 0,} \tag{7.614}$$

with rates controlled by the slowest irrelevant exponent:

$$\frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)} = \begin{cases} \mathcal{O}\Big(\mu^{\gamma_\star}\, \mathrm{poly}(\ln \mu)\Big) & \text{in case (A)}, \\ \mathcal{O}\Big(\ell^{-(\gamma_\star - \alpha)}\, \mathrm{poly}(\ln \ell)\Big) & \text{in case (B)}, \end{cases}$$

and likewise for $\delta Z_\rho / \overline{Z_\rho}$.

Proof. All statements are taken on the physical subspace $W = \mathrm{im}\,\mathcal{N}$ and for the band– and Nielsen–projected kernel $\Gamma_2^{\mathcal{N}}$ (cf. Definition 7.490); gauge–parameter safety on shell follows from Propositions 7.476 and 7.485 and Corollary 7.477 and is immaterial for the bounds below.

Step 1: Linear response of intra–multiplet splittings. By Proposition 7.493, for the ρ–block selected by $P^\rho(\ell)$ (cf. Definition 7.491) there exist bounded functions $C_\rho(\ell), C'_\rho(\ell)$ on the IR window such that

$$\delta m_\rho^2(\ell) \;\le\; C_\rho(\ell) \sum_{\tilde{B}} \left| \widetilde{\varepsilon}_{\tilde{B}}(\kappa/\ell) \right| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \qquad \delta Z_\rho(\ell) \;\le\; C'_\rho(\ell) \sum_{\tilde{B}} \left| \widetilde{\varepsilon}_{\tilde{B}}(\kappa/\ell) \right| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2). \tag{7.615}$$

Here the sum runs over the projected breaking operators that couple within the ρ–block; the traceless Wigner–Eckart structure ensures that only the non-singlet parts contribute linearly.

Step 2: RG running of the explicit breakings. By Step 4 irrelevance, the linearized RG solution on the window satisfies (see Proposition 7.450 and Corollary 7.456)

$$\widetilde{\varepsilon}_{\tilde{B}}(\mu) = \mathcal{O}\Big(\mu^{\,y_{\tilde{B}}}\,\mathrm{poly}(\ln \mu)\Big), \qquad \mathrm{Re}\; y_{\tilde{B}} < 0,$$

so that

$$\sum_{\tilde{B}} \Big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\Big| = \mathcal{O}\Big(\mu^{\,\gamma_\star}\,\mathrm{poly}(\ln \mu)\Big), \qquad \gamma_\star := \min_{\tilde{B}} |\,\mathrm{Re}\; y_{\tilde{B}}| > 0. \tag{7.616}$$

Combining (7.615) with (7.616) and absorbing bounded C_ρ, C'_ρ into the $\mathcal{O}(\cdot)$ gives

$$\delta m_\rho^2(\ell) = \mathcal{O}\Big(\mu^{\,\gamma_\star}\,\mathrm{poly}(\ln \mu)\Big), \qquad \delta Z_\rho(\ell) = \mathcal{O}\Big(\mu^{\,\gamma_\star}\,\mathrm{poly}(\ln \mu)\Big). \tag{7.617}$$

Step 3: Division by the multiplet means. Kato continuity for pole data on the window (cf. Lemma 7.492) implies that $\overline{m_\rho^2}(\ell)$ and $\overline{Z_\rho}(\ell)$ are continuous and strictly positive (the latter by positivity of physical residues, cf. Definitions 7.482 and 7.490 and standard QFT conventions [91, 82]). We treat the two alternatives for $\overline{m_\rho^2}$:

(A) If $\overline{m_\rho^2}(\ell) \geq m_{\rho,\min}^2 > 0$ on the window, divide (7.617) by the constant lower bound to obtain

$$\frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)} = \mathcal{O}\Big(\mu^{\,\gamma_\star}\,\mathrm{poly}(\ln \mu)\Big) \;\xrightarrow[\mu \downarrow 0]{}\; 0,$$

and the same argument yields $\delta Z_\rho / \overline{Z_\rho} \to 0$ since $\overline{Z_\rho}$ is bounded below on compact IR windows.

(B) If $\overline{m_\rho^2}(\ell) \asymp \ell^{-\alpha}$ on the window, write $\mu = \kappa/\ell$ to get

$$\frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)} = \mathcal{O}\Big(\ell^{-(\gamma_\star - \alpha)}\,\mathrm{poly}(\ln \ell)\Big).$$

Under the stated condition $\alpha < \gamma_\star$, this tends to 0 as $\ell \uparrow \infty$ along the IR ray. The same reasoning applies to residues provided $\overline{Z_\rho}$ is bounded below or varies at most polynomially (which holds on the plateau by smooth tracking and positivity).

Step 4: Uniformity and window controls. Uniformity of the $\mathcal{O}(\cdot)$ bounds on compact subwindows follows from the curvature/TV guard and window consistency (cf. eq. (7.548) and Proposition 7.462), which control the norms entering C_ρ, C'_ρ and preclude loss of isolation for the simple poles in the cluster (cf. Lemma 7.492).

Together, these steps prove (7.614) with the quoted rates. □

Remark 7.495.

- The proof depends only on the following:
  1. the linear-response bound Proposition 7.493,
  2. RG decay of breaking amplitudes Proposition 7.450 and Corollary 7.456, and
  3. smooth spectral tracking Lemma 7.492.
- Standard QFT pole/residue conventions underlie positivity and normalization [91, 82].

Remark 7.496 (Massless multiplets and Goldstone sectors)**.** If $\overline{m_\rho^2}(\ell) \to 0$ (e.g. Nambu–Goldstone modes; cf. standard treatments [91, 82]), use a scale–free dispersion such as

$$\frac{\delta m_\rho^2(\ell)}{\max\{m_{\mathrm{ref}}^2,\ \overline{m_\rho^2}(\ell)\}}$$

with a fixed IR reference $m_{\mathrm{ref}} > 0$, or diagnose reconvergence via residue/velocity degeneracy together with band–projected Ward residuals (Definition 7.468). Under the hypotheses of Theorem 7.494 (Step 4 irrelevance and the IR guards), the linear–response bounds (7.613) imply in particular the decay of *absolute* splittings $\delta m_\rho^2(\ell) \to 0$ along the IR ray.

Discrete estimators and acceptance.

Definition 7.497 (Multiplet dispersion estimators)**.** Let $v_k := \ln \ell_k$ be a *uniform* grid with step $h > 0$. For each ρ (cf. Definition 7.491), define

$$\overline{m_\rho^2}(v_k) := \frac{1}{d_\rho} \sum_{i \in \mathcal{I}_\rho(v_k)} m_i^2(v_k), \qquad \delta m_\rho^2(v_k) := \max_{i \in \mathcal{I}_\rho(v_k)} \left| m_i^2(v_k) - \overline{m_\rho^2}(v_k) \right|.$$

When $\overline{m_\rho^2}(v_k) > 0$, set the relative dispersion

$$\Delta_{m,\rho}^{\mathrm{rel}}(v_k) := \frac{\delta m_\rho^2(v_k)}{\overline{m_\rho^2}(v_k)},$$

otherwise use the absolute version $\delta m_\rho^2(v_k)$ (cf. the massless/Goldstone remark Remark 7.496). Estimate the IR trend by the centered slope (as in Definition 7.487)

$$\widehat{\partial_v \ln \Delta_{m,\rho}^{\mathrm{rel}}}(v_k) := \frac{\ln \Delta_{m,\rho}^{\mathrm{rel}}(v_{k+1}) - \ln \Delta_{m,\rho}^{\mathrm{rel}}(v_{k-1})}{2h},$$

with the optional low–pass LP_τ in v whose kernel satisfies eqs. (7.537) and (7.538) (introducing an $\mathcal{O}(\tau^2)$ bias per Lemma 7.488). Define $\Delta_{Z,\rho}^{\mathrm{rel}}$ and $\widehat{\partial_v \ln \Delta_{Z,\rho}^{\mathrm{rel}}}$ analogously, replacing m_i^2 by Z_i.

Definition 7.498 (Step 6 acceptance: multiplet reconvergence)**.** On the IR window $\mathcal{I}_{\mathrm{IR}}$ (cf. eqs. (7.542) and (7.551)), accept the ρ–multiplet as reconverging if:

1. **Monotone reconvergence.** For all $v_k \in \mathcal{I}_{\mathrm{IR}}$,

$$\widehat{\partial_v \ln \Delta_{m,\rho}^{\mathrm{rel}}}(v_k) \le -c_\rho < 0, \qquad \widehat{\partial_v \ln \Delta_{Z,\rho}^{\mathrm{rel}}}(v_k) \le -c'_\rho < 0.$$

2. **Plateau smallness at restoration.** At $v_R = \ln \ell_R$ (cf. eq. (7.551)),

$$\Delta_{m,\rho}^{\mathrm{rel}}(v_R) \le \varepsilon_{\mathrm{plat}}, \qquad \Delta_{Z,\rho}^{\mathrm{rel}}(v_R) \le \varepsilon_{\mathrm{plat}}.$$

3. **Gauge and basis safety.** Masses/residues are evaluated on shell and Nielsen–projected (Definition 7.457), and spreads across admissible gauge choices lie below $\varepsilon_{\mathrm{gauge}}$ (cf. Corollary 7.477 and Proposition 7.485). Changes of channel basis act by similarity on $\Gamma_2^{\mathcal{N}}$ (cf. Proposition 7.458 and Lemma 7.483); the diagnostics $\Delta_{m,\rho}^{\mathrm{rel}}$ and $\Delta_{Z,\rho}^{\mathrm{rel}}$, being built from eigenvalue locations and scalar residues, are invariant under such conjugations.

Multiplet bookkeeping and splitting metrics.

Definition 7.499 (IR multiplet index sets and dispersion metrics)**.** Fix the band– and Nielsen–projected two–point kernel $\Gamma_2^{\mathcal{N}}(p^2;\lambda_{\mathrm{UV}},\ell)$ on the physical subspace $W = \operatorname{im}\mathcal{N}$ (cf. Definitions 7.457 and 7.490). For each irrep ρ of the emergent symmetry G with dimension d_ρ, choose a continuous family of projectors $P^\rho(\ell) : W \to W$ on the IR window $\{\ln \ell \in \mathcal{I}_{\mathrm{IR}}\}$ such that $\operatorname{rank} P^\rho(\ell) = d_\rho$ and $\sum_\rho P^\rho(\ell) = \mathbf{1}_W$ (block decomposition of the physical sector).[14]

Let $\{(m_i^2(\ell), Z_i(\ell))\}_i$ be the simple physical poles/residues of $\Gamma_2^{\mathcal{N}}$ at scale ℓ (cf. Definitions 7.482 and 7.490 and eq. (7.612)). Define the *ρ–multiplet index set* at ℓ as

$$\mathfrak{M}_\rho(\ell) \;:=\; \Big\{ i : \text{ the one–particle mode } i \text{ has } v_i(\ell) \in \operatorname{im} P^\rho(\ell) \text{ (i.e. it is selected by } P^\rho(\ell)) \Big\},$$

so that $|\mathfrak{M}_\rho(\ell)| = d_\rho$ for all ℓ in the window. The *normalised averages* and *max–deviation dispersions* for masses and residues are

$$\boxed{\overline{m_\rho^2}(\ell) := \frac{1}{|\mathfrak{M}_\rho(\ell)|}\sum_{i\in\mathfrak{M}_\rho(\ell)} m_i^2(\ell), \qquad \delta m_\rho^2(\ell) := \max_{i\in\mathfrak{M}_\rho(\ell)} \big| m_i^2(\ell) - \overline{m_\rho^2}(\ell)\big|,} \tag{7.618}$$

$$\boxed{\overline{Z_\rho}(\ell) := \frac{1}{|\mathfrak{M}_\rho(\ell)|}\sum_{i\in\mathfrak{M}_\rho(\ell)} Z_i(\ell), \qquad \delta Z_\rho(\ell) := \max_{i\in\mathfrak{M}_\rho(\ell)} \big| Z_i(\ell) - \overline{Z_\rho}(\ell)\big|.} \tag{7.619}$$

When needed, use the *relative dispersions* $\Delta_{m,\rho}^{\mathrm{rel}} := \delta m_\rho^2/\overline{m_\rho^2}$ (defined when $\overline{m_\rho^2} > 0$) and $\Delta_{Z,\rho}^{\mathrm{rel}} := \delta Z_\rho/\overline{Z_\rho}$, which are scale–free and compare directly across channels (cf. Definition 7.491).

Lemma 7.500 (Well–posedness, label invariance, and continuity)**.** *Assume each pole in a ρ–cluster is simple and that $P^\rho(\ell)$ varies continuously in ℓ on the IR window. Then:*

1. (Well–posed index sets) *$\mathfrak{M}_\rho(\ell)$ is well defined up to permutations of labels and has constant cardinality d_ρ.*
2. (Label/basis invariance) *The functionals $\overline{m_\rho^2}$, δm_ρ^2, $\overline{Z_\rho}$, δZ_ρ are invariant under reordering of indices and under unitary basis rotations inside* $\operatorname{im} P^\rho(\ell)$.
3. (Kato continuity) *Each $m_i^2(\ell)$ and $Z_i(\ell)$ depends continuously on ℓ along the window, hence so do* (7.618)–(7.619).

Moreover, if one introduces the pairwise spreads

$$\Delta_{m,\rho}^{\mathrm{pair}}(\ell) := \max_{i,j\in\mathfrak{M}_\rho(\ell)} |m_i^2(\ell) - m_j^2(\ell)|, \qquad \Delta_{Z,\rho}^{\mathrm{pair}}(\ell) := \max_{i,j\in\mathfrak{M}_\rho(\ell)} |Z_i(\ell) - Z_j(\ell)|,$$

then for all ℓ in the window

$$\delta m_\rho^2(\ell) \;\le\; \Delta_{m,\rho}^{\mathrm{pair}}(\ell) \;\le\; 2\,\delta m_\rho^2(\ell), \qquad \delta Z_\rho(\ell) \;\le\; \Delta_{Z,\rho}^{\mathrm{pair}}(\ell) \;\le\; 2\,\delta Z_\rho(\ell).$$

[14] One practical construction: at some large $\ell_{\mathrm{ref}} \in \mathcal{I}_{\mathrm{IR}}$, identify the ρ–cluster by quantum numbers; then transport $P^\rho(\ell)$ along ℓ by Kato parallel transport [115].

Proof. (1) Since $P^{\rho}(\ell)$ has constant rank d_ρ and varies continuously, its image defines a continuous d_ρ–dimensional subbundle of W along the window. By definition, $\mathfrak{M}_\rho(\ell)$ consists of those simple eigenmodes whose right eigenvectors $v_i(\ell)$ lie in $\operatorname{im} P^{\rho}(\ell)$; simplicity prevents branching ambiguities inside the cluster (cf. Lemma 7.492). Thus $|\mathfrak{M}_\rho(\ell)| = \operatorname{rank} P^{\rho}(\ell) = d_\rho$, and the set is unique up to relabelling.

(2) Reordering indices clearly leaves (7.618)–(7.619) unchanged. For basis changes, let $U(\ell)$ be unitary on $\operatorname{im} P^{\rho}(\ell)$; the block of $\Gamma_2^{\mathcal{N}}$ transforms by similarity, $A_\rho \mapsto U^{*} A_\rho U$ (cf. Proposition 7.458 and Lemma 7.483). Eigenvalues $\{m_i^2(\ell)\}_i$ and scalar residues $\{Z_i(\ell)\}_i$ are invariant under similarity (see Definitions 7.482 and 7.490), hence so are the averages and deviations.

(3) Set $A(p^2,\ell) := \Gamma_2^{\mathcal{N}}(p^2;\lambda_{\mathrm{UV}},\ell)$; by hypothesis and the IR guards, A is C^1 in (p^2,ℓ) on the admitted band. For a simple pole $p^2 = m_i^2(\ell)$ the Implicit Function Theorem/Kato perturbation theory gives continuous (indeed C^1) dependence of $m_i^2(\ell)$ and of the corresponding eigenprojectors/eigenvectors on ℓ; the residue formula

$$Z_i(\ell) = \Big(w_i(\ell)^{\top}\, \partial_{p^2} A\big(m_i^2(\ell),\ell\big)\, v_i(\ell) \Big)^{-1} \qquad \text{(cf. Definition 7.490 and eq. (7.612))}$$

is thus continuous as well (the denominator stays nonzero at simple poles) [115, Chs. II–IV]. Since $\overline{(\cdot)}$ and max are continuous on finite tuples, the claimed continuity follows.

For the pairwise bounds, observe for any finite set $\{x_i\}$ with mean $\bar{x}$ that

$$\max_{i,j} |x_i - x_j| \;\le\; \max_i |x_i - \bar{x}| + \max_j |\bar{x} - x_j| \;=\; 2 \max_k |x_k - \bar{x}|,$$

and also $\max_{i,j} |x_i - x_j| \ge \max_i |x_i - \bar{x}|$ because $\bar{x}$ lies between $\min x_i$ and $\max x_i$. Apply this to $\{m_i^2(\ell)\}_{i\in\mathfrak{M}_\rho(\ell)}$ and to $\{Z_i(\ell)\}_{i\in\mathfrak{M}_\rho(\ell)}$ to obtain the stated inequalities. □

Lemma 7.501 (Equivalence of dispersion metrics)**.** *Let $x_i \in \mathbb{R}$ $(i = 1,\dots,d)$ and set $R := \max_i |x_i - \overline{x}|$ (max–deviation from the mean) and $D := \max_{i,j} |x_i - x_j|$ (pairwise spread). Then*

$$R \;\le\; D \;\le\; 2R.$$

Hence $D \to 0$ iff $R \to 0$. Applied to $\{m_i^2(\ell)\}_{i\in\mathfrak{M}_\rho(\ell)}$ or $\{Z_i(\ell)\}_{i\in\mathfrak{M}_\rho(\ell)}$ this shows that pairwise–spread and mean–deviation give equivalent notions of multiplet reconvergence.

Proof. For any fixed i, by the triangle inequality,

$$|x_i - \overline{x}| \le \max_j |x_i - x_j| \le D,$$

and taking the maximum over i gives $R \le D$. For the reverse bound, choose indices $i^{\star}, j^{\star}$ with $|x_{i^{\star}} - x_{j^{\star}}| = D$. Then

$$D = |x_{i^{\star}} - x_{j^{\star}}| \le |x_{i^{\star}} - \overline{x}| + |x_{j^{\star}} - \overline{x}| \le 2R,$$

so $D \le 2R$. The equivalence $D \to 0 \Leftrightarrow R \to 0$ follows immediately. □

Remark 7.502 (Gauge and scheme safety)**.** Masses and residues are extracted on shell and within $W = \operatorname{im}\mathcal{N}$ (Nielsen projection), hence are gauge–parameter independent within the audit tolerance eq. (7.588) (cf. Proposition 7.485 and Corollary 7.477). Moreover, admissible basis/scheme changes act by similarity within W and do not affect $\{m_i^2, Z_i\}$ (or their dispersions) *as numbers*; see Proposition 7.458 and Lemmas 7.451 and 7.483.

Corollary 7.503 (Continuity of relative dispersions)**.** *Let ρ be fixed and work on the IR window. If $\overline{m_\rho^2}(\ell)$ (resp. $\overline{Z_\rho}(\ell)$) is bounded away from 0 on the window, then $\Delta^{\mathrm{rel}}_{m,\rho}(\ell) := \delta m_\rho^2(\ell)/\overline{m_\rho^2}(\ell)$ (resp. $\Delta^{\mathrm{rel}}_{Z,\rho}(\ell) := \delta Z_\rho(\ell)/\overline{Z_\rho}(\ell)$), as defined in Definition 7.499, is continuous in ℓ. Moreover,*

$$\Delta^{\mathrm{rel}}_{m,\rho}(\ell) \to 0 \quad \Longleftrightarrow \quad \delta m_\rho^2(\ell) \to 0,$$

and the analogous equivalence holds for residues.

Proof. By Lemma 7.500 (Kato continuity), each simple pole $m_i^2(\ell)$ and residue $Z_i(\ell)$ depends continuously on ℓ along the window; hence the functionals

$$\overline{m_\rho^2}(\ell),\ \delta m_\rho^2(\ell) \quad \text{and} \quad \overline{Z_\rho}(\ell),\ \delta Z_\rho(\ell)$$

defined in (7.618)–(7.619) are continuous (finite sums/means and maxima of continuous functions are continuous). See also [115, Chs. II–IV] for the underlying spectral continuity.

If $\overline{m_\rho^2}(\ell) \geq c_m > 0$ on the window, then the quotient

$$\Delta^{\mathrm{rel}}_{m,\rho}(\ell) = \frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)}$$

is the ratio of continuous functions with denominator bounded away from 0, hence is continuous. Furthermore,

$$\Delta^{\mathrm{rel}}_{m,\rho}(\ell) \to 0 \iff \delta m_\rho^2(\ell) \to 0,$$

since $c_m \leq \overline{m_\rho^2}(\ell) \leq C_m$ on compact subwindows implies $\frac{1}{C_m}\,\delta m_\rho^2(\ell) \leq \Delta^{\mathrm{rel}}_{m,\rho}(\ell) \leq \frac{1}{c_m}\,\delta m_\rho^2(\ell)$. The residue statement is identical when $\overline{Z_\rho}(\ell) \geq c_Z > 0$ on the window.

Finally, by Lemma 7.501, the choice between pairwise spread and mean–deviation is immaterial for diagnosing reconvergence; the present result concerns the (scale–free) ratio built from the mean–deviation. This completes the proof. □

The projector $P^\rho(\ell)$ organizes states into would–be symmetric multiplets (Definition 7.499); the dispersion $\delta(\cdot)$ measures intra-multiplet lifting of degeneracy, while the relative version removes overall scaling. Kato continuity ensures smooth tracking of pole/residue data (Lemma 7.492, [115]); Nielsen projection keeps gauge artifacts out (Definition 7.457), and gauge safety is guaranteed on shell (Proposition 7.485 and Corollary 7.477).

IR plateau acceptance (spectral).

Definition 7.504 (Spectral IR–plateau acceptance)**.** Let $\mathcal{I}_{\mathrm{IR}} \subset \mathbb{R}$ be the Step 3 IR window in $v = \ln \ell$ and let ℓ_R be the restoration length (cf. Definitions 7.430 and 7.478). For each multiplet ρ, with dispersions defined in Definition 7.499, we *accept* the spectral plateau if the relative dispersions are monotone nonincreasing on $\mathcal{I}_{\mathrm{IR}}$ and small at the restoration point:

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\left(\frac{\delta m_\rho^2(\ell)}{\overline{m_\rho^2}(\ell)}\right) \leq 0, \qquad \frac{\mathrm{d}}{\mathrm{d}\ln\ell}\left(\frac{\delta Z_\rho(\ell)}{\overline{Z_\rho}(\ell)}\right) \leq 0, \qquad \max\left\{\frac{\delta m_\rho^2(\ell_R)}{\overline{m_\rho^2}(\ell_R)}, \frac{\delta Z_\rho(\ell_R)}{\overline{Z_\rho}(\ell_R)}\right\} \leq \varepsilon_{\mathrm{spec}}.}$$

(7.620)

Here $\varepsilon_{\mathrm{spec}} \le \varepsilon_{\mathrm{plat}}$ is a fixed tolerance, and the monotonicity inequalities are evaluated with the same ripple guards as in eq. (7.548) (optionally after a low–pass in v obeying eqs. (7.537) and (7.538)). When $\overline{m_\rho^2}$ (or $\overline{Z_\rho}$) approaches zero, replace the ratio by the absolute dispersion or use a fixed IR reference in the denominator (cf. Remark 7.496).

Lemma 7.505 (Equivalent log–slope form; invariances)**.** *Let* $\Delta^{\mathrm{rel}}_{m,\rho} := \delta m_\rho^2/\overline{m_\rho^2}$ *and* $\Delta^{\mathrm{rel}}_{Z,\rho} := \delta Z_\rho/\overline{Z_\rho}$ *on the subset where denominators are* > 0*. Then* (7.620) *is equivalent to*

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\ln\Delta^{\mathrm{rel}}_{m,\rho}(\ell) \;\le\; 0, \qquad \frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\ln\Delta^{\mathrm{rel}}_{Z,\rho}(\ell) \;\le\; 0.$$

Moreover, the conditions in (7.620) *are invariant under*

(i) rigid scale reparametrisations $\ell \mapsto a\,\ell$ *(i.e.* $v \mapsto v + \ln a$*), and*
(ii) unitary rotations within the ρ*–block (basis changes in* $\operatorname{im} P^\rho$*).*

Proof. Equivalence of slope and log–slope. On the subset where denominators are > 0, the relative dispersions $\Delta^{\mathrm{rel}}_{m,\rho}$ and $\Delta^{\mathrm{rel}}_{Z,\rho}$ are strictly positive. For a positive C^1 function Δ,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\ln\Delta(\ell) = \frac{1}{\Delta(\ell)}\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\Delta(\ell),$$

so the sign of the derivative is preserved: $\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\Delta \le 0$ iff $\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln\Delta \le 0$. Applying this to $\Delta^{\mathrm{rel}}_{m,\rho}$ and $\Delta^{\mathrm{rel}}_{Z,\rho}$ yields the claimed equivalence.

Invariance under $\ell \mapsto a\,\ell$. The change $\ell \mapsto a\,\ell$ corresponds to a rigid shift $v = \ln\ell \mapsto v + \ln a$. Derivatives with respect to v (or $\ln\ell$) are invariant under rigid shifts, hence the monotonicity inequalities are unchanged pointwise along the (shifted) window. The threshold condition at the restoration point remains the same because it is evaluated at ℓ_R (which itself transforms as $\ell_R \mapsto a\,\ell_R$ under a mere change of units), so the numerical values of the ratios at restoration are unchanged.

Invariance under block–unitary basis changes. Let $U(\ell)$ be unitary on $\operatorname{im} P^\rho(\ell)$. The ρ–block of the projected kernel transforms by similarity:

$$A_\rho(p^2;\ell) \;\mapsto\; U(\ell)^* A_\rho(p^2;\ell)\,U(\ell) \quad \text{with} \quad A_\rho := P^\rho\,\Gamma_2^{\mathcal{N}}\,P^\rho\Big|_{\operatorname{ran} P^\rho}$$

(cf. Proposition 7.458 and Lemma 7.483). Eigenvalue locations $\{m_i^2(\ell)\}$ and scalar residues $\{Z_i(\ell)\}$ are invariant under similarity (see Definitions 7.482 and 7.490); therefore the averages and deviations (7.618)–(7.619) are basis–invariant, and so are their ratios. Since the invariants are unchanged pointwise in ℓ, their v–derivatives are also unchanged. This proves the claimed invariances.

Finally, continuity of the ratios on the subdomain with positive denominators follows from Lemma 7.500 (Kato continuity of m_i^2, Z_i and continuity of the mean and max functionals), ensuring that the derivatives above are well defined after applying the Step 3 ripple guards eq. (7.548) and, if used, the low–pass operators obeying eqs. (7.537) and (7.538). □

Proposition 7.506 (Sufficient conditions from irrelevance)**.** *Assume the Step 4 irrelevance hypothesis with* $\gamma_\star := \min_{\tilde B} |\operatorname{Re} y_{\tilde B}| > 0$ *(cf. Proposition 7.450 and Corollary 7.456) and the*

regularity/ripple guards on the IR window (cf. eq. (7.548) and Proposition 7.462). Suppose, in addition, that the multiplet mean obeys either

$$\text{(A)}\quad \overline{m_\rho^2}(\ell) \geq m_{\rho,\min}^2 > 0 \qquad \text{or} \qquad \text{(B)}\quad \overline{m_\rho^2}(\ell) \asymp \ell^{-\alpha} \quad \text{on the window with} \quad \alpha \leq \gamma_\star/2.$$

Then there exists $\ell_\star \geq \ell_R$ such that for all $\ell \geq \ell_\star$,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln\Delta_{m,\rho}^{\mathrm{rel}}(\ell) \;\leq\; -\frac{\gamma_\star}{2} \;<\; 0, \qquad \frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln\Delta_{Z,\rho}^{\mathrm{rel}}(\ell) \;\leq\; -\frac{\gamma_\star}{2} \;<\; 0.$$

Consequently, the monotone part of the spectral acceptance criterion (7.620) holds on $[\ell_\star,\infty)$. If, in addition, the plateau smallness at ℓ_R holds with the tolerance $\varepsilon_{\mathrm{spec}}$ (cf. Definition 7.504), then the spectral IR–plateau is accepted.

Proof. All statements are made on the BRST–physical/Nielsen subspace $W = \operatorname{im}\mathcal{N}$ for the band–projected kernel $\Gamma_2^{\mathcal{N}}$ (cf. Definitions 7.457 and 7.490); gauge safety on shell holds by Proposition 7.485 and Corollary 7.477.

Step 1: Linear response for intra–multiplet splittings. From Proposition 7.493 there exist bounded continuous functions $C_\rho(\ell), C'_\rho(\ell)$ on the IR window such that

$$\delta m_\rho^2(\ell) \;\leq\; C_\rho(\ell)\sum_{\tilde B}\left|\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\right| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2), \qquad \delta Z_\rho(\ell) \;\leq\; C'_\rho(\ell)\sum_{\tilde B}\left|\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\right| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2). \tag{7.621}$$

Step 2: RG decay and an eventual differential inequality. Let $\mu = \kappa/\ell$. By Step 4 irrelevance (Proposition 7.450 and Corollary 7.456),

$$\widetilde{\varepsilon}_{\tilde B}(\mu) = \mathcal{O}\Big(\mu^{\,y_{\tilde B}}\,\mathrm{poly}(\ln\mu)\Big), \quad \operatorname{Re} y_{\tilde B} < 0.$$

Writing $S(\ell) := \sum_{\tilde B}\left|\widetilde{\varepsilon}_{\tilde B}(\kappa/\ell)\right|$, one has

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln S(\ell) = -\frac{\sum_{\tilde B}\operatorname{Re} y_{\tilde B}\,|\widetilde{\varepsilon}_{\tilde B}| + \mathcal{O}(\|\widetilde{\varepsilon}\|^2)}{\sum_{\tilde B}|\widetilde{\varepsilon}_{\tilde B}|} = -\gamma_\star + o(1) \quad \text{as } \ell\to\infty,$$

since the slowest irrelevant sector dominates the sum (polylog factors are slowly varying). Hence there exists ℓ_1 such that for all $\ell \geq \ell_1$,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln S(\ell) \;\leq\; -\frac{3}{4}\gamma_\star. \tag{7.622}$$

Step 3: Log–slope for the relative mass dispersion. Consider

$$\ln\Delta_{m,\rho}^{\mathrm{rel}}(\ell) = \ln\delta m_\rho^2(\ell) - \ln\overline{m_\rho^2}(\ell).$$

By (7.621) and smallness of $\|\widetilde{\varepsilon}\|$, there exists ℓ_2 s.t. for $\ell \geq \ell_2$, $\delta m_\rho^2(\ell) = \Theta\Big(S(\ell)\Big)$ up to a slowly varying multiplicative factor $R_m(\ell)$ with $\ln R_m(\ell)$ bounded and $[\mathrm{d}/\mathrm{d}\ln\ell]\ln R_m(\ell) = o(1)$. (This follows from the first–order degenerate perturbation structure inside the finite ρ–cluster and the smooth tracking of projectors/eigenvectors, cf. Lemma 7.492 and the Wigner–Eckart decomposition in Proposition 7.493.) Therefore,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln\delta m_\rho^2(\ell) = \frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln S(\ell) + o(1) \;\leq\; -\frac{3}{4}\gamma_\star + o(1),$$

by (7.622). For the denominator:

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\ln\overline{m_\rho^2}(\ell) = \begin{cases} o(1), & \text{in case (A)},\\ -\alpha + o(1), & \text{in case (B)}, \end{cases}$$

using the hypothesis on $\overline{m_\rho^2}$ and continuity on the window (Lemma 7.500). Consequently,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\ln\Delta^{\mathrm{rel}}_{m,\rho}(\ell) = \begin{cases} -\frac{3}{4}\gamma_\star + o(1), & \text{in case (A)},\\ -(\frac{3}{4}\gamma_\star - \alpha) + o(1), & \text{in case (B)}. \end{cases}$$

Choose $\ell_\star \geq \max\{\ell_1, \ell_2, \ell_R\}$ large enough that the $o(1)$ term is bounded by $\gamma_\star/4$ and, in case (B), use $\alpha \leq \gamma_\star/2$. Then for all $\ell \geq \ell_\star$,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\,\ln\Delta^{\mathrm{rel}}_{m,\rho}(\ell) \;\leq\; -\frac{\gamma_\star}{2} \;<\; 0.$$

Step 4: Residues. The same argument applies to $\Delta^{\mathrm{rel}}_{Z,\rho}(\ell)$: by (7.621) and the residue–tracking formula in Definition 7.490 together with Lemma 7.492, the first–order variation is linear in the breakings with the same $S(\ell)$ control, yielding the identical log–slope bound.

Step 5: Acceptance. The obtained bounds give the monotone (log–slope) part of Definition 7.504 on $[\ell_\star, \infty)$. If, in addition, the restoration–point smallness at ℓ_R holds with $\varepsilon_{\mathrm{spec}}$, the full criterion (7.620) is satisfied and the spectral IR–plateau is accepted.

This completes the proof. □

- Step 4 irrelevance and its $\mu^{y_{\bar{B}}}\,\mathrm{poly}(\ln\mu)$ law are taken from Proposition 7.450 and Corollary 7.456 (RG canon [389, 91, 82]).
- Smooth spectral tracking and the stability of the finite ρ–cluster rely on Kato's theory [115] via Lemma 7.492.
- The additional assumption on $\overline{m_\rho^2}$ is the same scaling control used in Theorem 7.494; it is sharpened here to ensure a uniform $-\gamma_\star/2$ log–slope bound.

Discrete audit.

Definition 7.507 (Discrete spectral monotonicity checks)**.** Let $v_k := \ln\ell_k$ be a *uniform* grid with step $h > 0$. Define the centered finite–difference estimators (cf. Definition 7.487 and Lemma 7.488)

$$\widehat{\partial_v \Delta^{\mathrm{rel}}_{m,\rho}}(v_k) := \frac{\Delta^{\mathrm{rel}}_{m,\rho}(v_{k+1}) - \Delta^{\mathrm{rel}}_{m,\rho}(v_{k-1})}{2h},$$
$$\widehat{\partial_v \ln\Delta^{\mathrm{rel}}_{m,\rho}}(v_k) := \frac{\ln\Delta^{\mathrm{rel}}_{m,\rho}(v_{k+1}) - \ln\Delta^{\mathrm{rel}}_{m,\rho}(v_{k-1})}{2h},$$

and analogously for $\Delta^{\mathrm{rel}}_{Z,\rho}$, on the subset where the denominators in the definitions of the relative dispersions are strictly positive (cf. Definition 7.499 and Lemma 7.501). With the

optional low–pass operator LP_τ in v (kernels obeying eqs. (7.537) and (7.538), inducing an $\mathcal{O}(\tau^2)$ bias by Lemma 7.488), *accept* monotone reconvergence on the discrete IR window if

$$\widehat{\partial_v \Delta^{\mathrm{rel}}_{m,\rho}}(v_k) \le 0 \quad \text{and} \quad \widehat{\partial_v \Delta^{\mathrm{rel}}_{Z,\rho}}(v_k) \le 0 \quad \text{for all } v_k \in \mathcal{I}_{\mathrm{IR}},$$

and the restoration–point smallness holds:

$$\max\Big\{\Delta^{\mathrm{rel}}_{m,\rho}(\ln \ell_R),\ \Delta^{\mathrm{rel}}_{Z,\rho}(\ln \ell_R)\Big\} \ \le\ \varepsilon_{\mathrm{spec}} \quad \text{(cf. Definition 7.504)}.$$

When $\overline{m^2_\rho}$ or $\overline{Z_\rho}$ is near zero, replace the log–slope check by the slope of the absolute dispersion or use a fixed IR reference in the denominator (cf. Remark 7.496).

Intuition. Relative dispersions should *tighten* (be nonincreasing in $v = \ln \ell$) and already be small at restoration. Step 4 irrelevance provides an eventual negative log–slope (cf. Theorem 7.494 and Proposition 7.506); the ripple guards and the centered estimators (Lemma 7.488) ensure we detect genuine reconvergence rather than numerical wiggles.

Pseudo–NG option and RG consistency.

Definition 7.508 (Pseudo–Nambu–Goldstone (pNG) channel and spurion power)**.** Let $\widetilde{\mathcal{O}}_{\tilde{B}}$ be a Nielsen–projected breaking eigen–operator with irrelevant exponent $y_{\tilde{B}} < 0$ (Step 7.8.4; cf. Proposition 7.450 and Corollary 7.456). A *pNG channel* is a physical mode that would be exactly massless in the symmetric theory but acquires a small gap from explicit breaking by $\widetilde{\mathcal{O}}_{\tilde{B}}$. By spurion analysis/Wigner–Eckart (the spurion transforming like $\widetilde{\mathcal{O}}_{\tilde{B}}$), the leading pNG mass term arises from the minimal number $n_\star \in \mathbb{N}$ of spurion insertions required to form a singlet in the pNG channel; we call

$$\alpha := n_\star > 0$$

the *spurion power* (model/channel dependent). Consequently, the leading pNG scaling is governed by the $n_\star$–fold products of the running breakings,

$$\begin{aligned}\overline{m^2_{\mathrm{pNG}}}(\ell) &= \mathcal{O}\Big(\sum_{(\tilde{B}_1,\dots,\tilde{B}_{n_\star})} \prod_{j=1}^{n_\star} \widetilde{\varepsilon}_{\tilde{B}_j}(\kappa/\ell)\Big) \\ &= \mathcal{O}\Big(\mu^{\,n_\star \gamma_\star}\,\mathrm{poly}(\ln \mu)\Big), \\ &\qquad \text{where } \mu = \kappa/\ell \text{ and } \gamma_\star := \min_{\tilde{B}} |\operatorname{Re} y_{\tilde{B}}|.\end{aligned}$$

in agreement with the RG running and linear–response structure (cf. Proposition 7.493 and Theorem 7.494). Standard QFT treatments of NG/pNG modes and spurion methods include [91, 82].

Proposition 7.509 (pNG scaling from the RG solution)**.** *Work on the on–shell, band– and Nielsen–projected posture for the two–point kernel $\Gamma_2^{\mathcal{N}}(p^2; \lambda_{\mathrm{UV}}, \ell)$ on $W = \operatorname{im}\mathcal{N}$ (cf. Definitions 7.457 and 7.490). Let $\widetilde{\mathcal{O}}_{\tilde{B}}$ be a Nielsen–projected breaking eigen–operator with irrelevant exponent $y_{\tilde{B}} < 0$ (Step 7.8.4; cf. Proposition 7.450 and Corollary 7.456) and let $\alpha = n_\star > 0$*

be the spurion power for the pNG channel (cf. Definition 7.508). Then on the IR window $\mathcal{I}_{\mathrm{IR}}$ the pNG mass obeys the scaling law

$$\boxed{m_{\mathrm{pNG}}^2(\ell) \;=\; C_{\mathrm{pNG}}(\ell)\,\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big|^{\alpha} \;\sim\; C_{\mathrm{pNG}}(\ell)\,\mu^{\alpha y_{\tilde{B}}} \;=\; C_{\mathrm{pNG}}(\ell)\left(\frac{\kappa}{\ell}\right)^{\alpha y_{\tilde{B}}}, \qquad \mu=\kappa/\ell,}\tag{7.623}$$

where $C_{\mathrm{pNG}}(\ell)$ is slowly varying on the plateau (bounded and ℓ–Lipschitz under the curvature/TV guards; cf. eq. (7.548) and Proposition 7.462). Consequently,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\,\ln m_{\mathrm{pNG}}^2(\ell) \;=\; \alpha\, y_{\tilde{B}} \;+\; o(1) \quad \text{as } \mu\downarrow 0.$$

Proof. All statements are made on $W=\operatorname{im}\mathcal{N}$; gauge–parameter safety on shell follows from Proposition 7.485 and Corollary 7.477. Let $P^{\mathrm{pNG}}(\ell)$ denote the (rank–one) projector selecting the pNG channel within the relevant multiplet (cf. Definitions 7.499 and 7.508). Consider the reduced scalar kernel obtained by left/right projection onto the pNG mode at scale ℓ:

$$a_\ell(p^2) \;:=\; w_{\mathrm{pNG}}(\ell)^{\top}\,\Gamma_2^{\mathcal{N}}(p^2;\lambda_{\mathrm{UV}},\ell)\,v_{\mathrm{pNG}}(\ell),$$

with $w_{\mathrm{pNG}}^{\top}v_{\mathrm{pNG}}=1$ and $v_{\mathrm{pNG}}(\ell)\in\operatorname{ran}P^{\mathrm{pNG}}(\ell)$ (cf. residue normalisation in Definition 7.490). In the exact symmetric limit (spurion switched off) the pNG mode is massless, so $a_\ell(0)=0$ and the pole at $p^2=0$ is simple with finite residue; equivalently $\partial_{p^2}a_\ell(0)=Z_{\mathrm{sym}}(\ell)^{-1}\neq 0$ by standard QFT pole–residue practice [91, 82].

Turning on the explicit breaking by $\widetilde{\mathcal{O}}_{\tilde{B}}$, spurion/Wigner–Eckart selection rules imply that the first symmetry–allowed invariant in the pNG channel arises at order $n_\star=\alpha$ in the spurion field (cf. Definition 7.508); lower orders vanish by representation constraints. Hence, for small breaking and p^2 near 0,

$$a_\ell(p^2)=\underbrace{\partial_{p^2}a_\ell(0)}_{Z_{\mathrm{sym}}(\ell)^{-1}}\,p^2 \;-\; \sum_{n\geq\alpha} c_n(\ell)\,\big(\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big)^n \;+\; \mathcal{O}\big(p^4\big) \;+\; \mathcal{O}\big(\|\widetilde{\varepsilon}\|^{\alpha+1}\big),$$

where the coefficients $c_n(\ell)$ are bounded and ℓ–Lipschitz on the IR window by the curvature/TV guards and the smooth tracking of eigenvectors/projectors (Kato continuity; cf. Lemma 7.492 and [115, Chs. II–IV]). The pNG mass solves the pole condition $a_\ell(m_{\mathrm{pNG}}^2(\ell))=0$, giving at leading nontrivial order

$$m_{\mathrm{pNG}}^2(\ell)=\; Z_{\mathrm{sym}}(\ell)\,c_\alpha(\ell)\,\big|\widetilde{\varepsilon}_{\tilde{B}}(\mu)\big|^{\alpha}\,\Big(1+\mathcal{O}\big(|\widetilde{\varepsilon}_{\tilde{B}}|\big)\Big).$$

Absorb $Z_{\mathrm{sym}}(\ell)c_\alpha(\ell)$ and the slowly varying subleading factors (including possible polylogarithms from the RG) into $C_{\mathrm{pNG}}(\ell)$; boundedness and ℓ–Lipschitz continuity of C_{pNG} follow from the IR window guards and from the smoothness of the coefficients above.

Finally, Step 4 irrelevance provides the RG running $\widetilde{\varepsilon}_{\tilde{B}}(\mu)=\mathcal{O}\big(\mu^{\,y_{\tilde{B}}}\,\mathrm{poly}(\ln\mu)\big)$ with $y_{\tilde{B}}<0$ (cf. Proposition 7.450 and Corollary 7.456). The slowly varying polylog factor is again absorbed into $C_{\mathrm{pNG}}(\ell)$ on the plateau, yielding (7.623). Differentiating $\ln m_{\mathrm{pNG}}^2(\ell)=\ln C_{\mathrm{pNG}}(\ell)+\alpha\ln|\widetilde{\varepsilon}_{\tilde{B}}(\mu)|$ with respect to $\ln\mu$ and using that $\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\ln C_{\mathrm{pNG}}(\ell)=o(1)$ on the IR window (slow variation) gives $\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\ln m_{\mathrm{pNG}}^2(\ell)=\alpha\,y_{\tilde{B}}+o(1)$ as $\mu\downarrow 0$. □

Remark 7.510 (Multiple breakings and crossovers)**.** If several irrelevant spurions $\{\widetilde{\mathcal{O}}_{\tilde{B}_j}\}$ contribute with powers α_j and exponents $y_j < 0$, then by the same spurion analysis and RG running one obtains

$$m^2_{\mathrm{pNG}}(\ell) \;\sim\; \sum_j C_j(\ell)\, \mu^{\alpha_j y_j},$$

with slowly varying $C_j(\ell)$. As $\mu \downarrow 0$, the *slowest* decaying contribution (largest $\alpha_j y_j$ in the sense of least negative) dominates the log–slope; on finite IR windows this can produce apparent crossovers before the asymptotic regime is reached (cf. Proposition 7.450 and Corollary 7.456 and standard pNG/spurion treatments [91, 82]).

Estimators and RG consistency checks.

Definition 7.511 (Log–slope estimators for pNG scaling)**.** Let $t_k := \ln \mu_k$ be a *uniform* grid with step $\Delta t > 0$ on the IR window (so $\mu_k = \kappa/\ell_k$ and $t_k = \ln \kappa - \ln \ell_k$). Define the centered log–slope estimator for the pNG mass (cf. Lemma 7.488):

$$\widehat{s}_{\mathrm{pNG}}(\mu_k) := \frac{\ln m^2_{\mathrm{pNG}}(\mu_{k+1}) - \ln m^2_{\mathrm{pNG}}(\mu_{k-1})}{2\,(t_{k+1} - t_{k-1})} = \frac{\ln m^2_{\mathrm{pNG}}(\mu_{k+1}) - \ln m^2_{\mathrm{pNG}}(\mu_{k-1})}{2\,\Delta t}.$$

To estimate the spurion power α appearing in the scaling law (7.623) of Proposition 7.509, set

$$\widehat{\alpha}_{\tilde{B}}(\mu_k) := \frac{\widehat{s}_{\mathrm{pNG}}(\mu_k)}{\widehat{y}_{\tilde{B}}(\mu_k)},$$

where $\widehat{y}_{\tilde{B}}$ is the Step 4 slope estimator for the breaking eigen–coupling (cf. the centered–difference construction in Definition 7.446). Optionally apply a low–pass in t with kernel obeying eqs. (7.537) and (7.538), which induces an $\mathcal{O}(\tau^2)$ bias by Lemma 7.488. Consistency with Proposition 7.509 requires $\widehat{s}_{\mathrm{pNG}}(\mu_k) \to \alpha\, y_{\tilde{B}}$ and hence $\widehat{\alpha}_{\tilde{B}}(\mu_k) \to \alpha$ along the IR window.

Proposition 7.512 (Gauge/basis safety and scale invariance)**.** *The quantities m^2_{pNG}, $\widehat{s}_{\mathrm{pNG}}$, and $\widehat{\alpha}_{\tilde{B}}$ are:*

(i) gauge–parameter independent within the tolerance eq. (7.588) when evaluated on shell and Nielsen–projected (Definition 7.457);

(ii) invariant under admissible basis/scheme changes on $W = \mathrm{im}\,\mathcal{N}$ (similarity in the ρ–block; cf. Proposition 7.458 and Lemmas 7.451 and 7.483);

(iii) independent of the audit constant κ in $\mu = \kappa/\ell$ (a rigid shift of $t = \ln \mu$ cancels in centered differences).

Proof. (i) *Gauge safety.* On the on–shell, Nielsen–projected posture, the two–point kernel's pole positions are gauge–parameter independent (within the audit tolerance) by Proposition 7.485 and Corollary 7.477; the pNG mass m^2_{pNG} is such a pole location in the selected channel. Therefore $\ln m^2_{\mathrm{pNG}}$ and its centered finite differences inherit the same gauge independence; dividing by $\widehat{y}_{\tilde{B}}$ (which is itself gauge–safe under the same posture by Step 4's construction) preserves gauge safety for $\widehat{\alpha}_{\tilde{B}}$.

(ii) *Basis/scheme invariance.* Admissible basis/scheme changes act by similarity on the block $A_\rho = P^\rho \Gamma_2^{\mathcal{N}} P^\rho$ (cf. Proposition 7.458 and Lemma 7.483). Pole locations and scalar

residues are invariant under similarity (see Definitions 7.482 and 7.490), hence m^2_{pNG} is invariant as a number. Centered log–differences of an invariant scalar are invariant, and the Step 4 estimator $\widehat{y}_{\tilde{B}}$ is constructed to be scheme–stable (cf. Lemma 7.451), so $\widehat{s}_{\mathrm{pNG}}$ and $\widehat{\alpha}_{\tilde{B}}$ are basis/scheme invariant.

(iii) *Independence of* κ. Changing $\kappa \mapsto a\,\kappa$ shifts $t = \ln \mu$ by a constant: $t \mapsto t + \ln a$. For any function g, the centered difference $\big[g(t_{k+1}) - g(t_{k-1})\big] / \big[2\,(t_{k+1} - t_{k-1})\big]$ is invariant under rigid shifts of t. Hence $\widehat{s}_{\mathrm{pNG}}$ is independent of κ, and so is $\widehat{\alpha}_{\tilde{B}}$.

Finally, optional low–pass filtering in t preserves these invariances and introduces only the controlled $\mathcal{O}(\tau^2)$ bias described in Lemma 7.488. □

Definition 7.513 (Acceptance with pNG allowance)**.** Work on the on–shell, band– and Nielsen–projected posture (cf. Definitions 7.457 and 7.490) on the Step 3 IR window $\mathcal{I}_{\mathrm{IR}}$ with restoration length ℓ_R (cf. Definitions 7.430 and 7.478). A dataset *passes* Step 6 with a pNG mode present if:

1. **Non–pNG multiplets reconverge.** For every *non–pNG* multiplet ρ, the spectral IR–plateau criteria hold as in Definition 7.504.
2. **State–coherence guard.** The state–coherence/consistency guard is satisfied on and beyond ℓ_R (cf. eq. (7.566)).
3. **pNG RG–consistent scaling.** The pNG channel exhibits the scaling implied by Proposition 7.509:

$$\widehat{s}_{\mathrm{pNG}}(\mu_k) \;\in \Big[\alpha\, y_{\tilde{B}} - \delta,\; \alpha\, y_{\tilde{B}} + \delta\Big] \quad \text{for all} \quad \mu_k \in \mathcal{I}_\mu,$$

where $\widehat{s}_{\mathrm{pNG}}$ is the centered log–slope estimator of Definition 7.511, $y_{\tilde{B}}$ is the Step 4 irrelevant exponent (estimated by Definition 7.446), α is the spurion power from Definition 7.508, and $\mathcal{I}_\mu$ is the IR window in $\mu = \kappa/\ell$ (cf. Definition 7.461). The tolerance δ should exceed the known estimator/smoothing biases (cf. Lemma 7.488 and eqs. (7.537) and (7.538)) yet satisfy $\delta \ll |y_{\tilde{B}}|$ on the window. Optionally, when symmetry selection rules predict $\alpha \in \mathbb{N}$, require *integer compatibility* of $\widehat{\alpha}_{\tilde{B}} = \widehat{s}_{\mathrm{pNG}}/\widehat{y}_{\tilde{B}}$ (cf. Definition 7.511) within the same tolerance.

Intuition. A genuine pseudo–Goldstone may retain a small gap while all other multiplets reconverge. Spurion/Wigner–Eckart analysis fixes the leading power α of the breaking amplitude, and Step 4 RG running gives $y_{\tilde{B}} < 0$; together they imply the pNG scaling $m^2_{\mathrm{pNG}} \propto |\tilde{\varepsilon}_{\tilde{B}}|^\alpha \sim \mu^{\alpha y_{\tilde{B}}}$ (Definition 7.508 and Proposition 7.509; see also [91, 82]). Matching the observed pNG log–slope to $\alpha y_{\tilde{B}}$ closes the RG/spectral consistency loop, while the non–pNG multiplets must satisfy the standard reconvergence and restoration ledgers (Definition 7.504).

No state–visibility volume decay (QIII guard).

Definition 7.514 (Volume–uniform state visibility)**.** All spectral diagnostics in Step 6 are conditioned on *uniform* state coherence as in eq. (7.566):

$$\sup_V \Big|1 - \Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}}, \ell; T^\star, V)\Big| \;\le\; \varepsilon_{\mathrm{plat}} \qquad \text{for all} \quad \ell \ge \ell_R,$$

with the same instrumentation (P_x, K_{IR}) and on–shell/Nielsen posture (cf. Definitions 7.457 and 7.475).

Proposition 7.515 (QIII vs. QII classification guard)**.** *If Definition 7.514 fails on any tail $\ell \geq \ell_\circ$ (i.e. the left–hand side grows with V or does not stay $\leq \varepsilon_{\text{plat}}$), then the observed IR behaviour is* not *QIII: spectral claims (multiplet reconvergence, pNG scaling) are reclassified as QII–like (volume–decoherence–driven). Conversely, if the guard holds, all conclusions of Step 6 (Theorem 7.494 and Definitions 7.504 and 7.513) apply* uniformly in V.

Proof. We work throughout on the on–shell, band– and Nielsen–projected posture for the two–point kernel $\Gamma_2^{\mathcal{N}}(p^2; \lambda_{\text{UV}}, \ell)$ on $W = \operatorname{im}\mathcal{N}$ (cf. Definitions 7.457 and 7.490); on shell, gauge safety holds by Proposition 7.485 and Corollary 7.477.

(A) A failure of volume-uniform state visibility implies that the system is not Q III. The quantity $\Lambda_{\text{state}}(\lambda_{\text{UV}}, \ell; T^\star, V)$ in eq. (7.566) monitors coherence/visibility of one–particle contributions in the channel of interest at time scale $T^\star$ and volume V. If

$$\sup_V \left|1 - \Lambda_{\text{state}}(\lambda_{\text{UV}}, \ell; T^\star, V)\right| > \varepsilon_{\text{plat}} \quad \text{along some tail } \ell \geq \ell_\circ,$$

then either (i) the vacuum–to–one–particle matrix elements decay with V, driving the corresponding LSZ residue to zero, or (ii) the would–be pole contribution is swamped by incoherent multi–particle/continuum effects that do not vanish uniformly in V (both mechanisms are standard in the finite–volume spectral analysis of QFT; cf. [91, 82]). In either case, the extraction of *volume–independent* simple poles and residues used in Step 6 (see Definitions 7.482 and 7.490) becomes unreliable on that tail. The intra–multiplet diagnostics $\{\overline{m_\rho^2}, \delta m_\rho^2, \overline{Z_\rho}, \delta Z_\rho\}$ (Definition 7.499) and their relative versions then reflect volume–driven decoherence rather than genuine RG restoration; accordingly the phenomenon must be classified as QII–like (volume decoherence), not QIII (spectral reconvergence).

(B) Holding of the guard ⇒ uniformity in V of Step 6 conclusions. Assume Definition 7.514. Then there exist V–independent bounds (on compact IR subwindows) for: (i) the residues at simple poles (they stay bounded away from 0 by eq. (7.566) and QFT pole–residue relations [91, 82]); (ii) operator norms and first derivatives of the band–limited kernel and its ρ–blocks (curvature/TV guards and window consistency eq. (7.548) and Proposition 7.462); and (iii) spectral gaps isolating the finite ρ–clusters. These yield resolvent bounds uniform in V, so Kato's perturbation/Implicit Function Theorem arguments (Lemma 7.492; see also [115, Chs. II–IV]) apply uniformly: the pole locations $m_i^2(\ell)$ and residues $Z_i(\ell)$ vary continuously in ℓ with constants independent of V.

The linear–response bounds for intra–multiplet splittings (Proposition 7.493) depend only on the blockwise operator norms and derivatives of $\Gamma_2^{\mathcal{N}}$, and hence the constants $C_\rho(\ell), C'_\rho(\ell)$ can be chosen uniformly in V. Combining these uniform bounds with the Step 4 irrelevance running (Proposition 7.450 and Corollary 7.456) yields the reconvergence rates of Theorem 7.494 uniformly in V, and the acceptance criteria Definition 7.504 (and, with a pNG channel, Definition 7.513) hold uniformly as well. Therefore all Step 6 conclusions apply uniformly in the volume under the guard Definition 7.514.

The two implications (A) and (B) establish the proposition. □

Discrete estimators and audit path.

Definition 7.516 (Spectral estimators on (v, p^2)–grids)**.** Let $v_k := \ln \ell_k$ be a *uniform* grid with step $h > 0$ and let $\{p_r^2\}_r$ be a monotone momentum grid inside the admitted band

$\mathfrak{B}(\lambda_{\mathrm{UV}}, \ell_k)$ (cf. Definition 7.468). Work on the band– and Nielsen–projected two–point kernel $\Gamma_2^{\mathcal{N}}(p^2; \lambda_{\mathrm{UV}}, \ell)$ on $W = \operatorname{im}\mathcal{N}$ (cf. Definitions 7.457 and 7.490); let $\lambda_i(p^2; \ell)$ denote its eigenvalues, labelled continuously in (p^2, ℓ) near each simple pole $p^2 = m_i^2(\ell)$ (cf. Lemma 7.492).

For each (i, k), choose an index $r = r(i, k)$ that *locally brackets the zero* (i.e. $\lambda_i(p_{r-1}^2; \ell_k)\,\lambda_i(p_{r+1}^2; \ell_k) \le 0$) or, when no sign change is observed, minimises the *absolute* value $|\lambda_i(p_r^2; \ell_k)|$. Define the *Newton–stencil mass estimator*

$$\boxed{\widehat{m}_i^2(\ell_k) \;:=\; p_r^2 \;-\; \frac{\lambda_i(p_r^2; \ell_k)}{\widehat{\partial_{p^2}\lambda_i}(p_r^2; \ell_k)},} \tag{7.624}$$

where $\widehat{\partial_{p^2}\lambda_i}(p_r^2; \ell_k)$ is the *second–order* three–point derivative at p_r^2. For a quasi–uniform local mesh $h_\pm := p_{r\pm1}^2 - p_r^2$ one may use the standard nonuniform three–point formula

$$\widehat{\partial_{p^2}\lambda_i}(p_r^2; \ell_k) = -\frac{h_+}{h_-(h_- + h_+)}\,\lambda_i(p_{r-1}^2; \ell_k) + \frac{h_+ - h_-}{h_- h_+}\,\lambda_i(p_r^2; \ell_k) + \frac{h_-}{h_+(h_- + h_+)}\,\lambda_i(p_{r+1}^2; \ell_k).$$

Define the *residue estimator* by

$$\boxed{\widehat{Z}_i(\ell_k) \;:=\; \Big[\, \widehat{\partial_{p^2}\lambda_i}\Big(\widehat{m}_i^2(\ell_k); \ell_k\Big) \,\Big]^{-1},} \tag{7.625}$$

evaluating the same three–point formula after recentering the stencil at the grid point closest to $\widehat{m}_i^2(\ell_k)$.

Construct the multiplet dispersions $\overline{m_\rho^2}$, δm_ρ^2, $\overline{Z_\rho}$, δZ_ρ from eqs. (7.618) and (7.619), using the sets $\mathfrak{M}_\rho(\ell_k)$ of Definition 7.499. Optionally apply a low–pass in v satisfying eqs. (7.537) and (7.538) to the sequences $\{\widehat{m}_i^2(\ell_k)\}_k$ and $\{\widehat{Z}_i(\ell_k)\}_k$ before forming dispersions; this introduces only an $\mathcal{O}(\tau^2)$ bias (cf. Lemma 7.488).

Lemma 7.517 (Consistency and rates of the discrete spectral estimators)**.** *Assume for each (i, k) that $p^2 \mapsto \lambda_i(p^2; \ell_k)$ is C^3 in a neighbourhood of its simple zero $p^2 = m_i^2(\ell_k)$, with*

$$\partial_{p^2}\lambda_i\Big(m_i^2(\ell_k); \ell_k\Big) = Z_i(\ell_k)^{-1} \neq 0, \qquad \|\partial_{p^2}^2\lambda_i\|,\ \|\partial_{p^2}^3\lambda_i\| \text{ bounded near } m_i^2(\ell_k).$$

If the local mesh is quasi–uniform in the sense that $h_\pm = p_{r\pm1}^2 - p_r^2$ satisfy $\theta^{-1} \le h_+/h_- \le \theta$ for some fixed $\theta > 0$, then as the momentum grid is refined (with $h := \max\{h_-, h_+\} \to 0$),

$$\widehat{m}_i^2(\ell_k) = m_i^2(\ell_k) + \mathcal{O}(h^2), \qquad \widehat{Z}_i(\ell_k) = Z_i(\ell_k) + \mathcal{O}(h^2).$$

Proof. Fix (i, k) and write $\lambda(p) := \lambda_i(p^2; \ell_k)$ with p^2 as the scalar variable; let $m^2 := m_i^2(\ell_k)$ and $a := \lambda'(m^2) = Z_i(\ell_k)^{-1} \neq 0$. By Taylor's theorem with integral remainder,

$$\lambda(p^2) = a(p^2 - m^2) + \tfrac{1}{2}b(p^2 - m^2)^2 + \tfrac{1}{6}c(p^2 - m^2)^3 + \mathcal{O}\Big(|p^2 - m^2|^4\Big),$$

with $b = \lambda''(m^2)$ and $c = \lambda^{(3)}(\xi)$ bounded near m^2.

(1) Derivative consistency. The three–point nonuniform formula used for $\widehat{\partial_{p^2}\lambda}(p_r^2)$ is the unique second–order accurate interpolatory stencil on $\{p_{r-1}^2, p_r^2, p_{r+1}^2\}$; standard Peano kernel estimates give

$$\widehat{\partial_{p^2}\lambda}(p_r^2) = \lambda'(p_r^2) + \mathcal{O}(h^2) \quad \text{with } h := \max\{h_-, h_+\},$$

provided $h_\pm$ are boundedly comparable (quasi–uniform) and $\lambda \in C^3$.

(2) Newton–stencil mass estimator. Set $\phi(p^2) := p^2 - \lambda(p^2)/\lambda'(p^2)$ (the exact Newton map). For a simple zero and C^2 smoothness, $\phi(m^2) = m^2$ and $\phi'(m^2) = 0$ with ϕ'' bounded; hence a single Newton step from any p_r^2 in a sufficiently small neighbourhood of m^2 yields

$$p_r^2 - \frac{\lambda(p_r^2)}{\lambda'(p_r^2)} \;=\; m^2 + \mathcal{O}\Big((p_r^2 - m^2)^2\Big).$$

Replacing λ' by the second–order estimator $\widehat{\partial_{p^2}\lambda}$ introduces only an additional $\mathcal{O}(h^2)$ perturbation in the denominator. Since by the bracketing or absolute–minimum choice we have $|p_r^2 - m^2| \le h$ and $\lambda'(m^2) = a \neq 0$, a standard perturbation argument (expanding the denominator around $\lambda'(p_r^2)$ and using the boundedness of $1/\lambda'$ near m^2) gives

$$\widehat{m}_i^2(\ell_k) = p_r^2 - \frac{\lambda(p_r^2)}{\widehat{\partial_{p^2}\lambda}(p_r^2)} = m^2 + \mathcal{O}\Big(h^2\Big).$$

(3) Residue estimator. By definition $Z_i(\ell_k) = \Big[\lambda'(m^2)\Big]^{-1}$. Using the derivative estimator at the recentered stencil nearest to $\widehat{m}_i^2$, write

$$\widehat{Z}_i(\ell_k) = \Big[\lambda'(\widehat{m}_i^2) + \Big(\widehat{\partial_{p^2}\lambda} - \lambda'\Big)(\widehat{m}_i^2)\Big]^{-1}.$$

The first term equals $Z_i(\ell_k)^{-1} + \mathcal{O}(h^2)$ by (2) and C^2 smoothness; the second term is $\mathcal{O}(h^2)$ by (1). Since $Z_i(\ell_k)^{-1} \neq 0$ and the perturbation is small, a Neumann–series expansion of the inverse yields $\widehat{Z}_i(\ell_k) = Z_i(\ell_k) + \mathcal{O}(h^2)$.

The stated rates follow. □

Lemma 7.518 (Gauge/basis and scale invariances)**.** *The discrete spectral estimators* (7.624)–(7.625) *and the derived dispersions* $\overline{m_\rho^2}, \delta m_\rho^2, \overline{Z_\rho}, \delta Z_\rho$ *(cf. Definition 7.499) are:*

(i) gauge–parameter independent within the tolerance eq. (7.588) *when evaluated on shell and Nielsen–projected (Definition 7.457);*

(ii) invariant under admissible basis/scheme changes acting by similarity on $W = \operatorname{im}\mathcal{N}$ *(cf. Proposition 7.458 and Lemmas 7.451 and 7.483);*

(iii) invariant under reparametrisations $\ell \mapsto a\,\ell$ *(rigid shifts* $v = \ln \ell \mapsto v + \ln a$*) and under positive rescalings of the reference response* $\mathcal{R}$ *used in defining the admitted band in Definition 7.468.*

Proof. We work in the on–shell, band– and Nielsen–projected posture for $\Gamma_2^{\mathcal{N}}(p^2; \lambda_{\mathrm{UV}}, \ell)$ (cf. Definitions 7.457 and 7.490).

(i) Gauge–parameter independence. On shell, the gauge–parameter dependence of $\Gamma_2^{\mathcal{N}}$ is a similarity flow (Nielsen/Lax form), and pole positions/residues are gauge–parameter independent within the audit tolerance (see Proposition 7.485 and Corollary 7.477). The estimators (7.624)–(7.625) are built solely from the scalar eigenvalue branches $\lambda_i(p^2; \ell)$ and their p^2–derivatives at the pole; under similarity these eigenvalues are unchanged as functions of p^2. Hence $\widehat{m}_i^2(\ell_k)$ and $\widehat{Z}_i(\ell_k)$ inherit the same gauge safety, and so do the dispersion functionals formed from $\{m_i^2, Z_i\}$ (cf. Definition 7.499).

(ii) Basis/scheme invariance. Any admissible basis change within $\operatorname{im} P^{\rho}(\ell)$ acts by similarity on the ρ–block $A_{\rho} = P^{\rho}\Gamma_2^{\mathcal{N}}P^{\rho}$ (cf. Proposition 7.458 and Lemma 7.483). Similarity leaves eigenvalue locations and the scalar residues (defined by Definitions 7.482 and 7.490) invariant as numbers; therefore the discrete reconstructions (7.624)–(7.625) and the derived dispersions are basis/scheme invariant (see also Lemma 7.451).

(iii) Scale and $\mathcal{R}$ reparametrisations. A change of units $\ell \mapsto a\,\ell$ induces a rigid shift $v \mapsto v + \ln a$. Our spectral estimators are pointwise in ℓ (no v–differences are used at this stage), so the sequences $\{\widehat{m}_i^2(\ell_k)\}$ and $\{\widehat{Z}_i(\ell_k)\}$ are merely reindexed; any optional centered v–differences (when used elsewhere) are invariant under rigid shifts. As for $\mathcal{R}$ in Definition 7.468, positive rescalings of $\mathcal{R}$ do not change the admitted momentum band $\mathfrak{B}(\lambda_{\mathrm{UV}}, \ell)$ determined by the fixed instrumentation (P_x, K_{IR}) (cf. Definition 7.475); consequently the set of p^2 values used in Definition 7.516 is unaffected, and so are the estimators and dispersions.

Combining (i)–(iii) establishes the lemma. □

Definition 7.519 (Windowed reporting and spreads)**.** On the IR window $\mathcal{I}_{\mathrm{IR}}$ used in Definition 7.504, report:

1. **Windowed extrema and slopes:**

$$\max_{v_k \in \mathcal{I}_{\mathrm{IR}}} \Delta^{\mathrm{rel}}_{m,\rho}(v_k), \qquad \max_{v_k \in \mathcal{I}_{\mathrm{IR}}} \Delta^{\mathrm{rel}}_{Z,\rho}(v_k),$$

   and the centered log–slopes $\partial_v \widehat{\ln \Delta^{\mathrm{rel}}_{(\cdot),\rho}}$ on the same window (cf. Definitions 7.497 and 7.507).
2. **Instrumentation and gauge spreads:** Spreads under admissible instrumentation (P_x, K_{IR}) (cf. Definition 7.475) and across admissible gauges Ξ_{adm}, with Nielsen–projected, on–shell posture (cf. Definition 7.457). Gauge flatness is expected within the audit tolerance by Proposition 7.485 and eq. (7.588).
3. **Numerical settings:** The grid parameters $(h, \Delta p^2)$, any low–pass widths used in v (obeying eqs. (7.537) and (7.538)), and the interpolation/stencil order employed in the spectral estimators eqs. (7.624) and (7.625).

All items are conditioned on the volume–uniform state–visibility guard Definition 7.514.

Intuition. We only trust spectral reconvergence when the *state* stays uniformly visible in volume (QIII guard; Definition 7.514). Operationally, we solve and differentiate the band– and Nielsen–projected two–point problem on (v, p^2)–grids (Definition 7.516); centered stencils with light low–pass yield second–order–accurate, nearly unbiased pole/residue estimates (Lemmas 7.488 and 7.517), which then feed the multiplet dispersions used for plateau acceptance (Definition 7.504).

Acceptance criteria (spectral reconvergence).

Definition 7.520 (Step 6 acceptance: spectral reconvergence)**.** Work on the IR window $\mathcal{I}_{\mathrm{IR}}$ in $v = \ln \ell$ with ℓ_R as in Definitions 7.430 and 7.504. The dataset *passes* Step 6 if the following hold:

1. **Multiplet closure.** For every multiplet ρ, the spectral plateau conditions of Definition 7.504 hold at and beyond ℓ_R, i.e.

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\left(\frac{\delta m_\rho^2}{\overline{m_\rho^2}}\right)\le 0, \qquad \frac{\mathrm{d}}{\mathrm{d}\ln\ell}\left(\frac{\delta Z_\rho}{\overline{Z_\rho}}\right)\le 0 \quad \text{on } \mathcal{I}_{\mathrm{IR}},$$
$$\max\left\{\frac{\delta m_\rho^2(\ell_R)}{\overline{m_\rho^2}(\ell_R)}, \frac{\delta Z_\rho(\ell_R)}{\overline{Z_\rho}(\ell_R)}\right\}\le \varepsilon_{\mathrm{spec}}.$$

2. **Gauge safety.** For all quoted poles and residues, gauge–parameter slopes vanish within tolerance on $\mathcal{I}_{\mathrm{IR}}$ (Nielsen–projected, on shell):

$$\frac{\partial m_i^2(\ell;\xi)}{\partial\xi}=0, \qquad \frac{\partial Z_i(\ell;\xi)}{\partial\xi}=0,$$
up to $\varepsilon_{\mathrm{gauge}}$ for all $\forall\,\xi\in\mathcal{X}_{\mathrm{adm}}$ (cf. *Proposition 7.485and Corollary 7.477*).

3. **QIII guard.** State visibility is volume–uniform (no volume–law decay) on/beyond ℓ_R:

$$\sup_V\left|1-\Lambda_{\mathrm{state}}(\lambda_{\mathrm{UV}},\ell;T^\star,V)\right|\le\varepsilon_{\mathrm{plat}} \quad \text{for all } \ell\ge\ell_R$$
(cf. *Definition 7.514and eq.* (7.566)).

4. **pNG allowance.** Any pseudo–NG mode present satisfies the RG–consistent scaling law

$$m^2_{\mathrm{pNG}}(\ell)\ \propto\ \left|\widetilde{\varepsilon}_{\tilde B}(\mu)\right|^{\alpha}\ \sim\ \mu^{\alpha y_{\tilde B}} \quad (\mu=\kappa/\ell),$$
as in Proposition 7.509 and eq. (7.623), with the remaining multiplets still fulfilling (i).

Proposition 7.521 (Soundness of Step 6 acceptance)**.** *If Definition 7.520 holds and Steps 2–4 are satisfied (positive law–slope on the window, finite restoration length, and* $\mathrm{Re}\,y_{\tilde B}<0$ *for excited projected breakings; cf. eq.* (7.542)*, Definitions 7.430 and 7.478, Proposition 7.450, and Corollary 7.456), then multiplet reconvergence* (7.614) *obtains for all non–pNG multiplets, and any pNG mode exhibits the log–slope*

$$\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\ln m^2_{\mathrm{pNG}}(\ell)=\alpha\,y_{\tilde B}+o(1) \quad \text{as } \mu\downarrow 0.$$

Proof. All statements are made on the band– and Nielsen–projected posture for $\Gamma_2^{\mathcal{N}}$ on $W=\mathrm{im}\,\mathcal{N}$ (cf. Definitions 7.457 and 7.490); on shell, gauge safety holds by Proposition 7.485 and Corollary 7.477. Window regularity (curvature/TV guards and Step 3 mask) is assumed from Steps 2–3 (cf. eq. (7.548) and Proposition 7.462).

(A) Non–pNG multiplets reconverge. By item (i) of Definition 7.520 and Lemma 7.505, each relative dispersion $\Delta^{\mathrm{rel}}_{m,\rho}=\delta m_\rho^2/\overline{m_\rho^2}$ and $\Delta^{\mathrm{rel}}_{Z,\rho}=\delta Z_\rho/\overline{Z_\rho}$ is nonincreasing in v on $\mathcal{I}_{\mathrm{IR}}$ and small at $v_R=\ln\ell_R$. Step 4 irrelevance provides decay of the explicit breakings (cf. Proposition 7.450 and Corollary 7.456); combined with the linear–response bounds of Proposition 7.493 and the sufficient–conditions lemma Proposition 7.506, there exists $\ell_\star\ge\ell_R$ such that

$$\frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln\Delta^{\mathrm{rel}}_{m,\rho}(\ell)\le-\gamma_\star/2<0, \qquad \frac{\mathrm{d}}{\mathrm{d}\ln\ell}\ln\Delta^{\mathrm{rel}}_{Z,\rho}(\ell)\le-\gamma_\star/2<0 \quad \text{for all } \ell\ge\ell_\star,$$

where $\gamma_\star := \min_{\tilde{B}} |\operatorname{Re} y_{\tilde{B}}| > 0$. Integrating these differential inequalities and using smallness at ℓ_R yields

$$\Delta^{\mathrm{rel}}_{m,\rho}(\ell),\ \Delta^{\mathrm{rel}}_{Z,\rho}(\ell)\ \longrightarrow\ 0\quad(\ell\uparrow),$$

i.e. (7.614). By Corollary 7.503 (continuity of the ratios) and Lemma 7.501 (equivalence of dispersion metrics), this is equivalent to vanishing absolute intra–multiplet splittings relative to the means.

(B) QIII guard ⇒ uniform one–particle interpretation. Item (iii) invokes Definition 7.514. By Proposition 7.515, this ensures that the pole/residue extraction and the bounds above hold *uniformly in the volume* V; Kato continuity and simple–pole isolation (cf. Lemma 7.492 and [115, Chs. II–IV]) apply with V–independent constants. Hence the reconvergence conclusion is volume–uniform (QIII, not QII).

(C) pNG scaling. If a pNG channel is present, item (iv) requires the RG–consistent law of Proposition 7.509: $m^2_{\mathrm{pNG}}(\ell) = C_{\mathrm{pNG}}(\ell)\,|\widetilde{\varepsilon}_{\tilde{B}}(\mu)|^{\alpha}$ with slowly varying $C_{\mathrm{pNG}}(\ell)$. Differentiating $\ln m^2_{\mathrm{pNG}}$ with respect to $\ln\mu$ and using the Step 4 running of $\widetilde{\varepsilon}_{\tilde{B}}$ gives $\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\ln m^2_{\mathrm{pNG}} = \alpha\, y_{\tilde{B}} + o(1)$ as $\mu\downarrow 0$, as claimed.

Putting (A)–(C) together proves the proposition: non–pNG multiplets reconverge spectrally on the IR plateau with rates controlled by $\gamma_\star$ (Theorem 7.494), the one–particle interpretation is stable (QIII guard), and any pNG mode exhibits the predicted log–slope. Standard QFT pole/residue conventions underlie the on–shell analysis [91, 82]. □

Outputs for Step 6 (synthesised).

Definition 7.522 (Step 6 outputs)**.** All items below are produced on the IR window $\mathcal{I}_{\mathrm{IR}}$ in $v = \ln\ell$ (cf. eqs. (7.542) and (7.551) and Proposition 7.462), on shell and Nielsen–projected (Definition 7.457), with fixed instrumentation (P_x, K_{IR}) (Definition 7.475), and under the volume–uniform state–visibility guard (Definition 7.514). Report:

1. **Global RG/plateau diagnostics.** Plots of $v\mapsto \Lambda_{\mathrm{law}}(v)$ and $v\mapsto \varsigma^{(\tau)}_{\mathrm{law}}(v)$ together with shaded $\mathcal{I}_{\mathrm{IR}}$ and a marker at $v = \ln\ell_R$ (cf. Definition 7.478 and eqs. (7.542) and (7.551)).
2. **Multiplet reconvergence panels (per ρ).** Plots of

$$v\ \mapsto\ \Delta^{\mathrm{rel}}_{m,\rho}(v) := \frac{\delta m^2_\rho(v)}{\overline{m^2_\rho}(v)},\qquad v\ \mapsto\ \Delta^{\mathrm{rel}}_{Z,\rho}(v) := \frac{\delta Z_\rho(v)}{\overline{Z_\rho}(v)},$$

   with fitted (negative) centered log–slopes $\partial_v\widehat{\ln\Delta^{\mathrm{rel}}_{(\cdot),\rho}}$ (cf. Definitions 7.497, 7.499, 7.504 and 7.507). Mark $v = \ln\ell_R$.
3. **Pole/residue tables and gauge/band spreads.** Tables at/beyond ℓ_R of $\{m_i^2, Z_i\}$, grouped by multiplet ρ, together with: (i) spreads across admissible gauges $\mathcal{X}_{\mathrm{adm}}$ (Nielsen–projected) using the centered discrete gauge–slope checks from Definition 7.487, i.e. the estimators in (7.608) (consistent with the continuous zero–slope result Proposition 7.485); (ii) spreads across admissible band–limiting choices (P_x, K_{IR}) consistent with Definition 7.475.

4. **Numerical/audit settings.** The grid parameters $(h, \Delta p^2)$, any low–pass widths in v and in ξ obeying eqs. (7.537) and (7.538), and the interpolation/stencil order used for the spectral estimators (7.624)–(7.625) (cf. Definition 7.516 and Lemmas 7.488 and 7.517).
5. **(Optional pNG panel).** A plot of $\ln m^2_{\mathrm{pNG}}$ vs. $\ln \mu$ on the IR window in $\mu = \kappa/\ell$ (cf. Definition 7.461), with fitted slope $\widehat{s}_{\mathrm{pNG}}$ and comparison to the Step 4 prediction $\alpha\, y_{\tilde{B}}$ (Propositions 7.450 and 7.509 and Corollary 7.456); also report the inferred spurion power $\widehat{\alpha}_{\tilde{B}} = \widehat{s}_{\mathrm{pNG}}/\widehat{y}_{\tilde{B}}$ (cf. Definition 7.511).
6. **Rate interpretation.** A short cross–reference explaining observed decay rates via Step 4 irrelevance (slowest $\gamma_\star$) and smooth spectral tracking, citing Theorem 7.494, Proposition 7.506, and Lemma 7.492 and the Ward–diagnostics posture Definition 7.468; standard spectral/QFT references [91, 82, 115].

Interpretation. As explicit breakings run to zero, symmetry–forbidden intra–multiplet splittings collapse. Kato continuity on the band– and Nielsen–projected kernel guarantees smooth pole/residue tracking (Lemma 7.492; [115]); Step 4 irrelevance quantifies decay rates (Proposition 7.450 and Corollary 7.456), yielding spectral reconvergence on the IR plateau (Theorem 7.494). Gauge safety follows from the on–shell Nielsen posture (Proposition 7.485 and Corollary 7.477); the QIII state–visibility guard ensures a stable one–particle interpretation *uniformly in volume* (Definition 7.514 and Proposition 7.515). For pNG channels, the spurion/Wigner–Eckart selection rule and RG running give $m^2_{\mathrm{pNG}} \propto |\widetilde{\varepsilon}_{\tilde{B}}|^{\alpha} \sim \mu^{\alpha y_{\tilde{B}}}$ (Definition 7.508 and Proposition 7.509; [91, 82]).

7.8.7 Plateau Certification (Q III Mask)

Objective. We construct a *mask* $\mathfrak{M}_{\mathrm{mask}} \subset \mathbb{R}^2$ in the plane

$$u := \ln \lambda_{\mathrm{UV}}, \qquad v := \ln \ell,$$

that localises the IR plateau where (i) the law heals with positive robust slope and small curvature, (ii) the state remains coherent uniformly in the volume, and (iii) the identity ledger closes (small Ward residuals and gauge–flat on–shell data). The mask gates all downstream IR statements (Steps 7.8.4–7.8.6) and underlies integrated readouts.

Definition (pointwise mask). With the robust slope/curvature guards from eqs. (7.539), (7.542) and (7.548), the state–coherence guard from eq. (7.566), and the Ward/Nielsen conditions from eqs. (7.591), (7.602) and (7.607), define

$$\begin{aligned}\mathfrak{M}_{\mathrm{mask}} := \Big\{ (u,v) : \varsigma^{(\tau)}_{\mathrm{law}}(u,v) \;\geq\; \varsigma_{\min}, \quad & \big|\partial_v^2 (\mathsf{LP}_\tau\, \Lambda_{\mathrm{law}})(u,v)\big| \;\leq\; \varepsilon_{\mathrm{curv}}, \\ & \sup_V \big|1 - \Lambda_{\mathrm{state}}(u,v;V)\big| \;\leq\; \varepsilon_{\mathrm{plat}}, \\ & \mathcal{W}(u,v) \;\leq\; \varepsilon_{\mathrm{plat}}, \\ & \partial_\xi m^2_\alpha(u,v;\xi) = 0, \quad \partial_\xi Z_\alpha(u,v;\xi) = 0 \;\; \forall\, \xi \in \mathcal{X}_{\mathrm{adm}} \Big\}.\end{aligned} \tag{7.626}$$

Reading guide. The first two lines enforce a monotone, gently curved law-healing profile (via the low-pass robust slope $\varsigma_{\mathrm{law}}^{(\tau)}$ and curvature bound). The third line is the uniform state-coherence guard in volume. The fourth controls the band-projected Ward residual $\mathcal{W}$, and the last line imposes Nielsen flatness of quoted on–shell poles and residues across the admissible gauges $\mathcal{X}_{\mathrm{adm}}$ (cf. eq. (7.607)) [117, 243, 442].

Lemma 7.523 (Closedness, tolerance monotonicity, and scale reparametrisation)**.** *Assume the ingredients entering eq. (7.626) are jointly continuous in (u, v) and in any auxiliary indices, and that the probed sets are compact: the admissible gauges $\mathcal{X}_{\mathrm{adm}}$, the IR momentum band used in $\mathcal{W}$ (cf. eq. (7.591)), and the volume set over which the state guard is tested. Then:*

1. *$\mathfrak{M}_{\mathrm{mask}}$ is a closed subset of $\mathbb{R}^2$.*
2. (Tolerance monotonicity) *Relaxing any threshold $\varsigma_{\mathrm{min}}\downarrow$, $\varepsilon_{\mathrm{curv}}\uparrow$, $\varepsilon_{\mathrm{plat}}\uparrow$ can only enlarge $\mathfrak{M}_{\mathrm{mask}}$ (set inclusion is monotone).*
3. (Scale reparametrisation) *For any $\Delta \in \mathbb{R}$, the coordinate change $v \mapsto v + \Delta$ (i.e. $\ell \mapsto e^{\Delta}\ell$) rigidly translates the mask in the v–direction without altering its shape:*

$$T_{\Delta}(\mathfrak{M}_{\mathrm{mask}}) = \{(u, v + \Delta) : (u, v) \in \mathfrak{M}_{\mathrm{mask}}\}.$$

Proof. Recall the pointwise definition eq. (7.626):

$$\mathfrak{M}_{\mathrm{mask}} = \{(u, v) : \text{C1–C5 hold at } (u, v)\},$$

with guards

$$\begin{aligned}
&\text{C1:} && \varsigma_{\mathrm{law}}^{(\tau)}(u, v) \geq \varsigma_{\mathrm{min}}, && \\
&\text{C2:} && \left|\partial_v^2(\mathsf{LP}_{\tau}\Lambda_{\mathrm{law}})(u, v)\right| \leq \varepsilon_{\mathrm{curv}}, && \\
&\text{C3:} && \sup_{V}\left|1 - \Lambda_{\mathrm{state}}(u, v; V)\right| \leq \varepsilon_{\mathrm{plat}} && \text{(cf. eq. (7.566)),} \\
&\text{C4:} && \mathcal{W}(u, v) \leq \varepsilon_{\mathrm{plat}} && \text{(cf. eqs. (7.591) and (7.602)),} \\
&\text{C5:} && \sup_{\xi \in \mathcal{X}_{\mathrm{adm}}}\left|\partial_{\xi} m_{\alpha}^2(u, v; \xi)\right| = 0, && \\
& && \sup_{\xi \in \mathcal{X}_{\mathrm{adm}}}\left|\partial_{\xi} Z_{\alpha}(u, v; \xi)\right| = 0 && \text{(cf. eq. (7.607)).}
\end{aligned}$$

(1) Closedness. Define the real-valued functions

$$\begin{aligned}
f_1(u, v) &:= \varsigma_{\mathrm{law}}^{(\tau)}(u, v) - \varsigma_{\mathrm{min}}, \\
f_2(u, v) &:= \varepsilon_{\mathrm{curv}} - \left|\partial_v^2(\mathsf{LP}_{\tau}\Lambda_{\mathrm{law}})(u, v)\right|, \\
f_3(u, v) &:= \varepsilon_{\mathrm{plat}} - \sup_{V}\left|1 - \Lambda_{\mathrm{state}}(u, v; V)\right|, \\
f_4(u, v) &:= \varepsilon_{\mathrm{plat}} - \mathcal{W}(u, v), \\
f_5^{(m)}(u, v) &:= -\sup_{\xi \in \mathcal{X}_{\mathrm{adm}}}\left|\partial_{\xi} m_{\alpha}^2(u, v; \xi)\right|, \qquad f_5^{(Z)}(u, v) := -\sup_{\xi \in \mathcal{X}_{\mathrm{adm}}}\left|\partial_{\xi} Z_{\alpha}(u, v; \xi)\right|.
\end{aligned}$$

By hypothesis, the basic maps are continuous in (u, v) and jointly continuous in $(u, v; V)$ and $(u, v; \xi)$. Since the probed sets (volumes, momentum band, and $\mathcal{X}_{\mathrm{adm}}$) are compact,

the supremum of a continuous function over a compact index set is continuous in the base variables (standard maximum theorem). Hence each f_i is continuous. The mask is the finite intersection

$$\mathfrak{M}_{\mathrm{mask}} = \bigcap_{i=1}^{4} \{(u,v) : f_i(u,v) \geq 0\} \;\cap\; \{(u,v) : f_5^{(m)}(u,v) \geq 0\} \;\cap\; \{(u,v) : f_5^{(Z)}(u,v) \geq 0\},$$

an intersection of inverse images of the closed set $[0,\infty)$ under continuous maps, hence closed. *(2) Tolerance monotonicity.* Let $(\varsigma_{\min}, \varepsilon_{\mathrm{curv}}, \varepsilon_{\mathrm{plat}})$ and $(\varsigma'_{\min}, \varepsilon'_{\mathrm{curv}}, \varepsilon'_{\mathrm{plat}})$ be two tolerance sets with $\varsigma'_{\min} \leq \varsigma_{\min}$, $\varepsilon'_{\mathrm{curv}} \geq \varepsilon_{\mathrm{curv}}$, $\varepsilon'_{\mathrm{plat}} \geq \varepsilon_{\mathrm{plat}}$. Each guard is an inequality of the form "observable $\geq$ lower bound" or "observable $\leq$ upper bound." Weakening the lower bound or enlarging the upper bound can only convert failures into passes, never the reverse. Therefore $\mathfrak{M}_{\mathrm{mask}}(\varsigma_{\min}, \varepsilon_{\mathrm{curv}}, \varepsilon_{\mathrm{plat}}) \subseteq \mathfrak{M}_{\mathrm{mask}}(\varsigma'_{\min}, \varepsilon'_{\mathrm{curv}}, \varepsilon'_{\mathrm{plat}})$.
(3) Scale reparametrisation (rigid v–translation). Let $T_\Delta(u,v) := (u, v+\Delta)$. All guards in eq. (7.626) are built from (u,v) through the band parameter $\ell = e^v$ and through v–stationary operations in the v–coordinate: (i) the low-pass LP_τ used in the robust slope/curvature guards is translation-equivariant in v by construction (it is a stationary filter), hence

$$\mathsf{LP}_\tau[\Lambda_{\mathrm{law}}(\cdot + \Delta)](v) = (\mathsf{LP}_\tau \Lambda_{\mathrm{law}})(v+\Delta), \qquad \partial_v^k \text{ commutes with } T_\Delta;$$

(ii) the state guard uses $\sup_V |1 - \Lambda_{\mathrm{state}}(u,v;V)|$, which under $v \mapsto v+\Delta$ becomes composition by T_Δ in the base variables and leaves the inequality form unchanged (the probed V set is unaffected); (iii) the Ward residual $\mathcal{W}$ is computed on the IR band determined by $\ell = e^v$ (cf. eq. (7.591)); expressing it as a function of v therefore yields a graph that simply shifts under $v \mapsto v+\Delta$; (iv) the Nielsen flatness conditions $\sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} |\partial_\xi m_\alpha^2| = 0$ and similarly for Z_α are invariant under composing their (u,v)–dependence with T_Δ, since differentiation is in ξ and $\mathcal{X}_{\mathrm{adm}}$ is unchanged. Consequently, for every (u,v) the guards hold at (u,v) iff they hold at $(u, v+\Delta)$ after the reparametrisation, which is precisely $T_\Delta(\mathfrak{M}_{\mathrm{mask}}) = \{(u, v+\Delta) : (u,v) \in \mathfrak{M}_{\mathrm{mask}}\}$. □

Intuition. The mask is defined by finitely many "$\leq/\geq$" tests of continuous diagnostics; that makes it closed and ensures that easing any tolerance only grows the pass set. Because all diagnostics depend on the IR scale through $v = \ln \ell$ and use a stationary low-pass in v, changing the v zero (i.e. units of ℓ) just slides the certified region up or down the v-axis.

Proposition 7.524 (Upward closure in v and frontier)**.** *Assume the Step 3 guards (robust positive slope and curvature bound; cf. eqs. (7.539), (7.542) and (7.548)) and the Step 5 Ward decay/plateau (eqs. (7.591) and (7.602)) hold as formulated in eq. (7.626), and use the state–coherence guard of eq. (7.566). For each fixed $u \in \mathbb{R}$ the vertical section*

$$\mathfrak{M}_{\mathrm{mask}}(u) := \{\, v \in \mathbb{R} : \; (u,v) \in \mathfrak{M}_{\mathrm{mask}} \,\}$$

is an upper set*: if $v \in \mathfrak{M}_{\mathrm{mask}}(u)$ and $v' \geq v$, then $v' \in \mathfrak{M}_{\mathrm{mask}}(u)$. Define the frontier*

$$v_\star(u) := \inf \mathfrak{M}_{\mathrm{mask}}(u) \;\in [-\infty, \infty].$$

Then $\mathfrak{M}_{\mathrm{mask}} = \{(u,v) : v \geq v_\star(u)\}$, and $v_\star$ is lower semicontinuous in u.

Proof. Write the five pointwise guards in eq. (7.626) at (u, v) as:

$$\text{C1: } \varsigma^{(\tau)}_{\text{law}}(u,v) \geq \varsigma_{\min}, \qquad \text{C2: } \left|\partial_v^2(\mathsf{LP}_\tau \Lambda_{\text{law}})(u,v)\right| \leq \varepsilon_{\text{curv}},$$

$$\text{C3: } \sup_V \left|1 - \Lambda_{\text{state}}(u,v;V)\right| \leq \varepsilon_{\text{plat}}, \qquad \text{C4: } \mathcal{W}(u,v) \leq \varepsilon_{\text{plat}},$$

$$\text{C5: } \sup_{\xi \in \mathcal{X}_{\text{adm}}} \left|\partial_\xi m_\alpha^2(u,v;\xi)\right| = 0, \quad \sup_{\xi \in \mathcal{X}_{\text{adm}}} \left|\partial_\xi Z_\alpha(u,v;\xi)\right| = 0.$$

Upward closure. Fix u and suppose $(u, v) \in \mathfrak{M}_{\text{mask}}$. We show each guard persists for any $v' \geq v$:

• **C1 (robust slope).** By the Step 3 acceptance (eqs. (7.542) and (7.548)), the v–profile of the low–pass trend $\mathsf{LP}_\tau \Lambda_{\text{law}}$ is monotone increasing along the IR ray and its robust derivative $\varsigma^{(\tau)}_{\text{law}}$ stays above $\varsigma_{\min}$ across the IR window. Hence if $\varsigma^{(\tau)}_{\text{law}}(u,v) \geq \varsigma_{\min}$, then also $\varsigma^{(\tau)}_{\text{law}}(u,v') \geq \varsigma_{\min}$ for all $v' \geq v$.

• **C2 (curvature bound).** The Step 3 curvature guard is imposed *uniformly* on the same IR v–band used for C1 (via the same stationary low–pass LP_τ). Thus once $|\partial_v^2(\mathsf{LP}_\tau \Lambda_{\text{law}})| \leq \varepsilon_{\text{curv}}$ at (u, v), it remains within the bound for all $v' \geq v$ in that band.

• **C3 (state coherence).** The guard in eq. (7.566) is framed as an IR–anchored acceptance: beyond the restoration scale $v \geq \ln \ell_R$ it holds uniformly in V (by definition of the plateau certification window in Step 7). Hence, if $(u, v) \in \mathfrak{M}_{\text{mask}}$, then for every $v' \geq \max\{v, \ln \ell_R\}$ the inequality also holds. In particular, for $v' \geq v$ the guard persists (either we stay below $\ln \ell_R$ and the local acceptance is unchanged, or we enter the anchored region where it is uniform).

• **C4 (Ward residual).** Step 5 enforces IR decay of the band–projected Ward residual (eq. (7.602)), so $\mathcal{W}(u, v') \leq \mathcal{W}(u, v) \leq \varepsilon_{\text{plat}}$ for all $v' \geq v$.

• **C5 (Nielsen flatness).** The on–shell gauge slopes vanish throughout the admissible gauges on the IR window (cf. eq. (7.607)); composing with $v' \geq v$ does not affect differentiation in ξ, so the equalities persist.

All guards thus remain satisfied at (u, v') for any $v' \geq v$, proving that $\mathfrak{M}_{\text{mask}}(u)$ is an upper set.

Frontier and epigraph form. For each u, define $v_\star(u) := \inf \mathfrak{M}_{\text{mask}}(u)$ (with the usual convention $\inf \varnothing = +\infty$). Because $\mathfrak{M}_{\text{mask}}(u)$ is an upper set, one has

$$\mathfrak{M}_{\text{mask}}(u) = \{\, v \in \mathbb{R} : \; v \geq v_\star(u) \,\}.$$

Equivalently, $\mathfrak{M}_{\text{mask}} = \operatorname{epi} v_\star := \{(u, v) : v \geq v_\star(u)\}$.

Lower semicontinuity of $v_\star$. By Lemma 7.523, $\mathfrak{M}_{\text{mask}}$ is closed. The epigraph of a function is closed iff the function is lower semicontinuous (standard epigraph characterization; e.g., Rockafellar, *Convex Analysis*, Thm. 7.1). Hence $v_\star$ is lower semicontinuous. □

Reading guide. Each guard either improves or is fixed across the IR direction: the law's trend keeps healing (positive robust slope; bounded curvature), the Ward identity residual decays, and the state guard is uniform past $v = \ln \ell_R$. That converts every vertical slice of the mask into an "upper set," so the mask is exactly the epigraph of its frontier $v_\star(u)$; closedness of the mask forces $v_\star$ to be lower semicontinuous.

Corollary 7.525 (Relation to restoration lengths)**.** *Let $\ell_R(u)$ and $\ell_R^{[\mathcal{U}]}$ be the pointwise and UV–uniform restoration lengths from Definitions 7.428 and 7.430, and write $v_R(u) := \ln \ell_R(u)$ and $v_R^{[\mathcal{U}]} := \ln \ell_R^{[\mathcal{U}]}$. If the Step 5 acceptance holds at these scales—namely $\mathcal{W}$ satisfies the decay/plateau conditions of eqs. (7.591) and (7.602) at $v_R(u)$ (and uniformly at $v_R^{[\mathcal{U}]}$)—and the Step 3 robust-slope/curvature guards eqs. (7.539), (7.542) and (7.548) together with the state–coherence guard eq. (7.566) are enforced on the IR window anchored there, then*

$$v_\star(u) \;\le\; v_R(u), \qquad \sup_{u\in\mathcal{U}} v_\star(u) \;\le\; v_R^{[\mathcal{U}]}.$$

Proof. By eq. (7.626), a point (u, v) lies in the mask $\mathfrak{M}_{\mathrm{mask}}$ iff the five guards C1–C5 hold: robust slope (C1), bounded curvature (C2), state coherence (C3), small Ward residual (C4), and Nielsen flatness of on–shell data (C5). At $v = v_R(u)$, Step 5 acceptance gives C4 (decay and $\mathcal{W} \le \varepsilon_{\mathrm{plat}}$, cf. eq. (7.602)). By hypothesis, the Step 3 guards eqs. (7.542) and (7.548) provide C1 and C2 on the same IR window (the LP_τ-based trend and curvature bounds), while eq. (7.566) supplies C3 (uniform in V). Finally, the gauge-flatness requirement C5 is imposed via eq. (7.607) on that IR window. Hence all guards are satisfied at $(u, v_R(u))$, so $(u, v_R(u)) \in \mathfrak{M}_{\mathrm{mask}}$. By upward closure in v (Proposition 7.524), the vertical section is an upper set; therefore $v_\star(u) \le v_R(u)$.

For the uniform statement, by the definition of $\ell_R^{[\mathcal{U}]}$ (Definition 7.430), the same acceptance holds at $v_R^{[\mathcal{U}]}$ *for all* $u \in \mathcal{U}$, hence $(u, v_R^{[\mathcal{U}]}) \in \mathfrak{M}_{\mathrm{mask}}$ for every $u \in \mathcal{U}$. Thus $v_\star(u) \le v_R^{[\mathcal{U}]}$ for all $u \in \mathcal{U}$, and taking the supremum in u yields $\sup_{u\in\mathcal{U}} v_\star(u) \le v_R^{[\mathcal{U}]}$. □

Reading guide. The restoration length anchors the IR window where the identity ledger closes (small $\mathcal{W}$) and where the law's low–pass trend is monotone with controlled curvature while the state remains coherent. Since the mask's vertical slices are upper sets, the frontier $v_\star(u)$ cannot sit *above* the anchor: once the guards hold at v_R, they hold for all larger v, forcing $v_\star(u) \le v_R(u)$ (and uniformly on $\mathcal{U}$).

Definition 7.526 (UV–strip mask and certified half–space)**.** Let $\mathcal{U} = [u_{\min}, u_{\max}]$ be an admissible UV strip. Define the *restricted mask*

$$\mathfrak{M}_{\mathrm{mask}}^{[\mathcal{U}]} := \{(u, v) \in \mathfrak{M}_{\mathrm{mask}} :\; u \in \mathcal{U}\},$$

where $\mathfrak{M}_{\mathrm{mask}}$ is given pointwise by the guards in eq. (7.626). The associated *certified IR half–space* is

$$\mathcal{H}_{\mathrm{IR}}^{[\mathcal{U}]} := \Big\{(u, v) :\; u \in \mathcal{U},\; v \ge v_\star^{[\mathcal{U}]}\Big\}, \qquad v_\star^{[\mathcal{U}]} := \sup_{u\in\mathcal{U}} v_\star(u),$$

with $v_\star$ the vertical frontier of Proposition 7.524. By Proposition 7.524, $\mathcal{H}_{\mathrm{IR}}^{[\mathcal{U}]} \subseteq \mathfrak{M}_{\mathrm{mask}}^{[\mathcal{U}]}$, and by Corollary 7.525, $v_\star^{[\mathcal{U}]} \le \ln \ell_R^{[\mathcal{U}]}$ with $\ell_R^{[\mathcal{U}]}$ from Definition 7.430.

Reading guide (outside the definition). The restricted mask trims $\mathfrak{M}_{\mathrm{mask}}$ to a UV band $\mathcal{U}$. The number $v_\star^{[\mathcal{U}]}$ is the worst (largest) frontier across $u \in \mathcal{U}$; the resulting epigraph $\mathcal{H}_{\mathrm{IR}}^{[\mathcal{U}]}$ is guaranteed to lie inside the restricted mask by upward closure in v (Proposition 7.524) and is anchored by the uniform restoration scale (Corollary 7.525).

Lemma 7.527 (Basis/gauge/scheme safety of the mask)**.** *Evaluate all diagnostics in eq.* (7.626) *on shell and on the BRST physical sector using the projector* $\mathsf{P}_{\mathrm{phys}}$ *(so poles/residues are read from* $\mathbb{H}_{\mathrm{phys}} = \mathsf{P}_{\mathrm{phys}}\,\mathbb{H}\,\mathsf{P}_{\mathrm{phys}}$*). Then:*

1. (Gauge safety) $\mathfrak{M}_{\mathrm{mask}}$ *is invariant—up to the audit tolerance* $\varepsilon_{\mathrm{gauge}}$*—under admissible gauge–parameter changes* $\xi \in \mathcal{X}_{\mathrm{adm}}$ *(cf. eq.* (7.607)*, Proposition 7.458 and Corollary 7.459).*
2. (Basis/scheme safety) $\mathfrak{M}_{\mathrm{mask}}$ *is invariant under admissible field–basis changes and renormalisation–scheme reparameterisations (cf. Lemma 7.451).*
3. (Scale choice for μ) *The choice* $\mu = \kappa/\ell$ *changes* $v = \ln \ell$ *by a rigid shift* $v \mapsto v + \ln \kappa$*; hence* $\mathfrak{M}_{\mathrm{mask}}$ *is independent of* κ *modulo the translation guaranteed by Lemma 7.523*(3)*.*

Proof. (1) Gauge safety. On shell and on $\mathcal{H}_{\mathrm{phys}}$ the Nielsen identities imply vanishing gauge slopes for quoted on–shell data:

$$\sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} \left|\partial_\xi m_\alpha^2\right| = 0, \qquad \sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} \left|\partial_\xi Z_\alpha\right| = 0,$$

as encoded in eq. (7.607) (see also [117, 243, 442]). Moreover, the law/state visibilities and the Ward residual are computed from BRST–invariant correlators (after $\mathsf{P}_{\mathrm{phys}}$ projection) and, by Proposition 7.458 and Corollary 7.459, are invariant under admissible gauge variations up to the declared tolerance $\varepsilon_{\mathrm{gauge}}$. Since each guard in eq. (7.626) depends either on spectral on–shell data or on such invariant correlators, the pass/fail outcome of all five guards is unchanged (within $\varepsilon_{\mathrm{gauge}}$). Hence membership in $\mathfrak{M}_{\mathrm{mask}}$ is gauge–safe.

(2) Basis/scheme safety. Admissible basis redefinitions act by (blockwise) similarity on the quadratic operator, leaving the spectrum of $\mathbb{H}_{\mathrm{phys}}$ isospectral and transporting residues covariantly; admissible scheme changes correspond to smooth reparameterisations of renormalised quantities. By Lemma 7.451 and Proposition 7.458, the objects entering eq. (7.626) (robust trend/curvature of $\mathsf{LP}_\tau \Lambda_{\mathrm{law}}$, the state visibility bound, $\mathcal{W}$, and on–shell poles/residues) are invariant under these transformations, so the mask is unchanged.

(3) Scale choice for μ*.* Setting $\mu = \kappa/\ell$ with $\kappa > 0$ shifts the v–coordinate by a constant $\Delta = \ln \kappa$. By Lemma 7.523 (3), the mask is equivariant under rigid shifts $v \mapsto v + \Delta$, so κ only translates $\mathfrak{M}_{\mathrm{mask}}$ in v without changing its shape or any epigraphic statements (e.g., $v_\star$, $\mathcal{H}_{\mathrm{IR}}^{[\mathcal{U}]}$). □

Reading guide (outside the lemma). The mask depends only on BRST–physical, on–shell, and Nielsen–stable quantities: that makes it robust to gauge choices; similarity/renormalisation moves don't change spectra or the low–pass law trend; and changing the μ–convention merely shifts the v origin, which Lemma 7.523 shows cannot affect certification.

Discrete mask (audit path).

Definition 7.528 (Grid–level mask and morphological clean–up)**.** On grids $\{u_m\}_{m=1}^{M}$, $\{v_k\}_{k=1}^{K}$ (with $v_k = \ln \ell_k$), define the boolean indicator

$$\widehat{\chi}_{mk} := \mathbf{1}\begin{bmatrix} \widehat{\varsigma}_{\mathrm{law}}^{(\tau)}(u_m, v_k) \geq \varsigma_{\min}, \\ \left|\widehat{\partial_v^2}(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})\right| \leq \varepsilon_{\mathrm{curv}}, \\ \sup_V |1 - \widehat{\Lambda}_{\mathrm{state}}| \leq \varepsilon_{\mathrm{plat}}, \\ \widehat{\mathcal{W}} \leq \varepsilon_{\mathrm{plat}}, \\ \left|\widehat{\partial_\xi m_\alpha^2}\right|, \left|\widehat{\partial_\xi Z_\alpha}\right| \leq \varepsilon_{\mathrm{gauge}} \end{bmatrix},$$

where hats denote the discrete estimators from eqs. (7.547) and (7.608) and Definition 7.516. Apply an optional 3×3 majority filter in (m, k) (topology–preserving "opening/closing") to suppress one–pixel holes/spikes consistent with the curvature/TV guards. Set $\widehat{\mathfrak{P}}_{\mathrm{QIII}} := \{(u_m, v_k) : \widehat{\chi}_{mk} = 1\}$.

Proposition 7.529 (Consistency of the discrete mask)**.** *Under the regularity assumptions of Steps 7.8.2–7.8.6 and using second–order centered estimators in v and in ξ, there exist grid spacings $(\Delta u, \Delta v, \Delta\xi)$ small enough such that, for every compact rectangle $K \subset \mathbb{R}^2$,*

$$d_{\mathrm{H}}\Big(\widehat{\mathfrak{M}}_{\mathrm{mask}} \cap K \ , \quad \mathfrak{M}_{\mathrm{mask}} \cap K \Big) \xrightarrow[\Delta u, \Delta v, \Delta\xi \to 0]{} 0,$$

i.e. the discrete mask converges to the pointwise mask in the Hausdorff metric locally on $\mathbb{R}^2$.

Proof. Recall the pointwise mask $\mathfrak{M}_{\mathrm{mask}}$ from eq. (7.626) is the finite intersection of five closed guard sets (robust slope, curvature, state coherence, Ward residual, and Nielsen flatness). By Lemma 7.523(1), $\mathfrak{M}_{\mathrm{mask}}$ is closed.

Step 1: Uniform, second–order control of the guard functionals. For each guard introduce a continuous "margin" functional $f_r(u, v)$ so that the guard is $f_r(u, v) \geq 0$:

$$\begin{aligned} f_1 &:= \varsigma_{\mathrm{law}}^{(\tau)} - \varsigma_{\min}, \qquad f_2 := \varepsilon_{\mathrm{curv}} - \left|\partial_v^2(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})\right|, \\ f_3 &:= \varepsilon_{\mathrm{plat}} - \sup_V |1 - \Lambda_{\mathrm{state}}(u, v; V)|, \qquad f_4 := \varepsilon_{\mathrm{plat}} - \mathcal{W}(u, v), \\ f_{5m} &:= -\sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} \left|\partial_\xi m_\alpha^2\right|, \quad f_{5Z} := -\sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} \left|\partial_\xi Z_\alpha\right|. \end{aligned}$$

Steps 7.8.2–7.8.6 provide (i) a stationary low-pass LP_τ with second–order accuracy in v for trends/curvatures (preserving constants/linears up to $\mathcal{O}(\tau^2)$), (ii) centered finite-difference estimators for v-derivatives with $\mathcal{O}((\Delta v)^2)$ bias, and (iii) compactly probed suprema in V and $\mathcal{X}_{\mathrm{adm}}$ (nets with mesh $\Delta V, \Delta\xi$). Hence there exists $\varepsilon(\Delta u, \Delta v, \Delta\xi) \to 0$ such that on any compact K,

$$\sup_{(u,v)\in K} \max_r \left| f_r(u, v) - f_r^{\Delta}(u, v) \right| \ \leq \ \varepsilon(\Delta u, \Delta v, \Delta\xi),$$

where f_r^{Δ} denotes the corresponding discrete/estimated margin (centered in v and ξ, with the low-pass applied on the grid). This uses continuity of the underlying maps and the maximum theorem for suprema over compact index sets in V and $\mathcal{X}_{\mathrm{adm}}$.

Step 2: Set inclusions via margin thickening. For $\eta > 0$, define the inner/outer thickenings

$$\mathfrak{M}_{\mathrm{mask}}^{(-\eta)} := \bigcap_r \{f_r \geq \eta\}, \qquad \mathfrak{M}_{\mathrm{mask}}^{(+\eta)} := \bigcap_r \{f_r \geq -\eta\}.$$

If $\varepsilon(\Delta u, \Delta v, \Delta\xi) \leq \eta$, then for every (u, v):

$$\big(f_r \geq \eta\big) \implies \big(f_r^{\Delta} \geq 0\big), \qquad \big(f_r^{\Delta} \geq 0\big) \implies \big(f_r \geq -\eta\big).$$

Intersecting over all guards yields the set sandwich on K:

$$\mathfrak{M}_{\mathrm{mask}}^{(-\eta)} \cap K \;\subseteq\; \widehat{\mathfrak{M}}_{\mathrm{mask}} \cap K \;\subseteq\; \mathfrak{M}_{\mathrm{mask}}^{(+\eta)} \cap K.$$

Step 3: From sandwiches to Hausdorff convergence. Because each $\{f_r \geq c\}$ is closed and the f_r are continuous, $\mathfrak{M}_{\mathrm{mask}}^{(-\eta)} \downarrow \mathfrak{M}_{\mathrm{mask}}$ and $\mathfrak{M}_{\mathrm{mask}}^{(+\eta)} \uparrow \mathfrak{M}_{\mathrm{mask}}$ as $\eta \downarrow 0$, with convergence in the Painlevé–Kuratowski sense. On a compact K, this implies convergence in the Hausdorff metric:

$$d_{\mathrm{H}}\Big(\mathfrak{M}_{\mathrm{mask}}^{(-\eta)} \cap K,\ \mathfrak{M}_{\mathrm{mask}} \cap K\Big) \to 0, \quad d_{\mathrm{H}}\Big(\mathfrak{M}_{\mathrm{mask}}^{(+\eta)} \cap K,\ \mathfrak{M}_{\mathrm{mask}} \cap K\Big) \to 0.$$

Combining with the sandwich gives

$$\begin{aligned} 0 &\leq d_{\mathrm{H}}\Big(\widehat{\mathfrak{M}}_{\mathrm{mask}} \cap K,\ \mathfrak{M}_{\mathrm{mask}} \cap K\Big) \\ &\leq \max\left\{ \begin{aligned} &d_{\mathrm{H}}\Big(\mathfrak{M}_{\mathrm{mask}}^{(+\eta)} \cap K,\ \mathfrak{M}_{\mathrm{mask}} \cap K\Big), \\ &d_{\mathrm{H}}\Big(\mathfrak{M}_{\mathrm{mask}}^{(-\eta)} \cap K,\ \mathfrak{M}_{\mathrm{mask}} \cap K\Big) \end{aligned} \right\} \\ &\xrightarrow[\eta \downarrow 0]{} 0. \end{aligned}$$

Step 4: Grid union vs. point samples (pixel geometry). If $\widehat{\mathfrak{M}}_{\mathrm{mask}}$ is implemented as occupied grid *cells* (union of rectangles of size $\Delta u \times \Delta v$) rather than just marked nodes, the Hausdorff error gains an additional additive $O(\max\{\Delta u, \Delta v\})$ that vanishes as the grid refines. Optional binary morphological closing with structuring element of radius $o(\max\{\Delta u, \Delta v\})$ leaves the limit unchanged and only improves the finite-mesh bound.

Altogether, choosing $(\Delta u, \Delta v, \Delta\xi)$ so that $\varepsilon(\Delta u, \Delta v, \Delta\xi) \leq \eta$ and then letting $\eta \to 0$ proves the claim. □

Reading guide. Package each guard in eq. (7.626) as a continuous margin $f_r \geq 0$. The Step-2–6 estimators approximate f_r with sup-norm error $\to 0$ on any fixed window, so the discrete pass set sits between inner/outer thickenings of the true mask. Those thickenings collapse to the mask as the margins go to zero, which turns into Hausdorff convergence of the discrete mask to $\mathfrak{M}_{\mathrm{mask}}$ on the window.

Plateau mask outputs.

Definition 7.530 (Reporting artefacts for the mask)**.** All reports are *restricted* to the certified region defined by the mask $\mathfrak{M}_{\mathrm{mask}}$ of eq. (7.626) and its discrete estimator $\widehat{\mathfrak{M}}_{\mathrm{mask}}$.

(i) Trend heatmap with certified overlays.
A heatmap of the robust law slope $\varsigma^{(\tau)}_{\mathrm{law}}(u,v)$ (from eqs. (7.539), (7.542) and (7.548)), overlaid with the discrete mask $\widehat{\mathfrak{M}}_{\mathrm{mask}}$. Superimpose: (a) the frontier $v_\star(u)$ (see Proposition 7.524), (b) the certified half–space line $v = v_\star^{[\mathcal{U}]}$ for a chosen UV strip $\mathcal{U}$ (Definition 7.526), (c) the IR window $\mathcal{I}_{\mathrm{IR}}$ shading and markers at $v = \ln \ell_R(u)$ and $v = \ln \ell_R^{[\mathcal{U}]}$ (Definitions 7.428 and 7.430 and Corollary 7.525).

(ii) Windowed tables (mask-restricted diagnostics).
Tables of windowed summaries computed *on* $\widehat{\mathfrak{M}}_{\mathrm{mask}}$:

- **(a)** Median and quantiles of the Ward residual $\mathcal{W}$ (eqs. (7.591) and (7.602)).
- **(b)** Median and quantiles of on–shell gauge slopes $\partial_\xi m_\alpha^2$, $\partial_\xi Z_\alpha$ (Nielsen flatness; eq. (7.607)); report spreads across $\xi \in \mathcal{X}_{\mathrm{adm}}$.
- **(c)** Curvature proxy summaries $\left|\partial_v^2(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})\right|$ (bounded as in eq. (7.542)).
- **(d)** Robustness spreads across admissible band knobs ($P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$) and gauges (Nielsen–projected), as required by Lemma 7.527.

Include the marginal coverage statistics $\Phi_{v/u}$ and deficits (δ_u, δ_v) for the reported windows (cf. the mask marginals used in Step 7).

(iii) Cross-reference ledger (mask-gated).
A ledger linking upstream quantities, all evaluated *within* $\widehat{\mathfrak{M}}_{\mathrm{mask}}$:

- **(a)** Step 2: slope positivity and monotone trend acceptance (eqs. (7.539), (7.542) and (7.548)).
- **(b)** Step 3: restoration lengths (ℓ_R, $\ell_R^{[\mathcal{U}]}$) (Definitions 7.428 and 7.430 and Corollary 7.525).
- **(c)** Step 4: irrelevance exponents $y_{\tilde{B}}$ (quoted only where the mask certifies law healing and state coherence).
- **(d)** Step 6: spectral reconvergence (poles/residues read from $\mathbb{H}_{\mathrm{phys}}$; consistency with Lemma 7.527).

Intuition. $\mathfrak{M}_{\mathrm{mask}}$ is the "all–green" locus where the five guards of eq. (7.626) hold simultaneously. By Proposition 7.524 it is upward-closed in v (coarse-graining helps), hence admits the epigraph description via $v_\star(u)$; Definition 7.526 then provides a certified half–space for any UV strip. Restricting plots, tables, and cross-references to $\widehat{\mathfrak{M}}_{\mathrm{mask}}$ ensures every downstream exponent, scale, and spectral statement is quoted on a common, certified plateau.

Integrated (marginal) compliance. In addition to pointwise certification via eq. (7.626), we require that axis–integrated readouts inherit the mask's protection, suppressing isolated outliers. Let meas$(\cdot)$ denote one–dimensional Lebesgue measure and fix measurable windows $I_u \subset \mathbb{R}$ and $I_v \subset \mathbb{R}$. Define the integrated (marginal) compliance sets

$$\boxed{\mathfrak{M}^{(v)}_{\mathrm{mask}} := \Big\{ v \in I_v : \ \mathrm{meas}\Big(\{ u \in I_u : \ (u,v) \in \mathfrak{M}_{\mathrm{mask}}\}\Big) \ \geq \ (1-\delta_u)\ \mathrm{meas}(I_u)\Big\},} \tag{7.627}$$

$$\boxed{\mathfrak{M}^{(u)}_{\mathrm{mask}} := \Big\{ u \in I_u : \ \mathrm{meas}\Big(\{ v \in I_v : \ (u,v) \in \mathfrak{M}_{\mathrm{mask}}\}\Big) \ \geq \ (1-\delta_v)\ \mathrm{meas}(I_v)\Big\},} \tag{7.628}$$

for small audit tolerances $\delta_u, \delta_v \in [0,1)$. *Rule:* any report aggregated along the v–axis (resp. u–axis) must be restricted to $\mathfrak{M}^{(v)}_{\mathrm{mask}}$ (resp. $\mathfrak{M}^{(u)}_{\mathrm{mask}}$). Equivalently, if $\Phi_v(u; I_v)$ and $\Phi_u(v; I_u)$ are the marginal coverages from eq. (7.626), then $\mathfrak{M}^{(v)}_{\mathrm{mask}} = \{v : \inf_{u \in I_u} \Phi_u(v; I_u) \geq 1 - \delta_u\}$ and analogously for $\mathfrak{M}^{(u)}_{\mathrm{mask}}$.

Discrete mask estimator (audit path). On a rectangular grid $\{(u_m, v_k)\}$, define the per–guard booleans from eq. (7.626):

$$\chi_1 := \mathbf{1}\{\varsigma^{(\tau)}_{\mathrm{law}} \geq \varsigma_{\min}\}, \quad \chi_2 := \mathbf{1}\{\, |\partial_v^2(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})| \leq \varepsilon_{\mathrm{curv}}\,\}, \quad \chi_3 := \mathbf{1}\{\, \sup_V |1 - \Lambda_{\mathrm{state}}| \leq \varepsilon_{\mathrm{plat}}\,\},$$

$$\chi_4 := \mathbf{1}\{\, \mathcal{W} \leq \varepsilon_{\mathrm{plat}}\,\}, \quad \chi_5 := \mathbf{1}\Big\{ \sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} |\partial_\xi m_\alpha^2| = 0, \quad \sup_{\xi \in \mathcal{X}_{\mathrm{adm}}} |\partial_\xi Z_\alpha| = 0 \text{ within } \varepsilon_{\mathrm{gauge}}\ \forall \alpha\Big\},$$

and set $\chi_{\mathrm{mask}} := \prod_{r=1}^5 \chi_r \in \{0,1\}$. Optionally pre–filter the underlying fields along v with the same stationary low–pass LP_τ used in eqs. (7.537) to (7.539) to suppress salt–and–pepper while preserving first derivatives (bias $\mathcal{O}(\tau^2)$).

The discrete mask is the occupied grid set

$$\boxed{\widehat{\mathfrak{M}}_{\mathrm{mask}} := \Big\{(u_m, v_k) : \ \chi_{\mathrm{mask}}(u_m, v_k) = 1\Big\}.} \tag{7.629}$$

For integrated summaries on the grid, use the discrete marginals

$$\widehat{\mathfrak{M}}^{(v)}_{\mathrm{mask}} := \Big\{ v_k \in I_v : \ \frac{1}{|I_u|_{\mathrm{grid}}} \#\{m : \ u_m \in I_u, \ (u_m, v_k) \in \widehat{\mathfrak{M}}_{\mathrm{mask}}\} \ \geq \ 1 - \delta_u \Big\},$$

$$\widehat{\mathfrak{M}}^{(u)}_{\mathrm{mask}} := \Big\{ u_m \in I_u : \ \frac{1}{|I_v|_{\mathrm{grid}}} \#\{k : \ v_k \in I_v, \ (u_m, v_k) \in \widehat{\mathfrak{M}}_{\mathrm{mask}}\} \ \geq \ 1 - \delta_v \Big\},$$

where $|I_\bullet|_{\mathrm{grid}}$ denotes the number of grid points in the window. By Proposition 7.529 these discrete marginals converge to eqs. (7.627) and (7.628) as the mesh refines.

Intuition (outside the blocks). The marginals gate *axis–wise* readouts so a few bad columns/rows cannot dominate integrated summaries: at least a $(1-\delta)$ fraction along the orthogonal axis must pass the full mask. The discrete construction mirrors the five guards in eq. (7.626), preserves the same low–pass used for robust slope/curvature, and—by our convergence result—recovers the continuous marginals in the fine–mesh limit.

Acceptance statement (plateau certification). We adopt the continuous mask $\mathfrak{M}_{\mathrm{mask}} \subset \mathbb{R}^2$ given pointwise by the five guards in eq. (7.626), and its indicator $\chi_{\mathrm{mask}}(u,v) = \mathbf{1}[(u,v) \in \mathfrak{M}_{\mathrm{mask}}]$. Axis–integrated readouts use the marginal coverages $\Phi_v(u; I_v)$ and $\Phi_u(v; I_u)$ defined in eqs. (7.627) and (7.628), together with the uncovered–mass deficits $\delta_v(I_u, I_v)$ and $\delta_u(I_u, I_v)$ introduced alongside them.

Certification rule. We declare the plateau certified when the following hold:

- **Nonempty and IR–anchored.** The mask is nonempty and intersects the IR–anchored band:
$$\mathfrak{M}_{\mathrm{mask}} \neq \varnothing, \qquad \mathfrak{M}_{\mathrm{mask}} \cap \{(u,v) : v \geq \ln \ell_R\} \neq \varnothing,$$
with ℓ_R the restoration length of Definition 7.428. Equivalently, by the upward-closure epigraph form $\mathfrak{M}_{\mathrm{mask}} = \{(u,v) : v \geq v_\star(u)\}$ from Proposition 7.524, this demands $v_\star(u) \leq \ln \ell_R(u)$ (cf. Corollary 7.525).

- **Nontrivial marginals on reported windows.** For the chosen windows I_u, I_v, the marginal compliance sets are nonempty:
$$\{u \in I_u : \Phi_v(u; I_v) > 0\} \neq \varnothing, \qquad \{v \in I_v : \Phi_u(v; I_u) > 0\} \neq \varnothing,$$
ensuring that axis–integrated summaries inherit mask protection rather than being driven by isolated outliers. When desired, we additionally enforce coverage budgets $\delta_u, \delta_v \leq \delta_{\max}$ (user-chosen tolerances), again computed via eqs. (7.627) and (7.628).

- **Gauge and instrumentation robustness.** Within the admissible gauges $\mathcal{X}_{\mathrm{adm}}$ and admissible band knobs (P_x, K_{IR}), the mask is invariant up to the audit tolerance $\varepsilon_{\mathrm{gauge}}$:
$$\sup_{(u,v)} \left| \chi_{\mathrm{mask}}^{(P_x, K_{\mathrm{IR}}, \xi)}(u,v) - \chi_{\mathrm{mask}}^{(P_x', K_{\mathrm{IR}}', \xi')}(u,v) \right| \;\leq\; \varepsilon_{\mathrm{gauge}},$$
consistent with the Nielsen flatness requirement eq. (7.607) and the safety statements in Lemma 7.527 (gauge, basis/scheme, and rigid v–shift invariances; see also [117, 243, 442]).

Outputs for Step 7. We report only quantities restricted to the certified region (mask-gated) and its discrete estimator $\widehat{\mathfrak{M}}_{\mathrm{mask}}$:

1. **Certified map.** A heatmap of the robust law slope $\varsigma_{\mathrm{law}}^{(\tau)}(u,v)$ (eqs. (7.539), (7.542) and (7.548)), overlaid with the discrete mask $\widehat{\mathfrak{M}}_{\mathrm{mask}}$, the frontier $v_\star(u)$ (Proposition 7.524), the certified half–space bound $v = v_\star^{[\mathcal{U}]}$ for the chosen UV strip $\mathcal{U}$ (Definition 7.526), and the IR window shading $\mathcal{I}_{\mathrm{IR}}$ with markers at $v = \ln \ell_R(u)$ and $v = \ln \ell_R^{[\mathcal{U}]}$ (Definitions 7.428 and 7.430 and Corollary 7.525).

2. **Mask–restricted tables.** Windowed summaries computed *on* $\widehat{\mathfrak{M}}_{\mathrm{mask}}$: medians/quantiles of the Ward residual $\mathcal{W}$ (eqs. (7.591) and (7.602)); medians/quantiles of the on–shell gauge slopes $\partial_\xi m_\alpha^2, \partial_\xi Z_\alpha$ (Nielsen flatness, eq. (7.607)); and the curvature proxy $|\partial_v^2(\mathsf{LP}_\tau \Lambda_{\mathrm{law}})|$. Include robustness spreads across admissible (P_x, K_{IR}) and $\xi \in \mathcal{X}_{\mathrm{adm}}$ per Lemma 7.527. Also report marginal coverage fractions Φ_v, Φ_u and deficits (δ_u, δ_v) on the declared windows.

3. **Cross-reference ledger (mask-gated).** A concise ledger linking upstream ingredients, all evaluated within $\widehat{\mathfrak{M}}_{\mathrm{mask}}$:

   (a) Step 2–3 slope positivity and monotone trend acceptance (eqs. (7.539), (7.542) and (7.548));

(b) Step 3 restoration lengths $(\ell_R, \ell_R^{[\mathcal{U}]})$ (Definitions 7.428 and 7.430 and Corollary 7.525);

(c) Step 4 irrelevance exponents $y_{\tilde{B}}$ (quoted only where the mask certifies law healing/state coherence; cf. RG texts [389, 91, 82]);

(d) Step 6 spectral reconvergence (poles/residues read from $\mathbb{H}_{\text{phys}}$, consistent with gauge/basis safety, Lemma 7.527, and perturbation control [115]).

Concluding remarks for Step 7. Step 7 is where we stop spot–checking individual diagnostics and instead *certify a common IR stage* on which all downstream claims must stand. Concretely, we carve out a geometric region in scale–space—the mask $\mathfrak{M}_{\text{mask}} \subset \mathbb{R}^2$ over $(u, v) = (\ln \lambda_{\text{UV}}, \ln \ell)$—defined by the simultaneous pass of the five guards in eq. (7.626). Each guard targets a distinct failure mode: the *robust slope* $\varsigma_{\text{law}}^{(\tau)}$ asserts genuine law healing rather than noisy drift, the *curvature bound* keeps that trend plateau–like (the low–pass suppresses UV grit), *state coherence* excludes QII–type volume fragility, the *Ward residual* $\mathcal{W}$ enforces identity closure, and *Nielsen flatness* (zero gauge slopes) guarantees that quoted poles/residues are physical rather than gauge artifacts. Their intersection—the "all-green" pixels—is the certified mask.

Beyond existence, Step 7 explains the *shape* and *use* of this region. Coarse–graining helps once healing has begun, so vertical slices are upper sets; equivalently, the mask is the epigraph of a frontier $v_\star(u)$ (Proposition 7.524). This yields a clean interpretation: for any (u, v) with $v \geq v_\star(u)$, the point is certified. The *restoration lengths* $\ell_R(u)$ (and their UV–uniform counterpart on a strip) *anchor* this epigraph: $v_\star(u) \leq \ln \ell_R(u)$ and $\sup_{u \in \mathcal{U}} v_\star(u) \leq \ln \ell_R^{[\mathcal{U}]}$ (Corollary 7.525), so certification is IR–anchored by a scale already computed. For any chosen UV strip $\mathcal{U}$, the worst frontier $v_\star^{[\mathcal{U}]}$ furnishes a *certified IR half-space* lying inside the mask (Definition 7.526); this is the safest domain for aggregating exponents and spectra.

Step 7 also guards against *integration artifacts*. All integrated readouts (fits, tables, averages) are restricted to the marginal compliance sets $\mathfrak{M}_{\text{mask}}^{(v)}$ and $\mathfrak{M}_{\text{mask}}^{(u)}$ (eqs. (7.627) and (7.628)), which require that at least a $(1 - \delta)$ fraction of columns/rows pass the full mask. This prevents a narrow stripe of "good" points from legitimising a global claim.

Finally, Step 7 justifies the *finite-mesh audit* actually used in practice. The discrete estimator $\widehat{\mathfrak{M}}_{\text{mask}}$, built from the same five guards with centered, second-order estimators and the same low–pass, converges in the Hausdorff sense to the pointwise mask on any fixed window (Proposition 7.529). Together with gauge/basis/scheme safety (Lemma 7.527) and rigid-shift invariance in v (Lemma 7.523), this renders the certification *instrument-robust*.

In short, Step 7 is the *certification gate*: it turns local diagnostics (slope, curvature, state, Ward, Nielsen) into a single certified plateau region that is upward-closed, IR-anchored, robust to instrumentation and gauge, safe under integration, and faithfully approximated on the grid. Every downstream exponent, scale, or spectral multiplet should be quoted *within* that same $\mathfrak{M}_{\text{mask}}$.

7.8.8 Physicality Strengthens with ℓ

Objective. Across the certified mask $\mathfrak{M}_{\mathrm{mask}}$ (cf. eq. (7.626) and Step 7.8.7), we require that basic *physicality* properties not only hold but *improve* as coarse–graining increases ($v = \ln \ell$ grows): (i) nonnegativity of physical pole masses with a nondecreasing *mass margin*; (ii) strong hyperbolicity of the principal symbol of the quadratic IR dynamics with a nondecreasing *hyperbolicity margin*; and (iii) spectral positivity of two–point functions with a nondecreasing *spectral floor*. All statements are made *on shell* on the BRST physical sector and are *Nielsen–projected* (gauge–flat within tolerance; eq. (7.607) and Lemma 7.527). Dependence on ℓ is continuous by standard Kato perturbation theory for isolated poles/eigenvalues [115] (see also [255, 14, 91, 82]).

Mass operators: nonnegativity with improving margin. Let $\mathbb{H}_{\mathrm{phys}} = \mathsf{P}_{\mathrm{phys}}\,\mathbb{H}\,\mathsf{P}_{\mathrm{phys}}$ denote the quadratic operator on the physical sector (cf. eqs. (6.332) and (7.10)); read *on–shell* poles and residues from the corresponding two–point blocks. For $(u, v) \in \mathfrak{M}_{\mathrm{mask}}$, let $\mathcal{I}_{\mathrm{phys}}(u, v)$ index the Nielsen–stable physical poles at (u, v).

Definition 7.531 (Mass margin)**.** For $(u, v) \in \mathfrak{M}_{\mathrm{mask}}$, define

$$\boxed{\Delta_{\mathrm{mass}}(u, v) := \min_{i \in \mathcal{I}_{\mathrm{phys}}(u,v)} m_i^2(u, v) \;\geq\; 0.} \tag{7.630}$$

Reading guide (outside the definition). Δ_{mass} is the gap to tachyonic violation among all quoted physical poles; gauge safety follows from eq. (7.607) and Lemma 7.527. Continuity in v holds by Kato continuity of simple/isolated poles [115].

Definition 7.532 (Strengthening with ℓ)**.** We say the mass sector *strengthens* along $v = \ln \ell$ on $\mathfrak{M}_{\mathrm{mask}}$ if

$$\boxed{\partial_v\, \Delta_{\mathrm{mass}}(u, v) \;\geq\; 0 \quad \text{for all } (u, v) \in \mathfrak{M}_{\mathrm{mask}}.} \tag{7.631}$$

Reading guide. Within the certified mask, the law's robust monotone trend (eqs. (7.542) and (7.548)) couples with identity closure (eq. (7.602)) to prevent pole collisions from crossing into $m^2 < 0$ and to push the minimum m^2 upward (nondecreasing Δ_{mass}). Gauge/basis invariance of the quoted masses is ensured by Lemma 7.527.

Lemma 7.533 (Continuity, local Lipschitzness, and a.e. differentiability of masses)**.** *Fix $u \in \mathbb{R}$. Assume the hypotheses of Lemma 7.492 for the* band–projected, Nielsen–projected *two–point kernel on the certified region, i.e. along $(u, v) \in \mathfrak{M}_{\mathrm{mask}}$ the projected inverse two–point operator (or the relevant quadratic form on $\mathcal{H}_{\mathrm{phys}}$) is a C^1 Kato family in v, uniformly on compact momentum neighborhoods of each on–shell pole, with simple (algebraic multiplicity 1) physical poles except possibly at isolated values of v. Then for every physical channel $i \in \mathcal{I}_{\mathrm{phys}}(u, v)$:*

1. *$v \mapsto m_i^2(u, v)$ is* continuous *on $\{v : (u, v) \in \mathfrak{M}_{\mathrm{mask}}\}$.*
2. *There exists a closed, at most countable set $\Sigma(u) \subset \{v : (u, v) \in \mathfrak{M}_{\mathrm{mask}}\}$ (pole collisions/thresholds) such that on each connected component of the complement the map $v \mapsto m_i^2(u, v)$ is* continuously differentiable *and in fact* locally Lipschitz.[15]

[15] Local Lipschitz follows from uniform bounds on $\|\partial_v \mathcal{K}\|$ and a uniform lower bound on ∂_{m^2} of the dispersion functional at simple poles; see the proof.

Consequently, the mass margin $\Delta_{\mathrm{mass}}(u,v) := \min_{i\in\mathcal{I}_{\mathrm{phys}}(u,v)} m_i^2(u,v)$ *(cf. Definition 7.531 and eq. (7.630)) is* continuous *in* v *on* $\mathfrak{M}_{\mathrm{mask}}$ *and is* differentiable almost everywhere *in* v.

Proof. Setup. Work on the BRST physical sector with $\mathbb{H}_{\mathrm{phys}} = \mathsf{P}_{\mathrm{phys}}\mathbb{H}\mathsf{P}_{\mathrm{phys}}$ (cf. eqs. (6.332) and (7.10)); all quoted poles/residues are Nielsen–projected and gauge–flat per eq. (7.607) and Lemma 7.527. For fixed u and $(u,v) \in \mathfrak{M}_{\mathrm{mask}}$, each physical pole $m_i^2(u,v)$ is realized either as a simple eigenvalue of a Hermitian (or at least normal) effective mass operator on $\mathcal{H}_{\mathrm{phys}}$ at zero momentum, or as a simple real root of a scalar dispersion map $D_i(u,v;m^2) = 0$ obtained by analytic Fredholm reduction of the two–point kernel along the ith channel.

(1) Continuity. By the Kato–tracking hypothesis (Lemma 7.492), the relevant operator family (or dispersion map) is C^1 in v *in operator norm* on compact momentum neighborhoods of each pole. For simple poles, the spectral projection depends continuously on v and the associated eigenvalue (or real root) depends continuously on parameters (Kato, Thm. II-4.10, Thm. II-5.4 in [115]). Thus $v \mapsto m_i^2(u,v)$ is continuous wherever the pole remains simple. When simplicity fails, it can do so only at isolated v by the same perturbation theory; continuity of a continuous selection of eigenvalues across such points still holds (see Rellich's theorem and Kato's continuous selection results). Hence $m_i^2(u,\cdot)$ is continuous on $\{v : (u,v) \in \mathfrak{M}_{\mathrm{mask}}\}$.

(2) Piecewise C^1 *and local Lipschitz off a discrete set.* Let $\Sigma(u)$ denote the set of v where (i) a physical pole ceases to be simple (collision/threshold) or (ii) the index set $\mathcal{I}_{\mathrm{phys}}(u,v)$ changes by birth/decay of a channel. Under the C^1–in–v Kato hypothesis and simplicity elsewhere, $\Sigma(u)$ is closed and at most countable (indeed discrete on compact v–intervals). On each connected component $J \subset \{v : (u,v) \in \mathfrak{M}_{\mathrm{mask}}\} \setminus \Sigma(u)$, the Implicit Function Theorem applies to $D_i(u,v;m^2) = 0$ because $\partial_{m^2} D_i \neq 0$ at a simple pole; therefore $m_i^2(u,\cdot) \in C^1(J)$. Moreover, by the Hellmann–Feynman/Implicit differentiation formula,

$$\partial_v m_i^2(u,v) \;=\; -\frac{\partial_v D_i(u,v;m_i^2)}{\partial_{m^2} D_i(u,v;m_i^2)}\,,$$

and the denominator is bounded away from 0 on compact subintervals of J (simplicity + continuity). Since $\partial_v D_i$ is continuous, $\partial_v m_i^2$ is bounded on compact subintervals, whence m_i^2 is locally Lipschitz on J. (If one works directly with a selfadjoint effective mass operator $M_{\mathrm{eff}}(u,v)$, the standard Kato bound $\left|\partial_v m_i^2\right| \le \|\partial_v M_{\mathrm{eff}}\|$ gives the same conclusion; see [115, Sec. VII-1].)

(3) Consequences for the minimum. The mass margin $\Delta_{\mathrm{mass}}(u,v) = \min_i m_i^2(u,v)$ is the pointwise minimum of finitely many continuous functions (finitely many physical channels at fixed u in the band), hence is continuous. On each J as above, the m_i^2 are locally Lipschitz, so Δ_{mass} is also locally Lipschitz (the pointwise minimum of finitely many locally Lipschitz functions is locally Lipschitz). By Rademacher's theorem, locally Lipschitz functions are differentiable almost everywhere, proving the a.e. differentiability claim. Where the minimum is attained by a unique simple channel $i_\star$, one has the identification

$$\partial_v \Delta_{\mathrm{mass}}(u,v) = \partial_v m_{i_\star}^2(u,v) \quad \text{for a.e. } v \text{ with unique minimiser } i_\star.$$

All statements above are made on $\mathfrak{M}_{\mathrm{mask}}$, so they inherit gauge/basis/scheme safety from Lemma 7.527 and the required IR regularity (monotone trend, bounded curvature, and Ward

plateau) from Step 7 (eqs. (7.542), (7.548) and (7.602)), which guarantee stability of the simple–pole regime away from $\Sigma(u)$. □

Remark 7.534 (NG/pNG channels)**.** If exact NG or admissible pseudo–NG modes are present (cf. Definition 7.508 and Proposition 7.509), Δ_{mass} may approach 0 without violating eq. (7.630). In such cases it is convenient to monitor the *tachyon deficit*

$$\Theta_{\mathrm{mass}}(u,v) := \max\{0,\, -\min_i m_i^2(u,v)\},$$

and require $\partial_v \Theta_{\mathrm{mass}}(u,v) \le 0$ on $\mathfrak{M}_{\mathrm{mask}}$ (no growth of any negative excursion). This condition is equivalent to nondecreasing Δ_{mass} wherever all $m_i^2 \ge 0$, and it cleanly accommodates NG/pNG channels that sit at (or flow to) the origin.

Principal symbol: strong hyperbolicity with improving margin.

Definition 7.535 (Principal symbol, strong hyperbolicity, margin, and strengthening)**.** Work on the BRST physical sector with quadratic IR dynamics reduced at $(u,v) \in \mathfrak{M}_{\mathrm{mask}}$ (cf. eqs. (6.332), (7.10) and (7.626) and Lemma 7.527) to the first–order system

$$\partial_t \Phi \;+\; \sum_{j=1}^{d} A^j(u,v)\, \partial_j \Phi \;+\; B(u,v)\, \Phi \;=\; 0, \tag{7.632}$$

and define the *principal symbol* in direction $\hat{\boldsymbol{k}} \in \mathbb{S}^{d-1}$ by

$$A(u,v,\hat{\boldsymbol{k}}) \;:=\; \sum_{j=1}^{d} \hat{k}_j\, A^j(u,v). \tag{7.633}$$

All objects are computed on–shell and Nielsen–projected (gauge–flat within tolerance; eq. (7.607) and Lemma 7.527).

(Strong hyperbolicity). The system is *strongly hyperbolic* at (u,v) if there exists a positive–definite *symmetriser* $H(u,v,\hat{\boldsymbol{k}})$ with bounded condition number (uniformly in $\hat{\boldsymbol{k}}$) such that

$$H(u,v,\hat{\boldsymbol{k}})\, A(u,v,\hat{\boldsymbol{k}}) \;\text{ is symmetric for all }\; \hat{\boldsymbol{k}} \in \mathbb{S}^{d-1},$$

which yields an energy estimate and a well–posed Cauchy problem for (7.632) (see, e.g., [14, 91]).

(Hyperbolicity margin). For $(u,v) \in \mathfrak{M}_{\mathrm{mask}}$, the (direction–uniform) hyperbolicity margin is

$$\boxed{\Delta_{\mathrm{hyp}}(u,v) := \inf_{\hat{\boldsymbol{k}} \in \mathbb{S}^{d-1}} \lambda_{\min}\!\left(H(u,v,\hat{\boldsymbol{k}})^{1/2}\, \frac{A(u,v,\hat{\boldsymbol{k}}) + A(u,v,\hat{\boldsymbol{k}})^{\top}}{2}\, H(u,v,\hat{\boldsymbol{k}})^{1/2} \right) \;\ge\; 0.} \tag{7.634}$$

We say the system is *uniformly strongly hyperbolic* on $\mathfrak{M}_{\mathrm{mask}}$ if $\Delta_{\mathrm{hyp}}(u,v) > 0$ for all $(u,v) \in \mathfrak{M}_{\mathrm{mask}}$.

(Strengthening with ℓ). Hyperbolicity *strengthens* along $v = \ln \ell$ on the mask if

$$\boxed{\partial_v\, \Delta_{\mathrm{hyp}}(u,v) \;\ge\; 0 \qquad \text{for all } (u,v) \in \mathfrak{M}_{\mathrm{mask}}.} \tag{7.635}$$

Reading guide. Δ_{hyp} is the smallest symmetrised principal–symbol eigenvalue over directions; it quantifies the energy coercivity constant for the first–order reduction. Gauge/basis/scheme safety follows from Lemma 7.527; continuity in v along the mask follows from the same Kato continuity assumptions used for poles (Step 7), applied to $A^j(u,v)$ and $H(u,v,\hat{\boldsymbol{k}})$.

Spectral positivity: Källén–Lehmann density with improving floor. For each physical channel α, the (band–projected, on–shell) two–point function admits a Källén–Lehmann representation with a positive spectral density $\rho_\alpha(\mathfrak{s};u,v)\ge 0$ [14, 255, 82]. Fix an IR window $\mathfrak{S}_{\mathrm{IR}}$ in the spectral variable $\mathfrak{s}$ that contains all quoted poles and the first continuum threshold. All quantities are computed on the BRST physical sector and Nielsen–projected (gauge–flat within tolerance; eq. (7.607) and Lemma 7.527), with (u,v) restricted to the certified mask $\mathfrak{M}_{\mathrm{mask}}$ of eq. (7.626).

Definition 7.536 (Spectral floor and strengthening)**.** For $(u,v)\in\mathfrak{M}_{\mathrm{mask}}$, define the *spectral floor*

$$\boxed{\Delta_{\mathrm{spec}}(u,v) := \inf_{\alpha}\ \inf_{\mathfrak{s}\in\mathfrak{S}_{\mathrm{IR}}}\ \rho_\alpha(\mathfrak{s};u,v)\ \ \ge\ 0,} \tag{7.636}$$

and require *strengthening* along $v=\ln\ell$:

$$\boxed{\partial_v\,\Delta_{\mathrm{spec}}(u,v)\ \ge\ 0\quad\text{for all }(u,v)\in\mathfrak{M}_{\mathrm{mask}}.} \tag{7.637}$$

Remark 7.537 (Continuity, lower semicontinuity, and low–pass safety)**.** Under Step 5 regularity (band projection is positive and norm–continuous in (u,v)) and Kato continuity for the pole sector [115], the two–point functions vary continuously in operator norm on compact $\mathfrak{s}$–windows; the associated spectral measures $\rho_\alpha(\cdot;u,v)$ therefore vary continuously in the weak* topology on finite measures [115, Ch. VI]. Consequently, $(u,v)\mapsto\Delta_{\mathrm{spec}}(u,v)$ is *lower semicontinuous* on $\mathfrak{M}_{\mathrm{mask}}$ and is *a.e. differentiable in* v on any compact v–interval (via local Lipschitz of infima of weak*–continuous families on compact sets).

If an optional low–pass LP_τ in v is applied to the two–point function in a way that preserves the Löwner (positive–semidefinite) order—e.g., a convex combination $\int K_\tau(v-\tilde v)\,G(\tilde v)\,d\tilde v$ with $K_\tau\ge 0$, $\int K_\tau=1$—then the induced spectral densities satisfy

$$\rho_\alpha^{(\tau)}(\mathfrak{s};u,v)=\int K_\tau(v-\tilde v)\,\rho_\alpha(\mathfrak{s};u,\tilde v)\,d\tilde v\ \ \ge\ 0,$$

and Jensen's inequality gives $\Delta_{\mathrm{spec}}^{(\tau)}(u,v)\ \ge\ \inf_{\tilde v}\Delta_{\mathrm{spec}}(u,\tilde v)$, so the inequality eq. (7.637) is not weakened by such filtering.

Unified acceptance (physicality improves on the mask).

Definition 7.538 (Unified physicality margin)**.** On the certified mask $\mathfrak{M}_{\mathrm{mask}}$ (cf. eq. (7.626)), define

$$\boxed{\Delta_{\mathrm{phys}}(u,v) := \min\Big\{\Delta_{\mathrm{mass}}(u,v),\ \Delta_{\mathrm{hyp}}(u,v),\ \Delta_{\mathrm{spec}}(u,v)\Big\},\qquad (u,v)\in\mathfrak{M}_{\mathrm{mask}},} \tag{7.638}$$

where Δ_{mass} is the mass margin (Definition 7.531 and eq. (7.630)), Δ_{hyp} the hyperbolicity margin (Definition 7.535 and eq. (7.634)), and Δ_{spec} the spectral floor (Definition 7.536 and eq. (7.636)).

Lemma 7.539 (Nonnegativity, monotonicity, and regularity of the unified margin)**.** *Assume on* $\mathfrak{M}_{\text{mask}}$ *that each component margin is nonnegative and* strengthens *along* $v = \ln \ell$*:*

$$\begin{aligned} \Delta_{\text{mass}},\ \Delta_{\text{hyp}},\ \Delta_{\text{spec}} &\geq 0, \\ \partial_v \Delta_{\text{mass}} &\geq 0 && (\textit{eq. } (7.631)), \\ \partial_v \Delta_{\text{hyp}} &\geq 0 && (\textit{eq. } (7.635)), \\ \partial_v \Delta_{\text{spec}} &\geq 0 && (\textit{eq. } (7.637)). \end{aligned}$$

Then:

1. (Nonnegativity) $\Delta_{\text{phys}} \geq 0$ *on* $\mathfrak{M}_{\text{mask}}$.
2. (Monotonicity) *For each fixed* u, $v \mapsto \Delta_{\text{phys}}(u, v)$ *is nondecreasing on the vertical section* $\{v : (u, v) \in \mathfrak{M}_{\text{mask}}\}$.
3. (Regularity) Δ_{phys} *is lower semicontinuous on* $\mathfrak{M}_{\text{mask}}$*; moreover, on any compact* v*–interval where the components are locally Lipschitz in* v, Δ_{phys} *is locally Lipschitz and hence a.e. differentiable in* v*. At points where the minimiser is unique,*

$$\partial_v \Delta_{\text{phys}}(u, v) = \partial_v \Delta_j(u, v) \quad \textit{for } j \in \{\text{mass}, \text{hyp}, \text{spec}\} \textit{ realising the minimum.}$$

Proof. (1) Immediate: a pointwise minimum of nonnegative functions is nonnegative.

(2) Let $f_j(v) := \Delta_j(u, v)$ for $j \in \{\text{mass}, \text{hyp}, \text{spec}\}$. Each f_j is nondecreasing by the cited strengthening conditions. Hence $f(v) := \min_j f_j(v)$ is nondecreasing: for $v' \geq v$, $f(v') = \min_j f_j(v') \geq \min_j f_j(v) = f(v)$.

(3) *Lower semicontinuity.* Each component is l.s.c. on $\mathfrak{M}_{\text{mask}}$: (i) Δ_{mass} is continuous in v on the mask by Lemma 7.533 (Kato tracking for simple poles [115]); (ii) Δ_{hyp} is continuous since $(u, v, \hat{\boldsymbol{k}}) \mapsto H^{1/2}(\frac{A+A^\top}{2})H^{1/2}$ is continuous and the map $(M \mapsto \lambda_{\min}(M))$ is continuous on symmetric matrices, while the inf over compact $\mathbb{S}^{d-1}$ preserves continuity; (iii) Δ_{spec} is l.s.c. by weak* continuity of spectral measures (Step 5 regularity) as in Remark 7.537. The pointwise minimum of finitely many l.s.c. functions is l.s.c., so Δ_{phys} is l.s.c.

Local Lipschitz and a.e. differentiability. On any compact v–interval contained in a vertical section of the mask: - Δ_{mass} is locally Lipschitz away from a discrete set where pole simplicity can fail, by implicit differentiation/Hellmann–Feynman and operator C^1 dependence (see proof of Lemma 7.533 and [115, Sec. VII-1]); - Δ_{hyp} is locally Lipschitz if A^j, H are C^1 in v (then $\lambda_{\min}$ of a symmetric matrix depending C^1 on parameters is locally Lipschitz; the uniform inf over compact directions preserves it); - Δ_{spec} is locally Lipschitz if the two–point kernel depends Lipschitzly in operator norm on v over the IR window, which is satisfied under the Step 5 norm–continuity and stationary low–pass in v (convolution with a fixed kernel is 1–Lipschitz w.r.t. the sup norm). The pointwise minimum of finitely many locally Lipschitz functions is locally Lipschitz; by Rademacher, it is a.e. differentiable. When the minimiser is unique, the derivative equals that component's derivative; with multiple active minima, the one–sided Dini derivatives lie between the extremes of the active components. □

Remarks. (i) All statements are on–shell and Nielsen–projected, hence gauge/basis/scheme safe by Lemma 7.527 (see also eq. (7.607)). (ii) By Proposition 7.524, vertical sections of the mask are upper sets; coupled with monotonicity of Δ_{phys}, the unified margin provides a conservative, IR–anchored acceptance to accompany the restoration lengths (Corollary 7.525). (iii) Optional low–pass in v that preserves Löwner order does not degrade Δ_{spec} (and thus not Δ_{phys}), cf. Remark 7.537.

Definition 7.540 (Plateau floor of physicality)**.** The *plateau floor* is defined by

$$\boxed{\Delta_{\mathrm{phys}}^{(\mathrm{plateau})} := \inf_{(u,v)\in\mathfrak{M}_{\mathrm{mask}}} \Delta_{\mathrm{phys}}(u,v) \geq 0.} \tag{7.639}$$

Corollary 7.541 (Frontier reduction and IR anchoring of the floor)**.** *Under Section 7.8.8 and Proposition 7.524, vertical sections of $\mathfrak{M}_{\mathrm{mask}}$ are upper sets and $v \mapsto \Delta_{\mathrm{phys}}(u,v)$ is nondecreasing; hence*

$$\Delta_{\mathrm{phys}}^{(\mathrm{plateau})} \;=\; \inf_{u} \inf_{v\geq v_\star(u)} \Delta_{\mathrm{phys}}(u,v) \;=\; \inf_{u} \Delta_{\mathrm{phys}}\Big(u,\, v_\star(u)\Big),$$

where $v_\star$ is the frontier from Proposition 7.524. Moreover, by Corollary 7.525,

$$\Delta_{\mathrm{phys}}\Big(u,\, v_\star(u)\Big) \;\leq\; \Delta_{\mathrm{phys}}\Big(u,\, \ln \ell_R(u)\Big),$$

so the floor is IR-anchored by the restoration lengths.

Proof. For fixed u, $\mathfrak{M}_{\mathrm{mask}}(u) = \{v \geq v_\star(u)\}$ by Proposition 7.524. Monotonicity in v (from Section 7.8.8) implies $\inf_{v\geq v_\star(u)} \Delta_{\mathrm{phys}}(u,v) = \Delta_{\mathrm{phys}}(u, v_\star(u))$. Taking the infimum over u gives the first equality. The second statement uses $v_\star(u) \leq \ln \ell_R(u)$ from Corollary 7.525 and monotonicity in v. □

Remark 7.542 (pNG/NG allowance)**.** When NG/pNG channels are present (cf. Definition 7.508 and Proposition 7.509), implement the mass component via the tachyon–deficit proxy of Remark 7.534. The functionals Δ_{phys} and $\Delta_{\mathrm{phys}}^{(\mathrm{plateau})}$ are then unchanged while allowing $\min_i m_i^2 \to 0^+$.

Remark 7.543 (Gauge/basis/scheme safety)**.** All statements are on–shell and Nielsen–projected, hence gauge–flat within $\varepsilon_{\mathrm{gauge}}$ (cf. eq. (7.607) and Corollary 7.459); admissible basis/scheme changes act by similarity on the physical sector (Lemma 7.451). Therefore Δ_{phys} and $\Delta_{\mathrm{phys}}^{(\mathrm{plateau})}$ are invariant within the same tolerance (see also Lemma 7.527).

Discrete estimators and audit path.

Definition 7.544 (Discrete estimators on the (u_m, v_k) grid)**.** Work on the (u_m, v_k) grid of eq. (7.629), with uniform v–step h (so $h = \Delta v$) and band–admissible momentum/spectral grids as needed. All diagnostics are computed on–shell and Nielsen–projected (gauge–flat within tolerance; eq. (7.607) and Lemma 7.527) and restricted to the certified mask $\mathfrak{M}_{\mathrm{mask}}$ (eq. (7.626)).

(a) Mass margin and v–slope. Using per–channel discrete pole estimators $\widehat{m}_i^2(u_m, v_k)$ and (if needed) residues $\widehat{Z}_i(u_m, v_k)$ from the Step 6 spectral estimator (two–point block on $\mathbb{H}_{\mathrm{phys}}$), set

$$\boxed{\begin{aligned} \widehat{\Delta}_{\mathrm{mass}}(u_m, v_k) &:= \min_i \widehat{m}_i^2(u_m, v_k), \\ \widehat{\partial_v \Delta_{\mathrm{mass}}}(u_m, v_k) &:= \frac{\widehat{\Delta}_{\mathrm{mass}}(u_m, v_{k+1}) - \widehat{\Delta}_{\mathrm{mass}}(u_m, v_{k-1})}{2h}. \end{aligned}} \tag{7.640}$$

(b) Hyperbolicity margin and v–slope. Choose a finite angular grid $\{\hat{\boldsymbol{k}}_r\} \subset \mathbb{S}^{d-1}$ (e.g., quasi-uniform spherical design). Form principal symbols $A_{mkr} := A(u_m, v_k, \hat{\boldsymbol{k}}_r)$ (Definition 7.535), pick admissible symmetrisers $H_{mkr} \succ 0$ (consistent with Definition 7.535), and define

$$\boxed{\begin{aligned} \widehat{\Delta}_{\mathrm{hyp}}(u_m, v_k) &:= \min_r \ \lambda_{\min}\Big(H_{mkr}^{1/2} \, \tfrac{A_{mkr} + A_{mkr}^{\top}}{2} \, H_{mkr}^{1/2} \Big), \\ \widehat{\partial_v \Delta_{\mathrm{hyp}}}(u_m, v_k) &:= \frac{\widehat{\Delta}_{\mathrm{hyp}}(u_m, v_{k+1}) - \widehat{\Delta}_{\mathrm{hyp}}(u_m, v_{k-1})}{2h}. \end{aligned}} \tag{7.641}$$

(c) Spectral floor and v–slope. From the (band–projected, on–shell) two–point data in channel α, build a nonnegative spectral estimator $\widehat{\rho}_\alpha(\mathfrak{s}; u_m, v_k) \geq 0$ (e.g., constrained maximum-entropy; or rational/Prony fits with an explicit positivity constraint on the density over the IR window). On a spectral grid $\{\mathfrak{s}_s\} \subset \mathfrak{S}_{\mathrm{IR}}$,

$$\boxed{\begin{aligned} \widehat{\Delta}_{\mathrm{spec}}(u_m, v_k) &:= \min_\alpha \ \min_s \ \widehat{\rho}_\alpha(\mathfrak{s}_s; u_m, v_k), \\ \widehat{\partial_v \Delta_{\mathrm{spec}}}(u_m, v_k) &:= \frac{\widehat{\Delta}_{\mathrm{spec}}(u_m, v_{k+1}) - \widehat{\Delta}_{\mathrm{spec}}(u_m, v_{k-1})}{2h}. \end{aligned}} \tag{7.642}$$

(d) Low–pass before differencing. Apply the same stationary low–pass in v as eqs. (7.537) and (7.538) to each discrete margin sequence $\{\widehat{\Delta}_\bullet(u_m, v_k)\}_k$ before forming centered differences; this suppresses ripples while preserving first derivatives (bias $\mathcal{O}(\tau^2) + \mathcal{O}(h^2)$). At grid boundaries, use second–order one-sided differences or shrink the stencil.

Lemma 7.545 (Consistency and rates)**.** *Assume:*

(i) Simple–pole regularity.
The hypotheses of Definition 7.516 hold with simple poles and C^3 regularity in v in a neighborhood of each physical pole on the mask (cf. Lemma 7.533), so that the Step 6 pole estimators are second–order accurate in the momentum-grid variable p^2.

(ii) Principal symbol regularity.
$A(u, v, \hat{\boldsymbol{k}})$ is C^2 in $(v, \hat{\boldsymbol{k}})$ on $\mathfrak{M}_{\mathrm{mask}} \times \mathbb{S}^{d-1}$ and admits a uniformly positive symmetriser $H(u, v, \hat{\boldsymbol{k}})$ as in Definition 7.535.

(iii) Spectral density estimator.
For each channel α, the spectral estimator $\widehat{\rho}_\alpha(\mathfrak{s}; u, v)$ is positivity–preserving and consistent in the sup–norm on the IR window $\mathfrak{S}_{\mathrm{IR}}$, i.e.

$$\sup_{\mathfrak{s} \in \mathfrak{S}_{\mathrm{IR}}} \big| \widehat{\rho}_\alpha(\mathfrak{s}; u, v) - \rho_\alpha(\mathfrak{s}; u, v) \big| \leq \varepsilon_\rho$$

with $\varepsilon_\rho \to 0$ as the spectral grid refines.

Then, for the discrete margins of Definition 7.544 and as the grids are refined,

$$\widehat{\Delta}_{\mathrm{mass}} = \Delta_{\mathrm{mass}} + \mathcal{O}\Big((\Delta p^2)^2\Big), \qquad \widehat{\Delta}_{\mathrm{hyp}} = \Delta_{\mathrm{hyp}} + \mathcal{O}\Big(\Delta\hat{k}\Big), \qquad \widehat{\Delta}_{\mathrm{spec}} = \Delta_{\mathrm{spec}} + \mathcal{O}\Big(\varepsilon_\rho + \Delta\mathfrak{s}\Big),$$

uniformly on compact (u, v)–windows contained in $\mathfrak{M}_{\mathrm{mask}}$. Moreover, away from the discrete exceptional set where channel minima switch (cf. $\Sigma(u)$ in Lemma 7.533), the centered v–differences satisfy

$$\widehat{\partial_v \Delta_\bullet}(u_m, v_k) = \partial_v \Delta_\bullet(u_m, v_k) + \mathcal{O}(h^2), \qquad \bullet \in \{\mathrm{mass}, \mathrm{hyp}, \mathrm{spec}\},$$

with $h = \Delta v$. If an optional low–pass LP_τ is applied in v (eqs. (7.537) and (7.538)), choose $\tau = \mathcal{O}(h)$ so that the additional bias $\mathcal{O}(\tau^2)$ preserves the overall $\mathcal{O}(h^2)$ rate.

Proof. Mass margin. By Definition 7.531 and eq. (7.630), $\Delta_{\mathrm{mass}} = \min_i m_i^2$. Under Assumption (1) (Step 6 estimators with simple poles and C^3 regularity), each discrete pole location obeys $\widehat{m}_i^2 = m_i^2 + \mathcal{O}((\Delta p^2)^2)$ uniformly on compact windows (second–order consistency in the p^2 grid). The inequality

$$\Big|\min_i a_i - \min_i b_i\Big| \;\le\; \max_i |a_i - b_i|$$

then yields $\widehat{\Delta}_{\mathrm{mass}} - \Delta_{\mathrm{mass}} = \min_i \widehat{m}_i^2 - \min_i m_i^2 = \mathcal{O}((\Delta p^2)^2)$.

Hyperbolicity margin. Let $\varphi(u, v, \hat{\boldsymbol{k}}) := \lambda_{\min}\Big(H^{1/2}\, \frac{A + A^\top}{2}\, H^{1/2}\Big)$ so that by eq. (7.634), $\Delta_{\mathrm{hyp}}(u, v) = \inf_{\hat{\boldsymbol{k}} \in \mathbb{S}^{d-1}} \varphi(u, v, \hat{\boldsymbol{k}})$. Assumption (2) implies φ is C^1 in $\hat{\boldsymbol{k}}$ on the compact sphere (composition of C^2 maps with the continuous smallest–eigenvalue functional on symmetric matrices). For an ε–net $\{\hat{\boldsymbol{k}}_r\}$ with mesh $\Delta\hat{k}$, uniform continuity of φ gives

$$\begin{aligned} 0 \le \widehat{\Delta}_{\mathrm{hyp}} - \Delta_{\mathrm{hyp}} &= \min_r \varphi(u, v, \hat{\boldsymbol{k}}_r) - \inf_{\hat{\boldsymbol{k}}} \varphi(u, v, \hat{\boldsymbol{k}}) \\ &\le \sup_{\mathrm{dist}(\hat{\boldsymbol{k}}, \{\hat{\boldsymbol{k}}_r\}) \le \Delta\hat{k}} \Big|\varphi(u, v, \hat{\boldsymbol{k}}) - \varphi(u, v, \hat{\boldsymbol{k}}_r)\Big| \\ &= \mathcal{O}(\Delta\hat{k}). \end{aligned}$$

(If, in addition, the minimiser $\hat{\boldsymbol{k}}_\star$ is unique and interior with nondegenerate Hessian in the tangent space, a local quadratic fit in direction can refine the rate to $\mathcal{O}((\Delta\hat{k})^2)$; see the remark below.)

Spectral floor. By Definition 7.536 and eq. (7.636), $\Delta_{\mathrm{spec}} = \inf_\alpha \inf_{\mathfrak{s} \in \mathfrak{S}_{\mathrm{IR}}} \rho_\alpha(\mathfrak{s})$. On a grid $\{\mathfrak{s}_s\}$ with mesh $\Delta\mathfrak{s}$ and with a sup–norm consistent, positivity–preserving estimator,

$$\widehat{\Delta}_{\mathrm{spec}} = \min_\alpha \min_s \widehat{\rho}_\alpha(\mathfrak{s}_s) = \min_\alpha \min_s \Big[\rho_\alpha(\mathfrak{s}_s) + \mathcal{O}(\varepsilon_\rho)\Big] = \min_\alpha \Big[\inf_{\mathfrak{s}} \rho_\alpha(\mathfrak{s}) + \mathcal{O}(\Delta\mathfrak{s}) + \mathcal{O}(\varepsilon_\rho)\Big],$$

using uniform continuity of ρ_α on the compact IR window (Step 5 regularity) to pass from grid minima to the continuum infimum with error $\mathcal{O}(\Delta\mathfrak{s})$. Taking the minimum in α preserves the bound, yielding the stated rate.

Centered v–differences. On mask–restricted windows, Lemma 7.533 gives piecewise C^1 (indeed locally Lipschitz) dependence in v for m_i^2 and hence for Δ_{mass}; Assumption (2) yields the same for Δ_{hyp}; Remark 7.537 yields lower semicontinuity—and, under the mild Lipschitz–in–v assumption for the two–point kernel (Step 5), local Lipschitzness—for Δ_{spec}. On any subinterval avoiding the discrete set where minima switch, Taylor's theorem with the standard centered-difference formula gives

$$\frac{f(v+h)-f(v-h)}{2h} = f'(v) + \mathcal{O}(h^2)$$

for $f = \Delta_{\text{mass}}, \Delta_{\text{hyp}}, \Delta_{\text{spec}}$ provided $f \in C^3$ there (or f'' Lipschitz). This yields the $\mathcal{O}(h^2)$ rate. If the optional low–pass LP_τ is applied and preserves first moments (eq. (7.538)), the induced additional bias is $\mathcal{O}(\tau^2)$; choosing $\tau = \mathcal{O}(h)$ retains the overall $\mathcal{O}(h^2)$ rate. □

Remark (directional refinement). If the minimising direction $\hat{\boldsymbol{k}}_\star(u,v)$ is unique and non-degenerate (Hessian positive–definite on the tangent space), one may perform a local quadratic fit of $\varphi(u,v,\hat{\boldsymbol{k}})$ using neighboring samples around the discrete argmin to obtain $\widehat{\Delta}_{\text{hyp}} = \Delta_{\text{hyp}} + \mathcal{O}((\Delta\hat{k})^2)$. This mirrors the standard parabolic-refinement trick used in angular optimisation.

Lemma 7.546 (Gauge/basis invariance and mask restriction)**.** *All discrete margins and their centered v–slopes from Definition 7.544 are evaluated* on shell *and within the Nielsen–projected physical subspace. Then, across admissible gauges $\xi \in \mathcal{X}_{\text{adm}}$ and admissible basis/scheme changes, they are invariant within the audit tolerance $\varepsilon_{\text{gauge}}$ (cf. eq. (7.607), Corollary 7.459, and Lemmas 7.451 and 7.527). All audit checks are restricted to $(u_m, v_k) \in \mathfrak{M}_{\text{mask}}$ (cf. eqs. (7.626) and (7.629)).*

Proof. Restriction to the mask. By construction (eq. (7.629)), discrete evaluations are performed only at grid points in the certified set $\widehat{\mathfrak{M}}_{\text{mask}}$, which converges to $\mathfrak{M}_{\text{mask}}$ on windows (Proposition 7.529); hence all checks are mask–restricted.

Gauge invariance (within tolerance). On the physical sector, the Nielsen identities enforce vanishing gauge slopes for quoted on–shell quantities (eq. (7.607)), and Corollary 7.459 asserts gauge insensitivity within $\varepsilon_{\text{gauge}}$. Therefore: (i) Mass sector: m_i^2 and hence $\Delta_{\text{mass}} = \min_i m_i^2$ vary by at most $\mathcal{O}(\varepsilon_{\text{gauge}})$; the inequality $\left|\min_i a_i - \min_i b_i\right| \le \max_i |a_i - b_i|$ preserves the bound. Centered v–differences inherit the same tolerance since the forward/backward differences cancel common-mode perturbations and the remaining variation is bounded by the sup–norm change of Δ_{mass} across adjacent k. (ii) Hyperbolicity: A^j and admissible symmetrisers H computed from on–shell, BRST–invariant data (projected onto $\mathbb{H}_{\text{phys}}$) vary within $\mathcal{O}(\varepsilon_{\text{gauge}})$ by Lemma 7.527. The map $(A,H) \mapsto \lambda_{\min}\!\left(H^{1/2}\frac{A+A^\top}{2}H^{1/2}\right)$ is 1–Lipschitz up to a uniform constant with respect to the operator norm on $(A, H^{1/2})$, hence Δ_{hyp} varies by at most $C\,\varepsilon_{\text{gauge}}$ uniformly in direction; the discrete minimum over $\hat{\boldsymbol{k}}_r$ preserves the bound, as do centered differences in v. (iii) Spectral floor: The (band–projected, on–shell) two–point function is gauge–flat on the physical sector within $\varepsilon_{\text{gauge}}$ (Corollary 7.459 and Lemma 7.527); positivity–preserving spectral estimation thus changes $\widehat{\rho}_\alpha$ by at most $\mathcal{O}(\varepsilon_{\text{gauge}})$ in sup–norm on $\mathfrak{S}_{\text{IR}}$, yielding the same bound for $\widehat{\Delta}_{\text{spec}}$ and for its centered v–difference.

Basis/scheme invariance. Admissible field–basis changes act by (blockwise) similarity on the quadratic operator and transport residues covariantly; admissible renormalisation–scheme changes reparameterise renormalised quantities smoothly (cf. Lemmas 7.451 and 7.527). Spectra and principal symbols on $\mathbb{H}_{\mathrm{phys}}$ are therefore invariant under these transformations; the functionals defining Δ_{mass}, Δ_{hyp}, and Δ_{spec} (and their centered differences) depend only on these invariants, whence invariance within the same tolerance. □

Audit artefacts (reporting checklist). Alongside the discrete curves for the margins and their v–slopes (cf. Definition 7.544 and eqs. (7.640) to (7.642)), report the following audit artefacts, all restricted to the certified mask $\mathfrak{M}_{\mathrm{mask}}$ (eqs. (7.626) and (7.629)):

(i) Grids and filters. The step sizes and meshes (h, Δp^2, $\Delta\hat{k}$, $\Delta\mathfrak{s}$) and the low–pass width τ used before centered differencing (cf. eqs. (7.537) and (7.538)).

(ii) Symmetriser construction. How H was obtained for the principal symbol (e.g. energy inner product; Cholesky factorisation), consistent with Definition 7.535.

(iii) Spectral estimation method. The estimator for $\widehat{\rho}_\alpha$ and positivity constraints imposed over $\mathfrak{S}_{\mathrm{IR}}$ (cf. Definition 7.536); include the achieved sup–norm error/bias if available.

(iv) Mask–restricted summaries. Windowed minima and centered v–slopes of each margin $\widehat{\Delta}_{\mathrm{mass}}, \widehat{\Delta}_{\mathrm{hyp}}, \widehat{\Delta}_{\mathrm{spec}}$ on $\widehat{\mathfrak{M}}_{\mathrm{mask}}$, with spreads across admissible (P_x, K_{IR}) and gauges, as justified by Lemmas 7.527, 7.545 and 7.546.

Notes. Choose $\tau = \mathcal{O}(h)$ to preserve the $\mathcal{O}(h^2)$ centered–difference rate (Lemma 7.545). All items are computed on–shell and Nielsen–projected and are invariant across admissible gauges/bases within $\varepsilon_{\mathrm{gauge}}$ (eq. (7.607) and Lemma 7.546).

Compatibility guards.

Definition 7.547 (Evaluation domain and guards)**.** All Step 8 diagnostics are evaluated *only* on the certified mask $\mathfrak{M}_{\mathrm{mask}} \subset \mathbb{R}^2$ as defined in eq. (7.626). In addition, throughout Step 8 we require:

(i) State–coherence guard (uniform in volume).
$\sup_V \left|1 - \Lambda_{\mathrm{state}}(u, v; V)\right| \le \varepsilon_{\mathrm{plat}}$ for all $(u, v) \in \mathfrak{M}_{\mathrm{mask}}$ (cf. eq. (7.566)).

(ii) Nielsen flatness for on–shell inputs (gauge safety).
For all quoted on–shell poles or residues, the Nielsen slopes vanish, $\partial_\xi m_\alpha^2(u, v; \xi) = \partial_\xi Z_\alpha(u, v; \xi) = 0$ within tolerance for every $\xi \in \mathcal{X}_{\mathrm{adm}}$.

Lemma 7.548 (Well–posedness, continuity/Lipschitz regularity, and invariance)**.** *Under Definition 7.547, the Step 8 component margins* Δ_{mass}, Δ_{hyp}, Δ_{spec} *are* well defined *on* $\mathfrak{M}_{\mathrm{mask}}$, continuous in v *and, on any compact* v*-interval inside a vertical section of the mask,* locally Lipschitz and hence a.e. differentiable in v. *They are also* gauge-/basis-/scheme-invariant within $\varepsilon_{\mathrm{gauge}}$. *Consequently, the unified and floor quantities* Δ_{phys} *and* $\Delta_{\mathrm{phys}}^{(\mathrm{plateau})}$ *(cf. Definitions 7.538 and 7.540 and eqs.* (7.638) *and* (7.639)*) are well defined, lower semicontinuous (indeed locally Lipschitz under the same mild assumptions), and invariant within the same tolerance.*

Proof. Domain and on–shell inputs. All evaluations are restricted to $\mathfrak{M}_{\mathrm{mask}}$ (eq. (7.626)), where the five Step 7 guards hold simultaneously. The state–coherence guard ensures uniformity in V for on–shell inputs; Nielsen flatness removes gauge artefacts (eq. (7.607) and Corollary 7.459). Quotations are taken on the BRST physical sector (cf. eqs. (6.332) and (7.10) and Lemma 7.527).

Mass margin. By Definition 7.531 and eq. (7.630), $\Delta_{\mathrm{mass}}(u,v) = \min_{i\in\mathcal{I}_{\mathrm{phys}}} m_i^2(u,v)$. Kato's perturbation theory (simple, isolated poles) plus the Step 7 regularity imply continuity of $v \mapsto m_i^2(u,v)$ and piecewise C^1 (locally Lipschitz) dependence away from a discrete exceptional set (pole collisions/thresholds), cf. Lemma 7.533 and [115]. A pointwise minimum of finitely many continuous (locally Lipschitz) maps is continuous (locally Lipschitz); hence Δ_{mass} has the stated regularity and is a.e. differentiable in v (Rademacher).

Hyperbolicity margin. Let $A(u,v,\hat{\boldsymbol{k}})$ and an admissible symmetriser $H(u,v,\hat{\boldsymbol{k}}) \succ 0$ be as in Definition 7.535. Define

$$\varphi(u,v,\hat{\boldsymbol{k}}) := \lambda_{\min}\Big(H^{1/2}\,\tfrac{A+A^{\top}}{2}\,H^{1/2}\Big).$$

Continuity of A, H in v (Step 8 hypotheses) and continuity of $\lambda_{\min}$ on symmetric matrices imply continuity of φ in $(v,\hat{\boldsymbol{k}})$. Then $\Delta_{\mathrm{hyp}}(u,v) = \inf_{\hat{\boldsymbol{k}}\in\mathbb{S}^{d-1}} \varphi(u,v,\hat{\boldsymbol{k}})$ is continuous in v since the infimum is taken over compact $\mathbb{S}^{d-1}$ of a jointly continuous map. If A, H are C^1 in v, φ is locally Lipschitz, and the uniform infimum over $\hat{\boldsymbol{k}}$ preserves local Lipschitzness (uniform continuity on a compact set), yielding a.e. differentiability.

Spectral floor. By Definition 7.536 and eq. (7.636), $\Delta_{\mathrm{spec}} = \inf_\alpha \inf_{\mathfrak{s}\in\mathfrak{S}_{\mathrm{IR}}} \rho_\alpha(\mathfrak{s};u,v)$. Step 5 regularity (band projection positive and norm–continuous in v) together with Kato continuity in the pole sector ensure weak* continuity of the spectral measures $\rho_\alpha(\cdot;u,v)$ on the compact IR window $\mathfrak{S}_{\mathrm{IR}}$ [115, Ch. VI], so Δ_{spec} is lower semicontinuous in v (cf. Remark 7.537). If, in addition, the two–point kernel depends locally Lipschitzly in operator norm on v over $\mathfrak{S}_{\mathrm{IR}}$, then ρ_α varies locally Lipschitz in the bounded–variation norm, yielding local Lipschitzness (hence a.e. differentiability) of Δ_{spec}.

Invariance (gauge/basis/scheme). Nielsen projection implies gauge–parameter flatness for the quoted on–shell objects within $\varepsilon_{\mathrm{gauge}}$ (eq. (7.607) and Corollary 7.459). Admissible basis/scheme changes act by similarity and smooth reparametrisation on the physical sector (Lemmas 7.451 and 7.527). The functionals defining Δ_{mass} (min of pole masses), Δ_{hyp} (smallest symmetrised principal–symbol eigenvalue over directions), and Δ_{spec} (infimum of positive spectral densities on $\mathfrak{S}_{\mathrm{IR}}$) are invariant under these transformations, up to the audit tolerance.

Unified quantities. $\Delta_{\mathrm{phys}} = \min\{\Delta_{\mathrm{mass}}, \Delta_{\mathrm{hyp}}, \Delta_{\mathrm{spec}}\}$ (Definition 7.538 and eq. (7.638)) inherits lower semicontinuity (and local Lipschitzness under the mild assumptions above) from the components; invariance follows since minima preserve the tolerance bound. The plateau floor $\Delta_{\mathrm{phys}}^{(\mathrm{plateau})} = \inf_{(u,v)\in\mathfrak{M}_{\mathrm{mask}}} \Delta_{\mathrm{phys}}(u,v)$ (Definition 7.540 and eq. (7.639)) is well defined because $\mathfrak{M}_{\mathrm{mask}} \neq \varnothing$ under Step 7 acceptance (cf. acceptance statement) and the infimum of a bounded–below l.s.c. function on a nonempty set is finite; invariance follows from the componentwise invariance. □

Outputs for Step 8. We report four families of artefacts, all *restricted to the certified mask* $\mathfrak{M}_{\mathrm{mask}}$ (cf. eqs. (7.626) and (7.629)) and computed on–shell in the Nielsen–projected sector

(gauge–flat within tolerance; eq. (7.607) and Lemma 7.527):

- **Heatmaps.** Over (u, v), plot the fields $(u, v) \mapsto \Delta_{\mathrm{mass}}(u, v)$, $\Delta_{\mathrm{hyp}}(u, v)$, $\Delta_{\mathrm{spec}}(u, v)$, with $\mathfrak{M}_{\mathrm{mask}}$ overlaid (non–masked regions dimmed). This makes visible where the mass gap, strong–hyperbolicity margin, and spectral floor are simultaneously nonnegative and improving (cf. Definitions 7.531 and 7.536 and eq. (7.634)).

- **Derivative line–cuts.** For representative u–slices, show the centered v–derivatives $\partial_v \Delta_{\mathrm{mass}}$, $\partial_v \Delta_{\mathrm{hyp}}$, $\partial_v \Delta_{\mathrm{spec}}$ restricted to $\mathfrak{M}_{\mathrm{mask}}$, using the discrete estimators eqs. (7.640) to (7.642) (with optional low–pass per eqs. (7.537) and (7.538)). A nonnegative profile on these cuts evidences strengthening along $v = \ln \ell$ (cf. eqs. (7.631), (7.635) and (7.637)).

- **Plateau floor and spreads.** Quote the unified *plateau floor*

$$\Delta_{\mathrm{phys}}^{(\mathrm{plateau})} = \inf_{(u,v)\in\mathfrak{M}_{\mathrm{mask}}} \Delta_{\mathrm{phys}}(u, v),$$

  (cf. Definitions 7.538 and 7.540 and eqs. (7.638) and (7.639)), and accompany it with instrumentation/gauge spreads obtained by re–auditing over admissible (P_x, K_{IR}) and $\xi \in \mathcal{X}_{\mathrm{adm}}$:

$$\mathrm{err}_{\mathrm{inst/gauge}} := \max_{(P_x,K_{\mathrm{IR}}),\,\xi\in\mathcal{X}_{\mathrm{adm}}} \left| \Delta_{\mathrm{phys}}^{(\mathrm{plateau})}\Big[(P_x, K_{\mathrm{IR}}), \xi\Big] - \Delta_{\mathrm{phys}}^{(\mathrm{plateau})}\Big[(P'_x, K'_{\mathrm{IR}}), \xi'\Big] \right|.$$

  By Lemmas 7.539 and 7.546, the floor is nonnegative, monotone in v on vertical sections, and invariant to within $\varepsilon_{\mathrm{gauge}}$.

- **Audit table.** Summarise numerical settings: (a) symmetrisers H for the principal symbol (construction and conditioning; Definition 7.535); (b) spectral reconstructions $\widehat{\rho}$ (fit family, positivity constraints, IR window $\mathfrak{S}_{\mathrm{IR}}$; Definition 7.536); (c) low–pass kernel and width in v; and (d) grid spacings $(h, \Delta p^2, \Delta\hat{k}, \Delta\mathfrak{s})$ used in Definition 7.544. This enables reproducible verification of the rates in Lemma 7.545.

Interpretation. Nonnegative and *improving* mass, hyperbolicity, and spectral–positivity margins across $\mathfrak{M}_{\mathrm{mask}}$ demonstrate that coarse–graining not only restores symmetry but also *stabilises* the IR dynamics: poles move away from tachyonic regions, the first–order reduction retains (and tightens) strong hyperbolicity, and the Källén–Lehmann density maintains a nondecreasing floor in the IR window—consistent with monotone law healing and RG irrelevance ([14, 91, 82, 255, 115]).

Decision rule. Let $\mathcal{D} \subset \mathbb{R}^2$ be the probed (u, v)–domain, $\mathfrak{M}_{\mathrm{mask}}$ the certified plateau mask of eq. (7.626), and ℓ_R the restoration length of Definition 7.428. We classify behaviour into QI–QIV by a mutually exclusive, exhaustive rule, checked in the following order:

1. **QI (already unified).** For all $(u, v) \in \mathcal{D}$,

$$E_{\mathrm{law}}(e^v) \approx 0 \quad \text{and} \quad \sup_V \left|1 - \Lambda_{\mathrm{state}}(u, v; V)\right| \approx 0 \quad \text{within plateau tolerances.}$$

2. **QII (volume decoherence).** The state–coherence guard fails somewhere (cf. eq. (7.566)); i.e. there exists $(u, v) \in \mathcal{D}$ with

$$\sup_V \left|1 - \Lambda_{\text{state}}(u, v; V)\right| > \varepsilon_{\text{plat}},$$

even if the law shows partial healing.

3. **QIII (healing on a certified plateau).** The mask is nonempty and IR-anchored,

$$\mathfrak{M}_{\text{mask}} \neq \varnothing, \qquad \mathfrak{M}_{\text{mask}} \cap \{(u, v) : v \geq \ln \ell_R\} \neq \varnothing,$$

and, on $\mathfrak{M}_{\text{mask}}$,

$$\sup_{(u,v)\in\mathfrak{M}_{\text{mask}}} \left|1 - \Lambda_{\text{law}}(u, v)\right| \leq \varepsilon_{\text{plat}}, \qquad \varsigma^{(\tau)}_{\text{law}}(u, v) \geq \varsigma_{\min} \quad \text{(cf. } eq. \text{ (7.542)).}$$

4. **QIV (persistent explicit breaking).** Otherwise; equivalently, despite the guards there exists $\delta > 0$ such that, for all sufficiently large v,

$$\Lambda_{\text{law}}(u, v) \;\leq\; 1 - \delta \qquad \text{(no approach to unity on any candidate mask).}$$

The evaluation order (1)→(4) makes the outcomes disjoint; in particular, failure of the state–coherence guard in (2) precludes QIII. All checks using pole/residue data are on shell and Nielsen–projected (gauge–flat within $\varepsilon_{\text{gauge}}$; cf. eq. (7.607)).

Lemma 7.549 (Gauge/instrument robustness of the decision)**.** *Under admissible gauge variations and basis/scheme changes with Nielsen projection (Corollary 7.459 and Lemma 7.451) and across admissible instrument choices* (P_x, K_{IR})*, the quadrant outcome in Section 7.8.8 is invariant within the stated tolerances.*

Proof. By Lemma 7.527, the mask $\mathfrak{M}_{\text{mask}}$ and its frontier are invariant (within $\varepsilon_{\text{gauge}}$) under admissible gauge and basis/scheme changes and rigid shifts in v. The state–coherence guard (QII criterion) uses Λ_{state} evaluated on the physical sector; Nielsen flatness implies gauge–parameter insensitivity within tolerance (eq. (7.607) and Corollary 7.459). The law diagnostics (slope acceptance eq. (7.542) and proximity to unity) are computed using the same on–shell, band–projected data as in Step 7 and are instrument-robust by construction of the mask and its guards. Therefore, each threshold comparison that enters items (1)–(4) is stable under the stated variations, and the ordered decision rule returns the same quadrant (up to the quoted tolerances). □

Outputs (audit kit). We provide four audit artefacts, all restricted to the certified mask $\mathfrak{M}_{\text{mask}}$ (cf. eqs. (7.626) and (7.629)) and computed on–shell in the Nielsen–projected sector (gauge–flat within tolerance; eq. (7.607)):

- **Law heatmaps.** $(u, v) \mapsto 1 - \Lambda_{\text{law}}(u, v)$ with $\mathfrak{M}_{\text{mask}}$ overlaid and the line $v = \ln \ell_R$ marked.

- **Ward residuals.** Panels for $\mathcal{W}(u,v)$ and decay plots $v \mapsto \mathcal{W}(e^v)$ (cf. eqs. (7.591) and (7.602)).
- **Spectral reconvergence.** Line-cuts $v \mapsto \delta m_\rho^2/\overline{m_\rho^2}$ and $v \mapsto \delta Z_\rho/\overline{Z_\rho}$ with acceptance bands (cf. eqs. (7.618) to (7.620)).
- **Certified summary.** A table of key certified quantities $\{\ \ell_R,\ \mu_R,\ \varsigma_{\min},\ y_{\tilde{B}},\ \varepsilon_{\text{spec}}\ \}$ with spreads over admissible (P_x, K_{IR}) and gauges; see eqs. (7.554) and (7.588) for definitions/tolerances.

In short: keep the state coherent, let the law *heal* under coarse–graining, prove it via RG irrelevance (Section 7.8.4) + identity closure (Section 7.8.5) + spectral reconvergence (Section 7.8.6), and *certify* it on an IR plateau via the Q III mask (Section 7.8.7).

7.8.9 QIII Lessons & IR "Particle-like" Outlook

What we learned (QIII).

1. **Law heals under coarse–graining.** The law–visibility increases monotonically on the IR window with a *positive robust slope* $\varsigma_{\text{law}}^{(\tau)}$ (eqs. (7.539) and (7.542)), and the *restoration length* ℓ_R is finite (Definition 7.428).
2. **Breakings are RG–irrelevant.** After Nielsen projection, all excited breaking directions have $y_{\tilde{B}} < 0$ and $\widetilde{\varepsilon}_{\tilde{B}}(\mu) \to 0$ as $\mu \downarrow$ (Wilsonian ledger; Section 7.8.4, [389, 91, 82]).
3. **Identity closure in the IR.** Band–projected Ward residuals $\mathcal{W}(\ell)$ decay and sit within tolerance at ℓ_R; the ST identity is exact on shell; quoted IR poles/residues are *gauge–parameter flat* (Nielsen) on the mask (Section 7.8.5, [117, 243, 442]).
4. **Spectrum reconverges into multiplets.** Mass and residue splittings close on the plateau (eq. (7.620)); optional pseudo–NG modes follow the RG–dictated small–gap scaling (Proposition 7.509), while the state remains coherent (no volume decay; eq. (7.566)). Kato continuity ensures smooth evolution with ℓ [115].
5. **Physicality strengthens.** Nonnegative mass operators, strong hyperbolicity, and spectral positivity hold and *improve* across the certified mask $\mathfrak{M}_{\text{mask}}$ (Section 7.8.8); together with the slope and RG ledger, this completes the QIII certification.

IR "particle-like" outlook if emergence completes. On (and beyond) the QIII plateau $\mathfrak{M}_{\text{mask}}$ (eq. (7.626)), the on–shell pole structure and residues admit the following reading (Nielsen–flat, eq. (7.607); poles/residues read from the physical-sector quadratic form eqs. (6.332) and (7.10)):

- **Approaches the QI census.** *(a) Massless spin–2:* A pole at $p^2 = 0$ with transverse–traceless residue and positive norm signals a helicity–± 2 graviton–like excitation. Gauge–parameter stability follows from the identity ledger; causal propagation is supported by the hyperbolicity margin (Definition 7.535) and positivity by the spectral

floor (Definition 7.536) [14, 91, 255]. *(b) Unbroken massless vectors:* Poles at $p^2 = 0$ in conserved spin–1 channels with positive residues indicate unbroken gauge sectors; ST exactness on shell ensures the transverse/decoupling structure (Section 7.8.5, [117, 243]). *(c) Gapped scalars:* Scalar channels show $m_i^2(\ell_R) > 0$ with multiplet–consistent degeneracies and positive residues (eqs. (7.618) and (7.619); [82, 14]). As $\ell \uparrow$, the QIII outputs become indistinguishable (within tolerances) from the QI pattern.

- **Optional pseudo–NG modes.** If an approximate global symmetry was softly broken in Step 1, QIII allows small–gap scalar modes with $m_{\mathrm{pNG}}^2(\ell) \propto \ell^{-\alpha|y_{\bar{B}}|}$ (Proposition 7.509). Their presence is *consistent* with restoration provided multiplet splittings close (eq. (7.620)) and state visibility remains volume–uniform (eq. (7.566)). In the strict IR ($\ell \to \infty$), these gaps vanish if the associated breaking is truly irrelevant [91, 82].

- **No BEH reorganisation (unless emergent gauge becomes exact).** In QIII, global Ward structures are restored while the state stays coherent, so no Brout–Englert–Higgs (BEH) rearrangement is expected in the IR spectrum. If, however, the emergent symmetry is *gauged and exact* on the plateau (identity ledger shows full gauge structure and ST exactness with vanishing global residues), then the long–ℓ limit should be treated as **QI–like**: vector bosons are either exactly massless (unbroken phase) or acquire BEH masses with the usual Goldstone–eating pattern; diagnostics rely on the pole/residue reorganisation read from eqs. (6.332) and (7.10) and on the positivity/hyperbolicity guards ([14, 91]).

Bottom line. QIII shows that *keeping the state coherent* while letting the *law* evolve under coarse–graining produces an IR where symmetry is effectively restored: the law–visibility Λ_{law} approaches unity with a positive robust slope (Sections 7.8.2 and 7.8.3); explicit breakings die out under RG (Nielsen–projected exponents, Section 7.8.4); Ward, Slavnov–Taylor, and Nielsen identities *close* on shell (Section 7.8.5); spectra *reconverge into multiplets* (Section 7.8.6); and the physicality margins (mass, hyperbolicity, spectral positivity) *improve* across the certified mask (Section 7.8.8). When these conditions hold, the IR particle content *approaches the QI census*—with optional pseudo–NG modes governed by the irrelevant exponents—yielding a coherent, audit–ready account of emergent symmetry in the IR (Sections 7.8.2 to 7.8.8).

7.8.10 Concluding Census of Particle-like Modes on the QIII Plateau

Narrative summary. Having completed the QIII programme—positive robust law–slope and finite restoration length (eqs. (7.539) and (7.542) and Definition 7.428), RG–irrelevance of explicit breakings (Section 7.8.4), Ward/ST/Nielsen closure (Section 7.8.5), spectral reconvergence (Section 7.8.6), and mask certification (eq. (7.626))—the IR admits a clean, *on–shell* particle–like reading (Nielsen–flat within tolerance, eq. (7.607)). The actual census depends on which symmetry remains unbroken in the IR, but the counting itself is simple and audit–ready.

Census rule on the QIII mask. On the certified plateau $\mathfrak{M}_{\mathrm{mask}}$ (eq. (7.626)), poles and residues are extracted from the band–projected quadratic form on the physical sector (first–order reduction around eqs. (6.332) and (7.10)) and grouped into G_{IR}–multiplets (eq. (7.620)). The species count is:

- **Graviton–like:** *one* massless spin–2 species (helicities ± 2 in 3+1D; 2 physical dof) signalled by a transverse–traceless residue at $p^2 = 0$. Causal propagation is supported by the hyperbolicity margin (Definition 7.535); spectral positivity is witnessed by the spectral floor (Definition 7.536) [14, 91, 255].
- **Massless vectors:** $\dim G_{\mathrm{IR}}$ species, one per generator of the unbroken gauge group (each with 2 physical dof in 3+1D). ST exactness on shell ensures the transverse/decoupling structure (Section 7.8.5, [117, 243, 82, 14]).
- **Gapped scalars:** one scalar species per multiplet component that lies below the first continuum threshold. If the surviving multiplets are ρ with dimensions d_ρ, then $N_{\mathrm{scalar}} = \sum_\rho d_\rho$ (each with 1 dof); degeneracies close on the plateau (eq. (7.620)) [14, 82].
- **Pseudo–NG (optional/transient):** at finite ℓ there may be up to as many light scalar modes as approximate broken generators; their gaps scale as $m^2_{\mathrm{pNG}}(\ell) \propto \ell^{-\alpha|y_{\tilde{B}}|}$ with $y_{\tilde{B}} < 0$ from the RG ledger, so they fade as $\ell \uparrow$ if the associated breakings are truly irrelevant (Proposition 7.509 and Section 7.8.4).

Operational counting (audit path). Read the census directly from pole data on $\mathfrak{M}_{\mathrm{mask}}$:

1. a single $p^2 = 0$ pole with TT residue $\Rightarrow$ spin–2 (graviton–like);
2. one massless spin–1 pole per unbroken generator $\Rightarrow \dim G_{\mathrm{IR}}$ vectors;
3. the number of *isolated* scalar poles below the first threshold, grouped into G_{IR}–multiplets $\Rightarrow N_{\mathrm{scalar}} = \sum_\rho d_\rho$;
4. any additional light scalar poles whose m^2 decreases with ℓ as in Proposition 7.509 $\Rightarrow$ transient pseudo–NGs (allowed at finite ℓ, vanish asymptotically).

All pole/residue statements are on–shell and gauge–parameter flat (Nielsen), eq. (7.607).

Ballpark cases.

- *No unbroken IR gauge group* (pure global restoration): 1 massless spin–2 + N_{scalar} gapped scalars; pseudo–NGs typically disappear as $\ell \to \infty$ if irrelevance wins.
- $G_{\mathrm{IR}} = \mathrm{SU}(2) \times \mathrm{U}(1)$ *unbroken:* 1 spin–2 + $\big(3{+}1\big) = 4$ massless vectors + N_{scalar} gapped scalars; pseudo–NGs may be present at finite ℓ but shrink with the irrelevant exponents.

Headline formula. Summarising the species (not dof) count on the QIII plateau,

$$\boxed{N_{\text{modes}} \;\approx\; 1\ (\text{spin–2}) \;+\; \dim G_{\text{IR}}\ (\text{vectors}) \;+\; \sum_{\rho} d_\rho\ (\text{scalars}) \;+\; N_{\text{pNG}}(\text{finite } \ell),} \tag{7.643}$$

with $N_{\text{pNG}} \to 0$ as $\ell \to \infty$ if the QIII irrelevance conditions hold (Section 7.8.4 and Proposition 7.509). This census aligns with the QI–like outlook when emergence completes (Section 7.8.9) and rests on standard degrees–of–freedom counting and spectral positivity [14, 91, 82, 255].

Field provenance (gaiamiti vs. tantrakyma). As in the QI/QII analyses, we tag each particle–like mode on the QIII plateau by its *field provenance*. Using the same band instrumentation $P_x(\lambda_{\text{UV}})$ and $K_{\text{IR}}^{(\ell)}$ as before, and the same two–point extraction on the BRST physical sector (first–order reduction around eqs. (6.332) and (7.10)), we resolve the one–particle subspace into orthogonal, band–consistent components

$$\mathcal{H}_{1\text{p}} = \mathcal{H}_{\text{gai}} \;\oplus\; \mathcal{H}_{\text{tan}},$$

where $\mathcal{H}_{\text{gai}}$ ("gaiamiti") collects metric/geometry–type components (spin–2 block, geometric moduli) and $\mathcal{H}_{\text{tan}}$ ("tantrakyma") collects internal gauge and matter components (Yang–Mills and scalar matter). Let Π_{gai} and Π_{tan} be the corresponding projectors on the *Nielsen–projected* physical subspace, constructed in the same basis used to form the band–projected Hessian in eq. (7.10) and commuting with the band projection.

For each on–shell pole i with unit–norm eigenvector $u_i(u,v)$ of the physical two–point operator, define the sector *origin scores*

$$\boxed{\pi_{\text{gai}}(i;u,v) := \langle u_i, \Pi_{\text{gai}}\, u_i\rangle, \qquad \pi_{\text{tan}}(i;u,v) := \langle u_i, \Pi_{\text{tan}}\, u_i\rangle, \qquad \pi_{\text{gai}} + \pi_{\text{tan}} = 1,} \tag{7.644}$$

the last identity following from $\Pi_{\text{gai}} + \Pi_{\text{tan}} = \mathbf{1}_{\mathcal{H}_{1\text{p}}}$ and $\Pi_{\text{gai}}\Pi_{\text{tan}} = 0$ (up to numerical tolerances). With a small audit tolerance $\delta_{\text{orig}} \geq 0$ and for $(u,v) \in \mathfrak{M}_{\text{mask}}$ (eq. (7.626)), we partition each multiplet $\mathfrak{M}_\rho(\ell)$ (cf. eqs. (7.618) and (7.619)) by

$$\boxed{\begin{aligned}
\mathfrak{M}_\rho^{\text{gai}}(\ell;u,v) &:= \Big\{ i \in \mathfrak{M}_\rho(\ell) \;\Big|\; \pi_{\text{gai}}(i;u,v) \;\geq\; \pi_{\text{tan}}(i;u,v) + \delta_{\text{orig}} \Big\},\\
\mathfrak{M}_\rho^{\text{tan}}(\ell;u,v) &:= \Big\{ i \in \mathfrak{M}_\rho(\ell) \;\Big|\; \pi_{\text{tan}}(i;u,v) \;\geq\; \pi_{\text{gai}}(i;u,v) + \delta_{\text{orig}} \Big\},\\
\mathfrak{M}_\rho^{\text{hyb}}(\ell;u,v) &:= \Big\{ i \in \mathfrak{M}_\rho(\ell) \;\Big|\; \big|\pi_{\text{gai}}(i;u,v) - \pi_{\text{tan}}(i;u,v)\big| < \delta_{\text{orig}} \Big\}.
\end{aligned}} \tag{7.645}$$

By construction, $\mathfrak{M}_\rho^{\text{gai}}$ and $\mathfrak{M}_\rho^{\text{tan}}$ are disjoint and $\mathfrak{M}_\rho = \mathfrak{M}_\rho^{\text{gai}} \cup \mathfrak{M}_\rho^{\text{tan}} \cup \mathfrak{M}_\rho^{\text{hyb}}$. Modes with $\big|\pi_{\text{gai}} - \pi_{\text{tan}}\big| < \delta_{\text{orig}}$ are flagged as *hybrid*; they are rare on the certified mask thanks to spectral reconvergence (Section 7.8.6) and Kato continuity [115].

Canonical tags.

- **Graviton–like (spin–2):** always *gaiamiti*. The transverse–traceless $p^2{=}0$ pole lies in $\mathcal{H}_{\rm gai}$ by construction; causal propagation and positivity are supported by the Step 8 margins (eqs. (7.634) and (7.636)) [14, 91, 255].
- **Massless vectors:** *tantrakyma*. Each unbroken gauge generator gives a spin–1 $p^2{=}0$ pole with transversality enforced by the ST/Nielsen ledger (Section 7.8.5) [117, 243, 82].
- **Gapped scalars:** split by eq. (7.645). Geometric moduli (dilaton/radion–like) tag as *gaiamiti*; matter multiplets tag as *tantrakyma*. Degeneracies and residues close on $\mathfrak{M}_{\rm mask}$ (eq. (7.620)).
- **Pseudo–NG (optional):** provenance follows the *spurion ledger* from Step 1; a pseudo–NG tied to a breaking spurion S_B inherits the sector where S_B carries its quantum numbers [440]. Its gap scales with the irrelevant exponent (Section 7.8.4 and Proposition 7.509).

Tagged census (species, not dof). Decompose the headline count eq. (7.643) into sectoral contributions (on the QIII mask):

$$\boxed{\begin{aligned} N^{\rm gai}_{\rm modes} &= 1\ (\text{spin–2}) \ +\ \sum_{\rho} |\mathfrak{M}^{\rm gai}_{\rho}(\ell_R)|, \\ N^{\rm tan}_{\rm modes} &= \dim G_{\rm IR}\ (\text{vectors}) \ +\ \sum_{\rho} |\mathfrak{M}^{\rm tan}_{\rho}(\ell_R)| \ +\ N^{\rm tan}_{\rm pNG}(\text{finite } \ell), \end{aligned}} \tag{7.646}$$

where $N^{\rm tan}_{\rm pNG}$ counts any finite–ℓ pseudo–NGs sourced by tantrakyma spurions. Hybrids (if any) may be reported separately or assigned by the larger score in eq. (7.644) with an explicit note of $\delta_{\rm orig}$.

Audit note. The origin scores eq. (7.644) and partitions eq. (7.645) are evaluated only on $(u, v) \in \mathfrak{M}_{\rm mask}$ (eq. (7.626)), with all on–shell data Nielsen–projected and gauge–flat within tolerance (eq. (7.607)). Inner products and projectors act on the Nielsen–projected physical subspace. This preserves gauge/basis/scheme safety (cf. Lemmas 7.451 and 7.527) while keeping the tagging aligned with spectral reconvergence and the RG ledger [117, 243, 91, 82, 115].

7.9 Quadrant IV: Explicit Law Breaking with an Asymmetric State

Preconditions (Stage-I gate). Work anomaly-free so that the BRST differential $\zeta(\cdot) = \{\hat{Q}_{\rm BRST}, \cdot\}$ is nilpotent and the physical sector is $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$; all readouts (poles, residues, visibilities) are then gauge-parameter independent by Nielsen/Slavnov–Taylor identities on $\mathcal{H}_{\rm phys}$ [445, 106, 117].

Definition 7.550 (Quadrant IV overlay and diagnostics via law/state channels)**.** Let the UV/IR instrumentation be the scale-tags of Definitions 6.289 and 7.26 and the holosymmetric visibilities those of Definition 6.275. Quadrant IV is the regime in which (i) the *law* contains explicit symmetry-breaking sources and (ii) the *state* is asymmetric with a *unique* vacuum (no vacuum manifold). Concretely, on the band

$$\mathcal{L} \;=\; \mathcal{L}_0 \;+\; \sum_k \epsilon_k\, \mathcal{O}_k \;+\; \zeta\Psi, \qquad \epsilon_k \neq 0,$$

and the chosen background $(\bar{\Phi}, \bar{\Theta})$ is not G-invariant. On the physical sector $\mathcal{H}_{\text{phys}}$, the BRST-improved, adjoint-covariant Ward identities (eqs. (6.292) and (6.293)) isolate the explicit sources as the *only* origin of non-conservation,

$$\nabla^{(\text{ad})}_{\mu}\, \bar{J}^{\mu}_{a,\text{imp}} \;=\; \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a} \right\rangle_{\boldsymbol{\Psi}},$$

so that a *persistent* deviation of the law-visibility from unity and the *absence of exact NG modes* (only pseudo-NG) are the expected QIV signatures on certified plateaus (Definition 6.300). All diagnostics are evaluated cohomologically on $\mathcal{H}_{\text{phys}}$ and must satisfy Nielsen/Slavnov–Taylor gauge-parameter independence. Background references for BRST/ST are [445, 106, 117]; for SSB, pseudo-Goldstones, and GMOR-type scaling see [93, 94, 261, 91, 112].

Intuition. In QIV the **law is explicitly asymmetric** and the **state is uniquely selected** by those explicit terms. We should observe (i) a **law-visibility deficit** that does *not* heal under IR coarse-graining on certified bands, and (ii) **no exact NG** (only pseudo-NG) with masses controlled by the explicit couplings via GMOR-type relations. These expectations must be verified on $\mathcal{H}_{\text{phys}}$ under the UV/IR protocol of Section 6.12.

Recall (improved current). As defined in eq. (6.292), the (BRST-)improved Noether current is

$$\boxed{J^{\mu}_{a,\text{imp}} \;:=\; J^{\mu}_{a} \;-\; \zeta\, \Lambda^{\mu}_{a}}$$

where $\zeta(\cdot) = \{\hat{Q}_{\text{BRST}}, \cdot\}$ and Λ^{μ}_{a} is determined by the gauge-fermion variation $\delta_a\Psi = \alpha_a\, \chi_a + (\nabla_\mu \alpha_a)\Lambda^{\mu}_{a}$. (Operator form used in Ward identities: $\hat{J}^{\mu}_{a,\text{imp}} = \hat{J}^{\mu}_{a} - \zeta\, \Lambda^{\mu}_{a}$.)

Protocol (Goal → Gates → Setup → Steps → Exit)

Goal. Quantify explicit misalignment (law asymmetry with explicitly selected state), extract pseudo-NG spectra/mixings, and certify persistent non-conservation together with a bounded-away-from-unity law visibility on a joint plateau.

Gates (must pass before analysis counts).

1. **Stage-I/BRST viability:** anomaly-free BRST scaffold (Section 6.12); otherwise the candidate law fails before quadrant assignment.

2. **Plateau certification:** enforce slope/curvature/oscillation bounds at bandpoints and only report within Definition 6.300.

3. **Overlay neutrality:** holosymmetric overlays (Definition 6.275) are readouts and cannot alter quadrant logic.

Setup.

- Work **on the band** with $P_x(\lambda_{\mathrm{UV}})$ and within the IR window $K_{\mathrm{IR}}^{(\ell)}$ (Definitions 6.289 and 7.26); use the band/IR-tagged visibilities Λ_{law} and Λ_{state} (Definition 6.275).
- Law: $\mathcal{L} = \mathcal{L}_0 + \sum_k \epsilon_k \mathcal{O}_k + \zeta\Psi$ with **non-vanishing** explicit breakers ϵ_k. State: choose an **asymmetric** background; once $\epsilon_k \neq 0$ there is *no* vacuum manifold.

Steps. Detailed in the remainder: construct the band-limited mass/mixing ledger on $\mathcal{H}_{\mathrm{phys}}$, perform Ward $\Rightarrow$ pseudo-NG (GMOR-type) fits, and certify the joint plateau showing a persistent law-deficit.

Exit. Declare QIV when the certified joint plateau exhibits (i) non-healing law-visibility deficit, (ii) unique-vacuum state visibility (no thermodynamic orthogonality), and (iii) pseudo-NG masses consistent with the explicit sources—each BRST/Nielsen safe (Definition 6.300 and eqs. (6.292) and (6.293)).

7.9.1 UV/IR Instrumentation and Visibility Order Parameters

Definition 7.551 (Band-tagged operators, states, and branch unitaries in QIV)**.** Let $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ be the UV spectral projector and IR coarse-graining window of Definitions 6.289 and 7.26. For any operator $\hat{\mathcal{O}}$ and state ρ_0, define the band/IR-tagged objects

$$\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)} := K_{\mathrm{IR}}^{(\ell)}\, P_x(\lambda_{\mathrm{UV}})\, \hat{\mathcal{O}}\, P_x(\lambda_{\mathrm{UV}})\, K_{\mathrm{IR}}^{(\ell)}, \qquad \rho_0^{(\lambda_{\mathrm{UV}},\ell)} := P_x(\lambda_{\mathrm{UV}})\, \rho_0\, P_x(\lambda_{\mathrm{UV}}).$$

For the holosymmetric interferometer Definition 6.275, define the band-tagged branches

$$U_{A/B}^{(\lambda_{\mathrm{UV}},\ell)} := K_{\mathrm{IR}}^{(\ell)}\, P_x(\lambda_{\mathrm{UV}})\, U_{A/B}\, P_x(\lambda_{\mathrm{UV}})\, K_{\mathrm{IR}}^{(\ell)}, \quad |\Omega_{1/2}^{(\lambda_{\mathrm{UV}},\ell)}\rangle := K_{\mathrm{IR}}^{(\ell)}\, P_x(\lambda_{\mathrm{UV}})\, |\Omega_{1/2}\rangle\,.$$

Assume $[\zeta, P_x(\lambda_{\mathrm{UV}})] = [\zeta, K_{\mathrm{IR}}^{(\ell)}] = 0$ as in Section 6.12, so all tagged objects descend to the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$.

Intuition. We restrict both preparation and readout to a controlled UV/IR band so that all observables are regulator-stable. BRST-closed tags ensure everything is evaluable cohomologically on $\mathcal{H}_{\mathrm{phys}}$ (Nielsen/Slavnov–Taylor gauge-independence) [445, 106, 117].

Lemma 7.552 (Descent to the physical sector)**.** *Under the assumptions of Definition 7.551, for any operator $\hat{\mathcal{O}}$ with ghost number 0 and any ζ-closed state on the band, the tagged object $\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}$ is ζ-closed and defines a unique class in $H^0(\hat{Q}_{\mathrm{BRST}})$; expectation values computed with $\rho_0^{(\lambda_{\mathrm{UV}},\ell)}$ are independent of gauge parameters (Nielsen identity).*

Proof of Lemma 7.552. We split the argument into three parts.

(a) BRST-closure of the tagged operator. By Definition 7.551 the UV/IR taggers are BRST-closed and commute with the BRST differential: $[\zeta, P_x(\lambda_{\mathrm{UV}})] = [\zeta, K_{\mathrm{IR}}^{(\ell)}] = 0$. Hence, for any operator $\hat{\mathcal{O}}$ (ghost number 0),

$$\zeta\Big(\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) = \zeta\Big(K_{\mathrm{IR}}^{(\ell)} P_x\, \hat{\mathcal{O}}\, P_x K_{\mathrm{IR}}^{(\ell)}\Big) = K_{\mathrm{IR}}^{(\ell)} P_x\, \zeta(\hat{\mathcal{O}})\, P_x K_{\mathrm{IR}}^{(\ell)}.$$

If $\hat{\mathcal{O}}$ is chosen as a representative of its BRST cohomology class with $\zeta(\hat{\mathcal{O}}) = 0$ (which we can always do by replacing $\hat{\mathcal{O}} \mapsto \hat{\mathcal{O}} - \zeta(\hat{X})$ for some $\hat{X}$), then $\zeta\Big(\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) = 0$ as well. Thus the tagged operator is BRST-closed.

(b) Well-defined class in $H^0(\hat{Q}_{\mathrm{BRST}})$. Suppose $\hat{\mathcal{O}}$ and $\hat{\mathcal{O}}'$ are two ghost-number-zero representatives of the same cohomology class, $\hat{\mathcal{O}}' = \hat{\mathcal{O}} + \zeta(\hat{X})$. Tagging preserves BRST-exactness because the taggers commute with ζ:

$$\hat{\mathcal{O}}'^{(\lambda_{\mathrm{UV}},\ell)} - \hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)} = \Big(\zeta(\hat{X})\Big)^{(\lambda_{\mathrm{UV}},\ell)} = \zeta\Big(\hat{X}^{(\lambda_{\mathrm{UV}},\ell)}\Big).$$

Hence $\hat{\mathcal{O}}'^{(\lambda_{\mathrm{UV}},\ell)}$ and $\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}$ define the *same* class in $H^0(\hat{Q}_{\mathrm{BRST}})$. This shows that the class $[\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}] \in H^0(\hat{Q}_{\mathrm{BRST}})$ is uniquely defined by the class $[\hat{\mathcal{O}}] \in H^0(\hat{Q}_{\mathrm{BRST}})$.

(c) Gauge-parameter independence (Nielsen identity) of expectations. Let $\rho_0^{(\lambda_{\mathrm{UV}},\ell)} = P_x\, \rho_0\, P_x$ be a ζ-closed (band-tagged) state, i.e. $\zeta\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\Big) = 0$, as in Definition 7.551. For any operator $\hat{Y}$ we use that $\zeta(\cdot) = \{\hat{Q}_{\mathrm{BRST}}, \cdot\}$ is a graded derivation and that the (super)trace of a (super)commutator vanishes:

$$\mathrm{Tr}\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\, \zeta(\hat{Y})\Big) = \mathrm{Tr}\Big(\zeta\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\hat{Y}\Big)\Big) - \mathrm{Tr}\Big(\zeta\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\Big)\, \hat{Y}\Big) = 0 - 0 = 0.$$

Therefore expectation values are insensitive to adding ζ-exact pieces to either the operator or the state.

Now let α_{gf} be a gauge-fixing parameter. Algebraic renormalization (Slavnov–Taylor with α_{gf} promoted to a BRST doublet) gives the *Nielsen identity* [117]:

$$\partial_{\alpha_{\mathrm{gf}}}\, \hat{\mathcal{O}} = \zeta\Big(\hat{\mathcal{N}}_{\alpha_{\mathrm{gf}}}[\hat{\mathcal{O}}]\Big), \qquad \partial_{\alpha_{\mathrm{gf}}}\, \rho_0 = \zeta\Big(\hat{\mathcal{N}}_{\alpha_{\mathrm{gf}}}[\rho_0]\Big),$$

for suitable local insertions $\hat{\mathcal{N}}_{\alpha_{\mathrm{gf}}}[\cdot]$. Since P_x and $K_{\mathrm{IR}}^{(\ell)}$ commute with ζ, the same relations hold after tagging. Hence

$$\begin{aligned}
\partial_{\alpha_{\mathrm{gf}}}\, \mathrm{Tr}\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\, \hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) &= \mathrm{Tr}\Big((\partial_{\alpha_{\mathrm{gf}}}\rho_0^{(\lambda_{\mathrm{UV}},\ell)})\, \hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) \\
&\quad + \mathrm{Tr}\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\, \partial_{\alpha_{\mathrm{gf}}}\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) \\
&= \mathrm{Tr}\Big(\zeta\Big(\hat{\mathcal{N}}_{\alpha_{\mathrm{gf}}}[\rho_0]^{(\lambda_{\mathrm{UV}},\ell)}\Big)\, \hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}\Big) \\
&\quad + \mathrm{Tr}\Big(\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\, \zeta\Big(\hat{\mathcal{N}}_{\alpha_{\mathrm{gf}}}[\hat{\mathcal{O}}]^{(\lambda_{\mathrm{UV}},\ell)}\Big)\Big) = 0,
\end{aligned}$$

by the previous vanishing of expectations of ζ-exact insertions. Thus, expectation values computed with $\rho_0^{(\lambda_{\mathrm{UV}},\ell)}$ are gauge-parameter independent.

Conclusion. Parts (a)–(c) prove that $\hat{\mathcal{O}}^{(\lambda_{\mathrm{UV}},\ell)}$ is BRST-closed, represents a unique element of $H^0(\hat{Q}_{\mathrm{BRST}})$, and has gauge-parameter–independent expectation values on the physical sector, as claimed. □

Definition 7.553 (QIV holosymmetric visibilities (band-tagged))**.** With $U_{A/B}^{(\lambda_{\mathrm{UV}},\ell)}$ and $\rho_0^{(\lambda_{\mathrm{UV}},\ell)}$ as in Definition 7.551, define

$$\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)} := \mathrm{Tr}\Big[\Big(U_B^{(\lambda_{\mathrm{UV}},\ell)}\Big)^\dagger U_A^{(\lambda_{\mathrm{UV}},\ell)}\,\rho_0^{(\lambda_{\mathrm{UV}},\ell)}\Big], \qquad \Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)} := \langle\Omega_2^{(\lambda_{\mathrm{UV}},\ell)}|\Omega_1^{(\lambda_{\mathrm{UV}},\ell)}\rangle\,.$$

These are the operational order parameters for the law- and state-channels in QIV (cf. Definition 6.275 and Section 6.12).

Intuition. Λ_{law} compares the two interferometric branches of the *law* dynamics; Λ_{state} compares the prepared *states*. Band-tagging guarantees scale locality; BRST descent ensures physicality.

Definition 7.554 (Triadic channel projectors)**.** Let $\{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}$ be orthogonal, BRST-closed channel projectors (correlational, vacuum, spectral) commuting with $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$, as in the triadic split of Section 6.12. Define the channel-resolved visibilities by inserting Π_α into the definitions of Definition 7.553.

Proposition 7.555 (Additive channel decomposition)**.** *Under Definition 7.554, the visibilities decompose additively,*

$$\Lambda_\bullet^{(\lambda_{\mathrm{UV}},\ell)} = \sum_{\alpha\in\{\mathrm{corr,vac,spec}\}} \Lambda_\bullet^{(\alpha;\lambda_{\mathrm{UV}},\ell)}, \qquad \bullet\in\{\mathrm{law},\mathrm{state}\}.$$

Proof Proposition 7.555. We treat the law and state visibilities in turn and make explicit where each structural property is used.

Preliminaries. By Definition 7.554, the channel projectors $\{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}$ obey

$$\Pi_\alpha^\dagger = \Pi_\alpha, \quad \Pi_\alpha\Pi_\beta = \delta_{\alpha\beta}\Pi_\alpha, \quad \sum_\alpha \Pi_\alpha = \mathbb{1},$$

and commute with the UV/IR taggers $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$. Hence, for any band-tagged operator $X^{(\lambda_{\mathrm{UV}},\ell)}$ (e.g. $U_{A/B}^{(\lambda_{\mathrm{UV}},\ell)}$, $\rho_0^{(\lambda_{\mathrm{UV}},\ell)}$) we may freely insert $\sum_\alpha \Pi_\alpha$ and move the Π_α through the taggers.

State visibility. With the band-tagged branch states $|\Omega_{1/2}^{(\lambda_{\mathrm{UV}},\ell)}\rangle := K_{\mathrm{IR}}^{(\ell)}P_x(\lambda_{\mathrm{UV}})\,|\Omega_{1/2}\rangle$, we have

$$\Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)} = \langle\Omega_2^{(\lambda_{\mathrm{UV}},\ell)}|\Omega_1^{(\lambda_{\mathrm{UV}},\ell)}\rangle = \langle\Omega_2^{(\lambda_{\mathrm{UV}},\ell)}\Big|\Big(\sum_\alpha \Pi_\alpha\Big)\Big|\Omega_1^{(\lambda_{\mathrm{UV}},\ell)}\rangle\,.$$

Because $[\Pi_\alpha, K_{\mathrm{IR}}^{(\ell)}] = [\Pi_\alpha, P_x(\lambda_{\mathrm{UV}})] = 0$, inserting the resolution of the identity between the tagged states does not disturb band-tagging. Linearity then gives

$$\Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)} = \sum_\alpha \langle\Omega_2^{(\lambda_{\mathrm{UV}},\ell)}|\Pi_\alpha|\Omega_1^{(\lambda_{\mathrm{UV}},\ell)}\rangle = \sum_\alpha \Lambda_{\mathrm{state}}^{(\alpha;\lambda_{\mathrm{UV}},\ell)},$$

which is the desired additive decomposition for the state channel.

Law visibility (one-sided decomposition—always valid). We define the following quantities:

$$X^{(\lambda_{\mathrm{UV}},\ell)} := (U_B^{(\lambda_{\mathrm{UV}},\ell)})^\dagger U_A^{(\lambda_{\mathrm{UV}},\ell)}$$
$$\rho^{(\lambda_{\mathrm{UV}},\ell)} := \rho_0^{(\lambda_{\mathrm{UV}},\ell)}$$

Then

$$\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathrm{Tr}\Big[X^{(\lambda_{\mathrm{UV}},\ell)}\,\rho^{(\lambda_{\mathrm{UV}},\ell)}\Big] = \mathrm{Tr}\Big[\Big(\sum_\alpha \Pi_\alpha\Big) X^{(\lambda_{\mathrm{UV}},\ell)}\,\rho^{(\lambda_{\mathrm{UV}},\ell)}\Big] = \sum_\alpha \mathrm{Tr}\Big[\Pi_\alpha X^{(\lambda_{\mathrm{UV}},\ell)}\,\rho^{(\lambda_{\mathrm{UV}},\ell)}\Big].$$

Define the channel-resolved law visibility by the *one-sided* insertion

$$\Lambda_{\mathrm{law}}^{(\alpha;\lambda_{\mathrm{UV}},\ell)} := \mathrm{Tr}\Big[\Pi_\alpha X^{(\lambda_{\mathrm{UV}},\ell)}\,\rho^{(\lambda_{\mathrm{UV}},\ell)}\Big].$$

This yields $\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)} = \sum_\alpha \Lambda_{\mathrm{law}}^{(\alpha;\lambda_{\mathrm{UV}},\ell)}$ without requiring any commutation between Π_α and the branch unitaries or the preparation ρ_0; only linearity and $\sum_\alpha \Pi_\alpha = \mathbb{1}$ are used, together with commutation of Π_α with the UV/IR taggers (so that the insertion is legitimate at the band level).

Law visibility (symmetric two-sided form—under a stronger, often satisfied hypothesis). If, in addition, the triadic split is *functorial* for the holosymmetric branches—namely

$$[\Pi_\alpha, U_{A/B}^{(\lambda_{\mathrm{UV}},\ell)}] = 0 \quad \text{and} \quad [\Pi_\alpha, \rho_0^{(\lambda_{\mathrm{UV}},\ell)}] = 0,$$

(which holds in the common case where the channels define a block decomposition preserved by the branch dynamics and the prepared state is channel-diagonal), then the cross-channel traces vanish:

$$\mathrm{Tr}\Big[\Pi_\alpha X^{(\lambda_{\mathrm{UV}},\ell)}\,\Pi_\beta \rho^{(\lambda_{\mathrm{UV}},\ell)}\Big] = \mathrm{Tr}\Big[X^{(\lambda_{\mathrm{UV}},\ell)}\,\Pi_\alpha\Pi_\beta \rho^{(\lambda_{\mathrm{UV}},\ell)}\Big] = \delta_{\alpha\beta}\,\mathrm{Tr}\Big[X^{(\lambda_{\mathrm{UV}},\ell)}\,\Pi_\alpha \rho^{(\lambda_{\mathrm{UV}},\ell)}\Big].$$

Consequently the one-sided definition is equivalent to the *two-sided* (block-diagonal) form

$$\Lambda_{\mathrm{law}}^{(\alpha;\lambda_{\mathrm{UV}},\ell)} = \mathrm{Tr}\Big[\Pi_\alpha (U_B^{(\lambda_{\mathrm{UV}},\ell)})^\dagger U_A^{(\lambda_{\mathrm{UV}},\ell)}\,\Pi_\alpha \rho_0^{(\lambda_{\mathrm{UV}},\ell)}\Big],$$

which can be convenient for positivity or Cauchy–Schwarz estimates within each channel. Either way, the sum over α reproduces $\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}$.

Conclusion. Combining the state and law analyses yields, for $\bullet \in \{\mathrm{law}, \mathrm{state}\}$,

$$\Lambda_\bullet^{(\lambda_{\mathrm{UV}},\ell)} = \sum_{\alpha\in\{\mathrm{corr},\mathrm{vac},\mathrm{spec}\}} \Lambda_\bullet^{(\alpha;\lambda_{\mathrm{UV}},\ell)},$$

establishing the proposition. □

Proposition 7.556 (Gauge-parameter independence on $\mathcal{H}_{\mathrm{phys}}$)**.** *For any gauge-fixing parameter* α_{gf}, $\partial_{\alpha_{\mathrm{gf}}} \Lambda_\bullet^{(\lambda_{\mathrm{UV}},\ell)} = 0$ *on* $\mathcal{H}_{\mathrm{phys}}$, *for* $\bullet \in \{\mathrm{law}, \mathrm{state}\}$.

Proof Proposition 7.556. We prove the claim for both visibilities, making explicit the role of the Nielsen identity, BRST-closure of the UV/IR taggers, and the cohomological vanishing used in Lemma 7.552.

Preliminaries (Nielsen identity and band-tagging). Let $\alpha_{\rm gf}$ be any gauge-fixing parameter entering through the gauge-fermion Ψ. Algebraic renormalization promotes $\alpha_{\rm gf}$ to a BRST doublet and yields the *Nielsen identity* (linearized Slavnov–Taylor form) for band-tagged objects [117]:

$$\partial_{\alpha_{\rm gf}} X^{(\lambda_{\rm UV},\ell)} = \zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[X]^{(\lambda_{\rm UV},\ell)}\Big), \qquad \partial_{\alpha_{\rm gf}} \rho_0^{(\lambda_{\rm UV},\ell)} = \zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[\rho_0]^{(\lambda_{\rm UV},\ell)}\Big), \tag{7.647}$$

for suitable local insertions $\mathcal{N}_{\alpha_{\rm gf}}[\cdot]$. Here the UV/IR taggers $P_x(\lambda_{\rm UV})$ and $K_{\rm IR}^{(\ell)}$ commute with the BRST differential and are chosen $\alpha_{\rm gf}$-independent, as stipulated in Definition 7.551 and Section 6.12. In particular, $[\zeta, P_x] = [\zeta, K_{\rm IR}^{(\ell)}] = 0$ and $\partial_{\alpha_{\rm gf}} P_x = \partial_{\alpha_{\rm gf}} K_{\rm IR}^{(\ell)} = 0$.

We also use the cohomological trace facts (ghost number in parentheses): for any ghost-number-zero band state $\rho^{(\lambda_{\rm UV},\ell)}$ with $\zeta\Big(\rho^{(\lambda_{\rm UV},\ell)}\Big) = 0$ and any operator Y,

$$\mathrm{Tr}\Big(\rho^{(\lambda_{\rm UV},\ell)}\,\zeta(Y)\Big) = 0, \qquad \text{equivalently} \quad \mathrm{Tr}\Big(\zeta(Z)\Big) = 0 \text{ for any } Z \text{ of ghost number } -1, \tag{7.648}$$

which is precisely the content of Lemma 7.552 (on $\mathcal{H}_{\rm phys}$).

(A) State visibility. Recall $\Lambda_{\rm state}^{(\lambda_{\rm UV},\ell)} = \langle \Omega_2^{(\lambda_{\rm UV},\ell)} | \Omega_1^{(\lambda_{\rm UV},\ell)} \rangle$ with band-tagged branch states $|\Omega_{1/2}^{(\lambda_{\rm UV},\ell)}\rangle = K_{\rm IR}^{(\ell)} P_x\,|\Omega_{1/2}\rangle$ (Definition 7.551). Introduce the rank-one band operator $\rho_{21}^{(\lambda_{\rm UV},\ell)} := |\Omega_1^{(\lambda_{\rm UV},\ell)}\rangle\langle\Omega_2^{(\lambda_{\rm UV},\ell)}|$ so that $\Lambda_{\rm state}^{(\lambda_{\rm UV},\ell)} = \mathrm{Tr}\,\big(\rho_{21}^{(\lambda_{\rm UV},\ell)}\big)$. By (7.647), $\partial_{\alpha_{\rm gf}} \rho_{21}^{(\lambda_{\rm UV},\ell)} = \zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[\rho_{21}]^{(\lambda_{\rm UV},\ell)}\Big)$ (ghost number $0 \mapsto +1$), hence

$$\partial_{\alpha_{\rm gf}} \Lambda_{\rm state}^{(\lambda_{\rm UV},\ell)} = \mathrm{Tr}\Big(\partial_{\alpha_{\rm gf}} \rho_{21}^{(\lambda_{\rm UV},\ell)}\Big) = \mathrm{Tr}\Big(\zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[\rho_{21}]^{(\lambda_{\rm UV},\ell)}\Big)\Big) = 0,$$

by (7.648). This shows $\partial_{\alpha_{\rm gf}} \Lambda_{\rm state}^{(\lambda_{\rm UV},\ell)} = 0$ on $\mathcal{H}_{\rm phys}$.

(B) Law visibility. Write

$$\Lambda_{\rm law}^{(\lambda_{\rm UV},\ell)} = \mathrm{Tr}\Big[X^{(\lambda_{\rm UV},\ell)}\,\rho_0^{(\lambda_{\rm UV},\ell)}\Big], \qquad X^{(\lambda_{\rm UV},\ell)} := \Big(U_B^{(\lambda_{\rm UV},\ell)}\Big)^{\dagger} U_A^{(\lambda_{\rm UV},\ell)},$$

with band-tagged branches from Definition 7.551. Differentiating and using (7.647) twice (for U_A, U_B, and for ρ_0) we obtain

$$\begin{aligned}\partial_{\alpha_{\rm gf}} \Lambda_{\rm law}^{(\lambda_{\rm UV},\ell)} &= \mathrm{Tr}\Big[\Big(\partial_{\alpha_{\rm gf}} X^{(\lambda_{\rm UV},\ell)}\Big)\rho_0^{(\lambda_{\rm UV},\ell)}\Big] + \mathrm{Tr}\Big[X^{(\lambda_{\rm UV},\ell)}\,\partial_{\alpha_{\rm gf}} \rho_0^{(\lambda_{\rm UV},\ell)}\Big] \\ &= \mathrm{Tr}\Big[\zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[X]^{(\lambda_{\rm UV},\ell)}\Big)\,\rho_0^{(\lambda_{\rm UV},\ell)}\Big] + \mathrm{Tr}\Big[X^{(\lambda_{\rm UV},\ell)}\,\zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[\rho_0]^{(\lambda_{\rm UV},\ell)}\Big)\Big].\end{aligned}$$

Now apply the graded Leibniz rule for ζ and the cyclicity of the (super)trace to rewrite each term as a total ζ on the trace:

$$\mathrm{Tr}\Big[\zeta(A)\,B\Big] = -\,\mathrm{Tr}\Big[A\,\zeta(B)\Big] = \mathrm{Tr}\Big[\zeta(AB)\Big]$$

for ghost-number assignments consistent with $\mathrm{Tr}(\zeta(\cdot)) = 0$.

With $A = \mathcal{N}_{\alpha_{\rm gf}}[X]^{(\lambda_{\rm UV},\ell)}$ and $B = \rho_0^{(\lambda_{\rm UV},\ell)}$ in the first term, and $A = \mathcal{N}_{\alpha_{\rm gf}}[\rho_0]^{(\lambda_{\rm UV},\ell)}$, $B = X^{(\lambda_{\rm UV},\ell)}$ in the second, we get

$$\partial_{\alpha_{\rm gf}} \Lambda_{\rm law}^{(\lambda_{\rm UV},\ell)} = \mathrm{Tr}\Big[\zeta\Big(\mathcal{N}_{\alpha_{\rm gf}}[X]^{(\lambda_{\rm UV},\ell)}\, \rho_0^{(\lambda_{\rm UV},\ell)}\Big)\Big] + \mathrm{Tr}\Big[\zeta\Big(X^{(\lambda_{\rm UV},\ell)}\, \mathcal{N}_{\alpha_{\rm gf}}[\rho_0]^{(\lambda_{\rm UV},\ell)}\Big)\Big] = 0,$$

by (7.648). No additional hypothesis on the BRST-closure of the branches is required beyond (7.647) and the band/BRST commutations from Definition 7.551.

Conclusion. Both visibilities satisfy $\partial_{\alpha_{\rm gf}} \Lambda_\bullet^{(\lambda_{\rm UV},\ell)} = 0$ on $\mathcal{H}_{\rm phys}$ for $\bullet \in \{\mathrm{law}, \mathrm{state}\}$, as claimed. □

Theorem 7.557 (Quadrant-IV visibility signature on certified plateaus)**.** *Assume the explicit breakings in the law are nonzero and relevant/marginal on the band, $\mathcal{L} = \mathcal{L}_0 + \sum_k \epsilon_k \mathcal{O}_k + \zeta\Psi$ with $\epsilon_k \neq 0$, and the BRST-improved Ward identities hold on $\mathcal{H}_{\rm phys}$,*

$$\nabla_\mu^{(\rm ad)}\, \bar{J}^\mu_{a,\rm imp} = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a} \right\rangle_{\boldsymbol{\Psi}} \quad \textit{(eqs. (6.292) and (6.293)).}$$

Then there exists a plateau mask $\mathfrak{M}$ in the $(\lambda_{\rm UV}, \ell)$-grid (cf. Definition 6.300) and a constant $c(\{\epsilon_k\}) > 0$ such that, uniformly on $\mathfrak{M}$,

$$1 - \left|\Lambda_{\rm law}^{(\lambda_{\rm UV},\ell)}\right| \;\geq\; c(\{\epsilon_k\}) \;>\; 0, \qquad \lim_{V\to\infty} \left|\Lambda_{\rm state}^{(\lambda_{\rm UV},\ell)}\right| \;=\; 1,$$

and there are no exact NG modes (only pseudo-NG with GMOR-type masses proportional to spurions) [94, 261, 91, 112].

Proof Theorem 7.557. We prove the three claims in order: (I) a non–vanishing, *uniform* law–visibility deficit on a certified plateau; (II) trivial state–channel (overlap $\to 1$ at large volume); and (III) absence of exact NG together with GMOR–type scaling of pseudo–NG masses. Throughout we work on the physical sector $\mathcal{H}_{\rm phys}$, use the UV/IR taggers of Definition 7.551, the visibilities of Definition 7.553, and the channel split of Definition 7.554, with gauge–parameter independence ensured by Proposition 7.556 and BRST descent by Lemma 7.552.

(I) Non–healing law deficit on a certified plateau. Write

$$\Lambda_{\rm law}^{(\lambda_{\rm UV},\ell)} = \mathrm{Tr}\Big[X^{(\lambda_{\rm UV},\ell)}\, \rho_0^{(\lambda_{\rm UV},\ell)}\Big], \quad X^{(\lambda_{\rm UV},\ell)} := \Big(U_B^{(\lambda_{\rm UV},\ell)}\Big)^\dagger U_A^{(\lambda_{\rm UV},\ell)} \text{ (unitary)}.$$

For any density matrix ρ and unitary W,

$$1 - \mathrm{Re}\,\mathrm{Tr}(\rho W) = \tfrac{1}{2}\,\mathrm{Tr}\Big(\rho\,(I-W)^\dagger(I-W)\Big) - \tfrac{1}{2}\,\mathrm{Tr}\Big(\rho\,(W^\dagger - I)^2\Big) \;\geq\; \tfrac{1}{2}\,\mathrm{Tr}\Big(\rho\,(I-W)^\dagger(I-W)\Big), \tag{7.649}$$

since $W^\dagger W = I$ and $\mathrm{Tr}\Big(\rho A^\dagger A\Big) \geq 0$ for any A. Thus $1 - |\,\mathrm{Tr}(\rho W)| \geq 1 - \mathrm{Re}\,\mathrm{Tr}(\rho W) \geq \tfrac{1}{2}\,\mathrm{Tr}\Big(\rho\,(I-W)^\dagger(I-W)\Big)$. With $\rho = \rho_0^{(\lambda_{\rm UV},\ell)}$ and $W = X^{(\lambda_{\rm UV},\ell)}$,

$$1 - \left|\Lambda_{\rm law}^{(\lambda_{\rm UV},\ell)}\right| \;\geq\; \tfrac{1}{2}\,\mathrm{Tr}\Big(\rho_0^{(\lambda_{\rm UV},\ell)}\, \Delta^\dagger \Delta\Big), \qquad \Delta := I - X^{(\lambda_{\rm UV},\ell)}. \tag{7.650}$$

To relate Δ to the explicit breakings, write (Dyson/Duhamel expansion on the band)

$$X^{(\lambda_{\mathrm{UV}},\ell)} = \mathcal{T}\exp\Big(-i\int_0^1 ds\;\Delta\hat{H}^{(\lambda_{\mathrm{UV}},\ell)}(s)\Big), \qquad \Delta\hat{H}^{(\lambda_{\mathrm{UV}},\ell)}(s) := \Big(\sum_k \epsilon_k\,\hat{\mathcal{O}}_k\Big)_I^{(\lambda_{\mathrm{UV}},\ell)}(s),$$

where the subscript I denotes interaction picture with respect to the common s–dependent interpolation of the law branches (any smooth homotopy suffices; the bound below is homotopy–independent). Then

$$\Delta = \int_0^1 ds\,\Big(-i\Delta\hat{H}^{(\lambda_{\mathrm{UV}},\ell)}(s)\Big) + \int_{0<s_2<s_1<1} ds_1 ds_2\,\Big(-i\Delta\hat{H}(s_1)\Big)\Big(-i\Delta\hat{H}(s_2)\Big) + \cdots .$$

Keeping the exact (non–truncated) series, the quadratic form in (7.650) is bounded from below by the leading non–vanishing contribution and controlled by the *spectral* (T–odd) channel of the holosymmetric readout (see the triadic split of Definition 7.554 and the additive decomposition of Proposition 7.555). The BRST–improved adjoint–covariant Ward identity on $\mathcal{H}_{\mathrm{phys}}$,

$$\nabla_\mu^{(\mathrm{ad})}\,\bar{J}^\mu_{a,\mathrm{imp}} = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}\right\rangle_{\mathbf{\Psi}} \quad \text{(eqs. (6.292) and (6.293))},$$

implies that the spectral (commutator/T–odd) cumulants of the band dynamics are *nonzero* whenever $\{\epsilon_k\} \neq 0$ (the only source of non–conservation in QIV). Therefore there is a channel–wise constant $c_{\mathrm{spec}}(\{\epsilon_k\}) > 0$ such that, on any region where the UV/IR tags are stable (no large slope/curvature), the spectral contribution to the right–hand side of (7.650) is bounded below by $c_{\mathrm{spec}}(\{\epsilon_k\})$.

By Definition 6.300 (compactness of the $(\lambda_{\mathrm{UV}},\ell)$–grid, continuity of the tagged maps, and uniform boundedness of the band–restricted generators), there exists a nonempty *plateau mask* $\mathfrak{M}$ on which slopes/curvatures of the tagged observables are within tolerance; hence the spectral lower bound is uniform on $\mathfrak{M}$. Set

$$c(\{\epsilon_k\}) := \tfrac{1}{2}\,c_{\mathrm{spec}}(\{\epsilon_k\}) > 0.$$

Then (7.650) yields, uniformly on $\mathfrak{M}$,

$$1 - \left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\geq\; c(\{\epsilon_k\}) \;>\; 0,$$

establishing the non–healing law deficit. (Gauge–parameter independence of this bound follows from Proposition 7.556.)

(II) Trivial state channel and unique vacuum. Let $|\Omega_{1/2}^{(\lambda_{\mathrm{UV}},\ell)}\rangle = K_{\mathrm{IR}}^{(\ell)} P_x(\lambda_{\mathrm{UV}})\,|\Omega_{1/2}\rangle$ be the band–tagged branch states of Definition 7.551. In QIV, explicit breakings $\{\epsilon_k\} \neq 0$ remove the vacuum manifold and select a *unique* infinite–volume vacuum (GNS representation unique up to phase). Standard exponential clustering for gapped phases and uniqueness of the KMS/GNS state imply that any two finite–volume ground states prepared by local (finite–depth) circuits that respect the same law converge to the *same* infinite–volume state as $V \to \infty$. Since the UV/IR taggers $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ project to long–wavelength content, the

difference between the branch preparations is supported in a boundary layer whose relative weight vanishes with V. Therefore,

$$\Lambda_{\text{state}}^{(\lambda_{\text{UV}},\ell)}(V) = \langle \Omega_2^{(\lambda_{\text{UV}},\ell)} | \Omega_1^{(\lambda_{\text{UV}},\ell)} \rangle \xrightarrow[V\to\infty]{} 1.$$

Equivalently, the fidelity per unit volume tends to 1, which is the precise meaning of a *trivial* state channel (no thermodynamic orthogonality) on QIV plateaus. This discriminates QIV from QII, where multiple vacua give $\Lambda_{\text{state}}(V) \to 0$.

(III) No exact NG and GMOR–type pseudo–NG scaling. Goldstone's theorem requires a conserved Noether current for a continuous symmetry. In QIV, the BRST–improved Ward identity shows that the divergence is *nonzero* and entirely sourced by the explicit spurions: $\nabla_\mu^{(\text{ad})} \bar{J}^\mu_{a,\text{imp}} = \sum_k \epsilon_k \langle \mathcal{S}_{k,a} \rangle_{\mathbf{\Psi}} \neq 0$ on $\mathcal{H}_{\text{phys}}$. Hence no exact NG poles can occur. In the broken–basis (π, h), the band Hessian of Section 7.9 couples the would–be NG fields to the explicit sources; standard current–algebra/PCAC manipulations (integrate the Ward identity against the NG interpolating field and LSZ–reduce the two–point function) give the GMOR–type relation

$$\boxed{f_\pi^2\, m_\pi^2 = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\text{UV}})} \right\rangle_{\mathbf{\Psi}} + \mathcal{O}(\epsilon^2)}$$

where b denotes the broken generator associated with the pseudo–NG mode (i.e., the projection of the Ward source onto that broken direction), and $\mathcal{S}_{k,a}^{(\lambda_{\text{UV}})}$ is the source operator already used in eqs. (6.292) and (6.293). Here f_π is the NG decay constant in the $\epsilon \to 0$ limit. Thus the would–be NG acquire *pseudo–NG* masses proportional to the spurions on the plateau (and remain gauge–parameter independent by Proposition 7.556) [94, 261, 91, 112].

Conclusion. Combining (I)–(III) yields a nonempty plateau mask $\mathfrak{M}$ and a constant $c(\{\epsilon_k\}) > 0$ such that, uniformly on $\mathfrak{M}$,

$$1 - \left|\Lambda_{\text{law}}^{(\lambda_{\text{UV}},\ell)}\right| \geq c(\{\epsilon_k\}) > 0, \qquad \lim_{V\to\infty} \left|\Lambda_{\text{state}}^{(\lambda_{\text{UV}},\ell)}\right| = 1,$$

with no exact NG and pseudo–NG obeying GMOR–type scaling, as claimed. □

Corollary 7.558 (QIV discrimination against QIII and QII)**.** *On $\mathfrak{M}$, QIV satisfies $1 - |\Lambda_{\text{law}}| \geq c(\{\epsilon_k\}) > 0$ and $|\Lambda_{\text{state}}| \to 1$; by contrast, QIII has $1 - |\Lambda_{\text{law}}| \sim \ell^{\Delta-(d+z)} \to 0$ with $|\Lambda_{\text{state}}| \approx 1$, and QII has $|\Lambda_{\text{law}}| \approx 1$ with $|\Lambda_{\text{state}}(V)| \to 0$ as $V \to \infty$.*

Proof Corollary 7.558. Fix a certified plateau mask $\mathfrak{M}$ in the $(\lambda_{\text{UV}}, \ell)$–grid in the sense of Definition 6.300, and work on the physical sector $\mathcal{H}_{\text{phys}}$ with the UV/IR–tagged visibilities of Definition 7.553. Gauge–parameter independence of all statements below follows from Proposition 7.556 together with Lemma 7.552.

QIV behaviour. By Theorem 7.557, when the explicit breakings are nonzero and relevant/-marginal on the band, there exists $c(\{\epsilon_k\}) > 0$ such that, uniformly on $\mathfrak{M}$,

$$1 - \left|\Lambda_{\text{law}}^{(\lambda_{\text{UV}},\ell)}\right| \;\geq\; c(\{\epsilon_k\}) > 0, \qquad \lim_{V\to\infty} \left|\Lambda_{\text{state}}^{(\lambda_{\text{UV}},\ell)}(V)\right| = 1.$$

Thus QIV exhibits a *non–healing* law–visibility deficit and a *trivial* state channel (unique vacuum).

QIII contrast. In Quadrant III (explicit but *small* law breakings; state symmetric), the emergent–symmetry analysis of Section 7.8 says that if the leading breaking operators are RG–irrelevant with scaling dimension Δ, then on any certified plateau one has the improvement law

$$1 - \left|\Lambda_{\text{law}}^{(\lambda_{\text{UV}},\ell)}\right| = \mathcal{O}\Big(\ell^{\,\Delta-(d+z)}\Big) \xrightarrow[\ell\downarrow 0]{} 0, \qquad \left|\Lambda_{\text{state}}^{(\lambda_{\text{UV}},\ell)}\right| \approx 1.$$

(Here d is the spatial dimension and z the dynamical exponent; the statement is the band/IR form of the emergent–symmetry scaling summarized in Section 7.8.) Therefore, unlike QIV, QIII features a *healing* law channel (deficit vanishes with coarse–graining) while the state channel remains trivial.

QII contrast. In Quadrant II (law symmetric; *spontaneously* asymmetric state), the QII diagnostics of Section 7.7 give

$$\left|\Lambda_{\text{law}}^{(\lambda_{\text{UV}},\ell)}\right| \approx 1 \quad \text{on plateaus, while} \quad \lim_{V\to\infty}\left|\Lambda_{\text{state}}^{(\lambda_{\text{UV}},\ell)}(V)\right| = 0,$$

due to thermodynamic orthogonality of distinct vacua (SSB; see also [94, 261, 91] for the standard orthogonality/cluster arguments). Thus, contrary to QIV, QII has an *intact* law channel and a *nontrivial* (decohering) state channel.

Phase	Condition on $\lvert\Lambda_{\text{law}}\rvert$	Condition on $\lvert\Lambda_{\text{state}}\rvert$
QIV:	$1-\lvert\Lambda_{\text{law}}\rvert \;\geq\; c(\{\epsilon_k\}) > 0$	$\lvert\Lambda_{\text{state}}\rvert \;\to\; 1$
QIII:	$1-\lvert\Lambda_{\text{law}}\rvert \;\sim\; \ell^{\Delta-(d+z)} \;\to\; 0$	$\lvert\Lambda_{\text{state}}\rvert \;\approx\; 1$
QII:	$\lvert\Lambda_{\text{law}}\rvert \;\approx\; 1$	$\lvert\Lambda_{\text{state}}(V)\rvert \;\to\; 0 \;(V\to\infty)$

Table 7.3: Comparing the three behaviours on their certified plateaus (denoted generically by $\mathfrak{M}$ for each quadrant):

Discrimination. These signatures are mutually exclusive away from critical boundaries (which are excluded by the plateau tolerances in Definition 6.300), hence they distinguish QIV from QIII and QII as stated. □

Intuition. QIV shows a *non-healing* law deficit and a *trivial* state channel (unique vacuum); QIII heals in the IR (emergent symmetry), and QII displays thermodynamic decoherence of states (vacua orthogonalize).

7.9.2 Fix the Symmetry Reference & Spurions

Definition 7.559 (Reference symmetry data and spurion assignment)**.** Let G be the reference symmetry used in Sections 7.1 and 7.7, with generators $\{T_a\}$ (structure constants $f_{ab}{}^{c}$)

acting on the generalized field stack $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^\top$ via a (possibly reducible) representation ρ. Decompose the band law as in Definition 7.551:

$$\mathcal{L}^{(\lambda_{\mathrm{UV}},\ell)} = \left(\mathcal{L}_0 + \sum_k \epsilon_k \, \mathcal{O}_k + \zeta \Psi\right)^{(\lambda_{\mathrm{UV}},\ell)}.$$

A *spurion assignment* is a choice of transformation rules for the couplings $\{\epsilon_k\}$ such that

$$\delta_a(\epsilon_k \, \mathcal{O}_k) := (\delta_a \epsilon_k) \, \mathcal{O}_k + \epsilon_k \, \delta_a \mathcal{O}_k \;\; = \;\; \nabla_\mu^{(\mathrm{ad})} \, I_a^\mu \;\; + \;\; \zeta(B_a),$$

for some local improvement current I_a^μ (total-derivative improvement) and some local insertion B_a with $\zeta(B_a)$ BRST-exact. Equivalently, on $\mathcal{H}_{\mathrm{phys}}$ the explicit term is G-invariant up to improvements.

BRST improvement (gauge-fixing sector) The improvement term is defined as

$$J^\mu_{a,\mathrm{imp}} = J^\mu_a - \zeta \, \Lambda^\mu_a, \tag{7.651}$$

with the variation given by (eq. (6.292))

$$\delta_a \Psi = \alpha_a \, \chi_a + (\nabla_\mu \alpha_a) \Lambda^\mu_a. \tag{7.652}$$

Spurion improvement (explicit-breaking sector) The ward identity is given by (Definition 7.559)

$$\delta_a(\epsilon_k \mathcal{O}_k) = \nabla_\mu^{(\mathrm{ad})} I_a^\mu + \zeta(B_a). \tag{7.653}$$

Here Λ^μ_a and I^μ_a are *different* objects: Λ^μ_a is fixed by the variation of the gauge fermion Ψ, while I^μ_a collects total-derivative terms that arise when varying the explicit-breaking piece with spurions. Both are legitimate current improvements and can be combined consistently.

Compact band Ward identity (absorbing the spurion improvement). Since currents are defined up to improvements and BRST-exact pieces on $\mathcal{H}_{\mathrm{phys}}$, one may absorb I^μ_a into the improved current,

$$J^\mu_{a,\mathrm{imp}} \;\longrightarrow\; J^\mu_{a,\mathrm{imp}} + I^\mu_a,$$

which yields the scale-tagged Ward identity in the compact form used throughout:

$$\nabla_\mu^{(\mathrm{ad})} \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_k \epsilon_k \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\mathbf{\Psi}} \quad \text{on } \mathcal{H}_{\mathrm{phys}} \quad \text{(eq. (7.665))}.$$

Intuition. Treating ϵ_k as spurions means we "pretend" symmetry is exact by letting ϵ_k transform in a conjugate representation that cancels the non-invariance of $\mathcal{O}_k$. The remainder is a divergence (improvement) and a BRST-exact term, both harmless for Ward identities on $\mathcal{H}_{\mathrm{phys}}$.

Operator-level AR decomposition: local insertions and their properties

Definition 7.560 (Algebraic–renormalization (AR) decomposition of a local variation)**.** For each local operator $\mathcal{O}_k$ transforming in a (possibly reducible) G-module with generators δ_a, its renormalized local variation admits the AR decomposition

$$\delta_a \mathcal{O}_k \;=\; (R_a)_k{}^j\, \mathcal{O}_j \;+\; \partial_\mu L^\mu_{a,k} \;+\; \zeta(\Sigma_{a,k}), \tag{7.654}$$

where:

- R_a are the representation matrices on the operator index space (so $[R_a, R_b] = f_{ab}{}^c R_c$);
- $L^\mu_{a,k}$ is a local current-density (polynomial/analytic in fields and finitely many derivatives), with ghost number 0 and engineering dimension $\dim(\mathcal{O}_k) - 1$; it packages the total-derivative (Noether-improvement) part of $\delta_a \mathcal{O}_k$ once the linear mixing $(R_a)_k{}^j \mathcal{O}_j$ is peeled off;
- $\Sigma_{a,k}$ is a local functional with ghost number -1 such that $\zeta(\Sigma_{a,k})$ has ghost number 0 and represents the BRST-exact remainder of the variation that is not a total derivative.

Remark 7.561 (Name clash is avoided)**.** The symbol $L^\mu_{a,k}$ here is *not* the same as Λ^μ_a used in the BRST improvement of the Noether current, $J^\mu_{a,\mathrm{imp}} = J^\mu_a - \zeta\, \Lambda^\mu_a$ (eq. (6.292)). We reserve Λ^μ_a exclusively for eq. (6.292) and use $L^\mu_{a,k}$ for the operator-level insertion in (7.654).

Lemma 7.562 (Allowed redefinitions (equivalence class of insertions))**.** *The pair $(L^\mu_{a,k}, \Sigma_{a,k})$ in (7.654) is defined only up to*

$$L^\mu_{a,k} \;\mapsto\; L^\mu_{a,k} + \partial_\nu K^{[\nu\mu]}_{a,k} \;+\; \zeta(U^\mu_{a,k}), \qquad \Sigma_{a,k} \;\mapsto\; \Sigma_{a,k} \;-\; \partial_\mu U^\mu_{a,k}, \tag{7.655}$$

where $K^{[\nu\mu]}_{a,k}$ is antisymmetric in (ν,μ) and $U^\mu_{a,k}$ is a local functional of ghost number -1. These redefinitions leave the combination $\partial_\mu L^\mu_{a,k} + \zeta(\Sigma_{a,k})$ unchanged.

Proof. Since $\partial_\mu \partial_\nu K^{[\nu\mu]}_{a,k} = 0$ identically and $[\zeta, \partial_\mu] = 0$, we have

$$\partial_\mu\Big(L^\mu_{a,k} + \partial_\nu K^{[\nu\mu]}_{a,k} + \zeta(U^\mu_{a,k})\Big) + \zeta\Big(\Sigma_{a,k} - \partial_\mu U^\mu_{a,k}\Big) = \partial_\mu L^\mu_{a,k} + \zeta(\Sigma_{a,k}).$$

□

Lemma 7.563 (Ghost numbers, dimensions, and covariance)**.** *With the assignments $\mathrm{gh}(L^\mu_{a,k}) = 0$ and $\mathrm{gh}(\Sigma_{a,k}) = -1$, the combination $\partial_\mu L^\mu_{a,k} + \zeta(\Sigma_{a,k})$ has ghost number 0 and the same engineering dimension as $\mathcal{O}_k$. Moreover, under the G-action,*

$$\delta_b\Big(\delta_a \mathcal{O}_k - (R_a)_k{}^j \mathcal{O}_j\Big) = f_{ba}{}^c\, \Big(\partial_\mu L^\mu_{c,k} + \zeta(\Sigma_{c,k})\Big)\,,$$

up to further redefinitions of the form (7.655). Hence (7.654) is compatible with the Wess–Zumino consistency condition.

Proof. Ghost numbers. By construction $\mathrm{gh}(\mathcal{O}_k) = 0$, $\mathrm{gh}(\zeta) = +1$, and $\mathrm{gh}(\partial_\mu) = 0$. With $\mathrm{gh}(L^\mu_{a,k}) = 0$ and $\mathrm{gh}(\Sigma_{a,k}) = -1$,

$$\mathrm{gh}\Big(\partial_\mu L^\mu_{a,k}\Big) = 0, \qquad \mathrm{gh}(\zeta(\Sigma_{a,k})) = \mathrm{gh}(\zeta) + \mathrm{gh}(\Sigma_{a,k}) = 1 + (-1) = 0.$$

Hence $\mathrm{gh}\big(\partial_\mu L^\mu_{a,k} + \zeta(\Sigma_{a,k})\big) = 0$, matching $\mathrm{gh}(\delta_a \mathcal{O}_k - (R_a)_k{}^j \mathcal{O}_j)$.

Engineering dimensions. Let $\dim[\mathcal{O}_k] = \Delta_k$ (engineering dimension). The canonical decomposition

$$\delta_a \mathcal{O}_k - (R_a)_k{}^j \mathcal{O}_j \;=\; \partial_\mu L^\mu_{a,k} + \zeta(\Sigma_{a,k}) \tag{7.656}$$

must preserve dimensions. Since $\dim[\partial_\mu] = 1$ and ζ is dimensionless in the BRST complex, choosing

$$\dim[L^\mu_{a,k}] = \Delta_k - 1, \qquad \dim[\Sigma_{a,k}] = \Delta_k$$

ensures $\dim[\partial_\mu L^\mu_{a,k}] = \dim[\zeta(\Sigma_{a,k})] = \Delta_k$. These assignments can always be reached within the improvement freedom (7.655) (see below), which allows adding total derivatives and ζ–exact terms that do not change (7.656) but do adjust the dimensions of the representatives.

Covariance and Wess–Zumino (WZ) consistency. Define the remainder

$$\Delta_{a,k} \;:=\; \delta_a \mathcal{O}_k - (R_a)_k{}^j \mathcal{O}_j \;=\; \partial_\mu L^\mu_{a,k} + \zeta(\Sigma_{a,k}).$$

WZ consistency requires

$$\delta_b \Delta_{a,k} - \delta_a \Delta_{b,k} \;=\; f_{ba}{}^c \, \Delta_{c,k}. \tag{7.657}$$

Using that δ_b is an internal (global) symmetry derivation commuting with spacetime derivatives and with the BRST differential on local operators,[16]

$$\delta_b \Delta_{a,k} = \partial_\mu(\delta_b L^\mu_{a,k}) + \zeta(\delta_b \Sigma_{a,k}), \qquad \delta_a \Delta_{b,k} = \partial_\mu(\delta_a L^\mu_{b,k}) + \zeta(\delta_a \Sigma_{b,k}).$$

Subtracting and comparing with the right-hand side of (7.657) gives

$$\partial_\mu\Big(\delta_b L^\mu_{a,k} - \delta_a L^\mu_{b,k} - f_{ba}{}^c L^\mu_{c,k}\Big) \;+\; \zeta(\delta_b \Sigma_{a,k} - \delta_a \Sigma_{b,k} - f_{ba}{}^c \Sigma_{c,k}) \;=\; 0.$$

By locality and the improvement freedom (7.655), any local expression of ghost number 0 and dimension Δ_k that is annihilated by the operator $\partial_\mu \oplus \zeta$ can be written as a sum of a total derivative and a BRST–exact term. Concretely, there exist local tensors $U^{[\nu\mu]}_{ab,k}$ (antisymmetric in ν, μ), $V^\mu_{ab,k}$ and $W_{ab,k}$ with

$$\begin{aligned} \mathrm{gh}(U) &= 0, \quad \dim[U] = \Delta_k - 2; \\ \mathrm{gh}(V) &= -1, \quad \dim[V] = \Delta_k - 1; \\ \mathrm{gh}(W) &= -2, \quad \dim[W] = \Delta_k. \end{aligned}$$

such that

$$\delta_b L^\mu_{a,k} - \delta_a L^\mu_{b,k} - f_{ba}{}^c L^\mu_{c,k} = \partial_\nu U^{[\nu\mu]}_{ab,k} + \zeta(V^\mu_{ab,k}), \tag{7.658}$$

$$\delta_b \Sigma_{a,k} - \delta_a \Sigma_{b,k} - f_{ba}{}^c \Sigma_{c,k} = -\,\partial_\mu V^\mu_{ab,k} + \zeta(W_{ab,k}). \tag{7.659}$$

Plugging (7.658)–(7.659) back into the previous display and using $[\partial_\mu, \zeta] = 0$, $\zeta^2 = 0$, and $\partial_\mu \partial_\nu U^{[\nu\mu]}_{ab,k} \equiv 0$, one verifies (7.657).

[16] On the local algebra one has $[\delta_b, \partial_\mu] = 0$ and $[\delta_b, \zeta] = 0$; the latter expresses the G–invariance of the BRST complex (Nielsen/BRST robustness on $\mathcal{H}_{\mathrm{phys}}$).

Finally, redefine the representatives by the allowed improvements (the "AR redefinitions" (7.655))

$$L^{\mu}_{a,k} \;\mapsto\; L^{\mu}_{a,k} - \tfrac{1}{2}\Big(\partial_\nu U^{[\nu\mu]}_{ab,k} + \zeta V^{\mu}_{ab,k}\Big), \qquad \Sigma_{a,k} \;\mapsto\; \Sigma_{a,k} - \tfrac{1}{2}\Big(-\partial_\mu V^{\mu}_{ab,k} + \zeta W_{ab,k}\Big),$$

which leave $\partial_\mu L^{\mu}_{a,k} + \zeta(\Sigma_{a,k})$ unchanged but make the transformed objects strictly covariant:

$$\delta_b L^{\mu}_{a,k} - \delta_a L^{\mu}_{b,k} = f_{ba}{}^{c} L^{\mu}_{c,k}, \qquad \delta_b \Sigma_{a,k} - \delta_a \Sigma_{b,k} = f_{ba}{}^{c} \Sigma_{c,k}.$$

Thus (7.654) is compatible with WZ consistency, completing the proof. □

Corollary 7.564 (Induced spurion-sector objects are unique on $\mathcal{H}_{\text{phys}}$)**.** *Upon multiplying* (7.654) *by* ϵ_k *and summing over* k*, define*

$$I^{\mu}_{a} := \epsilon_k\, L^{\mu}_{a,k}, \qquad B_a := \epsilon_k\, \Sigma_{a,k}.$$

Under (7.655)*,* $I^{\mu}_{a} \mapsto I^{\mu}_{a} + \partial_\nu K^{[\nu\mu]}_{a}$ *and* $B_a \mapsto B_a - \partial_\mu U^{\mu}_{a}$*, so* $\nabla^{(\text{ad})}_{\mu} I^{\mu}_{a} + \zeta(B_a)$ *is unchanged and, on* $\mathcal{H}_{\text{phys}}$*, its insertions are insensitive to these redefinitions (Noether improvement and BRST exactness drop out).*

Proof. Step 1: Invariance of the composite operator. Starting from (7.654),

$$\delta_a \mathcal{O}_k - (R_a)_k{}^{j} \mathcal{O}_j \;=\; \partial_\mu L^{\mu}_{a,k} + \zeta(\Sigma_{a,k}),$$

multiply by ϵ_k and sum over k (explicit-breaking spurions are constants in QIV), obtaining

$$\epsilon_k\Big(\delta_a \mathcal{O}_k - (R_a)_k{}^{j} \mathcal{O}_j\Big) \;=\; \partial_\mu I^{\mu}_{a} + \zeta(B_a), \qquad I^{\mu}_{a} := \epsilon_k L^{\mu}_{a,k}, \quad B_a := \epsilon_k \Sigma_{a,k}. \tag{7.660}$$

Under the allowed improvements (7.655) one may take, without loss of generality,

$$L^{\mu}_{a,k} \mapsto L^{\mu}_{a,k} + \partial_\nu K^{[\nu\mu]}_{a,k}, \qquad \Sigma_{a,k} \mapsto \Sigma_{a,k} - \partial_\mu U^{\mu}_{a,k},$$

(possible extra ζ–exact pieces can be absorbed into a redefinition of U, K). Summing with ϵ_k gives

$$I^{\mu}_{a} \mapsto I^{\mu}_{a} + \partial_\nu K^{[\nu\mu]}_{a}, \qquad B_a \mapsto B_a - \partial_\mu U^{\mu}_{a},$$

with $K^{[\nu\mu]}_{a} := \epsilon_k K^{[\nu\mu]}_{a,k}$ and $U^{\mu}_{a} := \epsilon_k U^{\mu}_{a,k}$. Therefore

$$\begin{aligned} \partial_\mu I^{\mu}_{a} + \zeta(B_a) \;&\mapsto\; \partial_\mu\Big(I^{\mu}_{a} + \partial_\nu K^{[\nu\mu]}_{a}\Big) + \zeta(B_a - \partial_\mu U^{\mu}_{a}) \\ &=\; \partial_\mu I^{\mu}_{a} + \underbrace{\partial_\mu\partial_\nu K^{[\nu\mu]}_{a}}_{=0} + \zeta(B_a) - \underbrace{\partial_\mu \zeta(U^{\mu}_{a})}_{[\partial,\zeta]=0} \;=\; \partial_\mu I^{\mu}_{a} + \zeta(B_a). \end{aligned}$$

Since $\nabla^{(\text{ad})}_{\mu}$ acts as ∂_μ on adjoint scalars and as the adjoint covariant divergence on adjoint vectors, replacing ∂_μ by $\nabla^{(\text{ad})}_{\mu}$ in (7.660) preserves the same conclusion: the curl improvement contributes a double divergence that vanishes identically, and the ζ–improvement contributes a BRST-exact divergence. Hence the composite

$$\mathcal{J}_a \;:=\; \nabla^{(\text{ad})}_{\mu} I^{\mu}_{a} + \zeta(B_a)$$

is invariant under (7.655).

Step 2: Invariance of insertions on $\mathcal{H}_{\rm phys}$. Let $\mathcal{W}$ be any time-ordered product of BRST-closed, gauge-invariant operators supported away from the boundary (the standard observable class used on plateaus). Consider the change in any insertion:

$$\Delta \equiv \Big\langle\, T\{\mathcal{W}\ \mathcal{J}_a\}\,\Big\rangle \ \mapsto\ \Big\langle\, T\{\mathcal{W}\ (\mathcal{J}_a + \partial_\mu\partial_\nu K_a^{[\nu\mu]} - \partial_\mu\zeta(U_a^\mu))\}\,\Big\rangle.$$

The double divergence integrates to a boundary term (or, in momentum space, carries a factor $p_\mu p_\nu$ that vanishes in the zero-momentum limit used to define the plateau readouts). By the usual Noether-improvement argument, such total derivatives do not affect correlation functions of local observables with compact support. The BRST-exact contribution vanishes on $\mathcal{H}_{\rm phys}$ by the quartet mechanism/Nielsen identities: for BRST-closed $\mathcal{W}$, $\langle T\{\mathcal{W}\,\zeta(X)\}\rangle = 0$ because ζ acts as a graded derivation, $\zeta\mathcal{W} = 0$, and $\zeta\,|\Omega\rangle = \langle\Omega|\,\zeta = 0$ on the physical vacuum. Therefore Δ is unchanged.

Step 3: Covariance and uniqueness class. By Lemma 7.563, the representatives can be chosen to transform covariantly under the G–action, and they have the correct ghost numbers and engineering dimensions. The preceding steps show that all choices related by (7.655) yield the same composite $\mathcal{J}_a$ and the same physical insertions. Hence the induced spurion-sector objects are unique on $\mathcal{H}_{\rm phys}$, completing the proof. □

Remark 7.565 (Operational recipe and disambiguation)**.** To compute the spurion contribution in practice: (i) evaluate $\delta_a\mathcal{O}_k$ and separate the pure mixing $(R_a)_k{}^j\mathcal{O}_j$; (ii) integrate by parts to isolate $\partial_\mu L^\mu_{a,k}$; (iii) identify the remainder as $\zeta(\Sigma_{a,k})$. This $L^\mu_{a,k}$ is unrelated to the gauge-fermion insertion Λ^μ_a in eq. (6.292); the latter only enters $J^\mu_{a,\rm imp}$, while $L^\mu_{a,k}$ (through I^μ_a) enters the spurion-improved Ward identity Definition 7.559.

Lemma 7.566 (Existence and (cohomological) uniqueness of spurion laws)**.** *Given $\{\mathcal{O}_k\}$ forming a finite-dimensional G-module under δ_a, there exist linear spurion transformation laws $\delta_a\epsilon_k = -(R_a)_k{}^j\,\epsilon_j$ (with R_a the dual representation matrices to those acting on $\{\mathcal{O}_k\}$) that realize Definition 7.559. Any two such choices differ by redefinitions $\epsilon_k \mapsto \epsilon_k + \zeta(\chi_k)$ and improvements $I^\mu_a \mapsto I^\mu_a + \partial_\nu K_a^{[\nu\mu]}$ which are invisible on $\mathcal{H}_{\rm phys}$.*

Proof Lemma 7.566. **Step 1: Local variation of the breaking operators.** Because $\{\mathcal{O}_k\}$ is a G-module, the renormalized local variation admits the algebraic–renormalization decomposition

$$\delta_a\mathcal{O}_k = (R_a)_k{}^j\,\mathcal{O}_j \ +\ \partial_\mu L^\mu_{a,k} \ +\ \zeta(\Sigma_{a,k}), \tag{7.661}$$

with local insertions $L^\mu_{a,k}$ (ghost number 0) and $\Sigma_{a,k}$ (ghost number -1); here R_a furnish a (possibly reducible) matrix representation of $\mathfrak{g} = \mathrm{Lie}(G)$ on the operator index k, and the last term encodes BRST-exact pieces.

Step 2: Existence (constructive spurion rule). Define the spurion transformation as the *dual* action:

$$\delta_a\epsilon_k := -(R_a)_k{}^j\,\epsilon_j. \tag{7.662}$$

Then

$$\begin{aligned}\delta_a(\epsilon_k\mathcal{O}_k) &= (\delta_a\epsilon_k)\mathcal{O}_k + \epsilon_k\delta_a\mathcal{O}_k\\ &= -\epsilon_j(R_a)_k{}^j\mathcal{O}_k + \epsilon_k(R_a)_k{}^j\mathcal{O}_j \ +\ \partial_\mu(\epsilon_k L^\mu_{a,k}) \ +\ \zeta(\epsilon_k\Sigma_{a,k}).\end{aligned}$$

Relabel the dummy indices in the first two terms; they cancel identically. Hence

$$\delta_a(\epsilon_k \mathcal{O}_k) = \partial_\mu(\epsilon_k L^\mu_{a,k}) + \zeta(\epsilon_k \Sigma_{a,k}).$$

Setting

$$I^\mu_a := \epsilon_k L^\mu_{a,k}, \qquad B_a := \epsilon_k \Sigma_{a,k}, \tag{7.663}$$

we obtain exactly the structure required in Definition 7.559: $\delta_a(\epsilon_k \mathcal{O}_k) = \nabla^{(\mathrm{ad})}_\mu I^\mu_a + \zeta(B_a)$. This proves *existence*.

Step 3: Consistency with the Lie algebra (Wess–Zumino condition). Using (7.662),

$$[\delta_a, \delta_b]\epsilon_k = -(R_a)_k{}^j \delta_b \epsilon_j + (a \leftrightarrow b) = (R_a R_b - R_b R_a)_k{}^j \epsilon_j = -[R_a, R_b]_k{}^j \epsilon_j = f_{ab}{}^c \, \delta_c \epsilon_k,$$

since $[R_a, R_b] = f_{ab}{}^c R_c$. Thus the spurion assignment is algebraically consistent and transforms covariantly.

Step 4: Basis independence. Under a change of operator basis $\mathcal{O}'_k = M_k{}^j \mathcal{O}_j$, the representation matrices transform as $R'_a = M R_a M^{-1}$. Choosing the dual spurion basis $\epsilon' = (M^{-T})\,\epsilon$ makes (7.662) basis covariant: $\delta_a \epsilon' = -R'_a \, \epsilon'$. Therefore the construction is intrinsic to the G-module carried by $\{\mathcal{O}_k\}$.

Step 5: Cohomological uniqueness (ambiguities are ζ-exact or improvements). Suppose $\delta'_a \epsilon_k$ is another spurion rule that also realizes Definition 7.559, i.e.

$$\delta'_a(\epsilon_k \mathcal{O}_k) = \partial_\mu I'^\mu_a + \zeta(B'_a).$$

Subtracting the two realizations gives

$$\big(\delta'_a - \delta_a\big)\epsilon_k \; \mathcal{O}_k = \partial_\mu(I'^\mu_a - I^\mu_a) + \zeta(B'_a - B_a). \tag{7.664}$$

By (7.661), the cohomology of local functionals at ghost number 0 modulo total derivatives is spanned by the classes of $\{\mathcal{O}_k\}$; in that quotient the right-hand side of (7.664) vanishes. Hence, in $H^0(\zeta \mid d)$,

$$\Big[(\delta'_a - \delta_a)\epsilon_k\Big]\,[\mathcal{O}_k] = 0.$$

Because the classes $[\mathcal{O}_k]$ are linearly independent in the chosen basis, it follows that $(\delta'_a - \delta_a)\epsilon_k$ is *cohomologically trivial*: there exist local functionals χ_k of ghost number -1 such that

$$(\delta'_a - \delta_a)\epsilon_k = \zeta(\chi_k).$$

Plugging this into (7.664), the entire difference is absorbed into a ζ-exact term plus a total derivative. In other words, the two realizations differ by:

$$\epsilon_k \;\mapsto\; \epsilon_k + \zeta(\chi_k), \qquad I^\mu_a \;\mapsto\; I^\mu_a + \partial_\nu K^{[\nu\mu]}_a,$$

for some antisymmetric $K^{[\nu\mu]}_a$. Both changes are invisible on $\mathcal{H}_{\mathrm{phys}}$: ζ-exact deformations drop out of physical matrix elements, and Noether improvements (total divergences or antisymmetric superpotentials) do not affect Ward identities or conserved charges. This proves *cohomological uniqueness*.

Conclusion. The dual spurion rule (7.662) exists, is algebraically consistent, basis independent, and is unique up to BRST-exact redefinitions of the spurions and standard Noether improvements, as claimed. □

Definition 7.567 (Scale-tagged BRST-improved current and Ward identity)**.** Let $J^{\mu}_{a,\mathrm{imp}}$ be the improved current of eq. (6.292). Define its band-tagged version by

$$\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} := \Big(J^{\mu}_{a,\mathrm{imp}}\Big)^{(\lambda_{\mathrm{UV}},\ell)} = K^{(\ell)}_{\mathrm{IR}}\,P_x(\lambda_{\mathrm{UV}})\,J^{\mu}_{a,\mathrm{imp}}\,P_x(\lambda_{\mathrm{UV}})K^{(\ell)}_{\mathrm{IR}}.$$

On the physical sector $\mathcal{H}_{\mathrm{phys}}$ the *scale-tagged Ward identity* reads

$$\nabla^{(\mathrm{ad})}_{\mu}\,\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = \sum_k \epsilon_k \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\boldsymbol{\Psi}} \qquad \text{on } \mathcal{H}_{\mathrm{phys}}, \tag{7.665}$$

where $\mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a}$ is the (UV-tagged) source operator appearing in eq. (6.293).

Intuition. Because $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ commute with ζ and respect covariance, the textbook Ward identity of eq. (6.293) descends to the band and remains adjoint-covariant; the explicit spurions are the *only* sources of non-conservation in QIV.

Proposition 7.568 (Adjoint covariance of the band Ward identity)**.** *Under the spurion law of Lemma 7.566, the divergence $\nabla^{(\mathrm{ad})}_{\mu}\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}}$ transforms in the adjoint:*

$$\delta_b\Big(\nabla^{(\mathrm{ad})}_{\mu}\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}}\Big) = f_{ba}{}^{c}\,\nabla^{(\mathrm{ad})}_{\mu}\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{c,\mathrm{imp}},$$

and the right-hand side of (7.665) transforms accordingly, so (7.665) is covariant.

Proof Proposition 7.568. We proceed in three steps: (I) adjoint covariance for the *untagged* current, (II) descent to the band via UV/IR taggers, and (III) adjoint covariance of the explicit source term.

(I) Untagged improved current transforms in the adjoint. By definition (eq. (6.292)), the improved Noether current $J^{\mu}_{a,\mathrm{imp}}$ is obtained from the canonical Noether current by a BRST improvement. Its symmetry variation has the standard form

$$\delta_b J^{\mu}_{a,\mathrm{imp}} = f_{ba}{}^{c}\,J^{\mu}_{c,\mathrm{imp}} \;+\; \partial_{\nu}K^{[\nu\mu]}_{ab} \;+\; \zeta\Big(B^{\mu}_{ab}\Big), \tag{7.666}$$

where $K^{[\nu\mu]}_{ab}$ is an antisymmetric superpotential (Noether improvement) and B^{μ}_{ab} is a local insertion with $\zeta(B^{\mu}_{ab})$ BRST-exact. Applying the adjoint-covariant divergence $\nabla^{(\mathrm{ad})}_{\mu}$ (which acts as a derivation compatible with the adjoint action),

$$\delta_b\Big(\nabla^{(\mathrm{ad})}_{\mu}J^{\mu}_{a,\mathrm{imp}}\Big) = f_{ba}{}^{c}\,\nabla^{(\mathrm{ad})}_{\mu}J^{\mu}_{c,\mathrm{imp}} \;+\; \nabla^{(\mathrm{ad})}_{\mu}\partial_{\nu}K^{[\nu\mu]}_{ab} \;+\; \nabla^{(\mathrm{ad})}_{\mu}\zeta\Big(B^{\mu}_{ab}\Big).$$

The last two terms are improvements/BRST-exact and therefore cohomologically trivial on $\mathcal{H}_{\mathrm{phys}}$ (cf. Lemma 7.552), so the untagged divergence transforms in the adjoint, modulo trivial terms.

(II) Descent to the band. Define the band-tagged current as

$$\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} := K^{(\ell)}_{\mathrm{IR}} P_x(\lambda_{\mathrm{UV}})\, J^{\mu}_{a,\mathrm{imp}}\, P_x(\lambda_{\mathrm{UV}}) K^{(\ell)}_{\mathrm{IR}}. \tag{7.667}$$

By Definition 7.551, the taggers commute with both the BRST differential and the G-action: $[\zeta, P_x] = [\zeta, K^{(\ell)}_{\mathrm{IR}}] = 0$ and $[\delta_b, P_x] = [\delta_b, K^{(\ell)}_{\mathrm{IR}}] = 0$, and they preserve improvements. Therefore, acting with δ_b on the tagged object simply tags (7.666):

$$\delta_b \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}} = f_{ba}{}^{c}\, \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{c,\mathrm{imp}} \;+\; \partial_\nu \Big(K^{[\nu\mu]}_{ab}\Big)^{(\lambda_{\mathrm{UV}},\ell)} \;+\; \zeta\Big(B^{\mu}_{ab}\Big)^{(\lambda_{\mathrm{UV}},\ell)}.$$

Applying $\nabla^{(\mathrm{ad})}_{\mu}$ and using the same commutation/linearity properties gives

$$\delta_b\Big(\nabla^{(\mathrm{ad})}_{\mu} \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}}\Big) = f_{ba}{}^{c}\, \nabla^{(\mathrm{ad})}_{\mu} \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{c,\mathrm{imp}} \;+\; \nabla^{(\mathrm{ad})}_{\mu}\partial_\nu \Big(K^{[\nu\mu]}_{ab}\Big)^{(\lambda_{\mathrm{UV}},\ell)} \;+\; \nabla^{(\mathrm{ad})}_{\mu}\zeta\Big(B^{\mu}_{ab}\Big)^{(\lambda_{\mathrm{UV}},\ell)}.$$

Again, the last two terms are improvements/BRST-exact and thus invisible on $\mathcal{H}_{\mathrm{phys}}$ (Lemma 7.552). This proves the first displayed equality in the proposition.

(III) Adjoint covariance of the explicit source (right-hand side). Consider the right-hand side of the scale-tagged Ward identity (Definition 7.567):

$$\mathcal{R}^{(\lambda_{\mathrm{UV}})}_{a} := \sum_{k} \epsilon_k \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\boldsymbol{\Psi}}.$$

By Lemma 7.566, the spurions transform in the dual representation, $\delta_b \epsilon_k = -(R_b)_k{}^{j} \epsilon_j$. The source operators transform as

$$\delta_b \mathcal{S}_{k,a} = (R_b)_k{}^{j}\, \mathcal{S}_{j,a} \;+\; f_{ba}{}^{c}\, \mathcal{S}_{k,c} \;+\; \partial_\mu(\dots) \;+\; \zeta(\dots),$$

where the last two pieces are improvement/BRST-exact. Tagging is compatible with these variations by the commutation properties from Definition 7.551. Therefore

$$\begin{aligned}
\delta_b \mathcal{R}^{(\lambda_{\mathrm{UV}})}_{a} &= \sum_{k} \Big(\delta_b \epsilon_k\Big) \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\boldsymbol{\Psi}} \\
&\qquad + \sum_{k} \epsilon_k \left\langle \delta_b \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\boldsymbol{\Psi}} \\
&= \sum_{k} \Big(- (R_b)_k{}^{j} \epsilon_j \Big) \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\boldsymbol{\Psi}} \\
&\qquad + \sum_{k} \epsilon_k \Big[(R_b)_k{}^{j} \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{j,a} \right\rangle_{\boldsymbol{\Psi}} \\
&\qquad\qquad + f_{ba}{}^{c} \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,c} \right\rangle_{\boldsymbol{\Psi}} \\
&\qquad\qquad + \langle \partial_\mu(\dots) + \zeta(\dots) \rangle \Big].
\end{aligned}$$

The terms proportional to R_b cancel after relabeling dummy indices. Expectations of improvements and ζ-exact insertions vanish on $\mathcal{H}_{\mathrm{phys}}$ by Lemma 7.552. We are left with

$$\delta_b \mathcal{R}^{(\lambda_{\mathrm{UV}})}_{a} = f_{ba}{}^{c} \sum_{k} \epsilon_k \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,c} \right\rangle_{\boldsymbol{\Psi}} = f_{ba}{}^{c}\, \mathcal{R}^{(\lambda_{\mathrm{UV}})}_{c}.$$

Thus the right-hand side of (7.665) transforms in the adjoint.

Conclusion. Both sides of the band Ward identity (7.665) transform covariantly in the adjoint representation (modulo improvement/BRST-exact terms that drop on $\mathcal{H}_{\text{phys}}$). Hence the identity is adjoint-covariant, as claimed. □

Proposition 7.569 (Gauge-parameter independence of the band Ward identity)**.** *The relation* (7.665) *is independent of gauge-fixing parameters on* $\mathcal{H}_{\text{phys}}$.

Proof Proposition 7.569. Let α_{gf} denote any gauge-fixing parameter entering through the gauge-fermion Ψ. Promote α_{gf} to a BRST doublet in the algebraic–renormalization sense; the *Nielsen identity* (linearized Slavnov–Taylor form) then reads, for every band-tagged operator $X^{(\lambda_{\text{UV}},\ell)}$ and the band state $\rho_0^{(\lambda_{\text{UV}},\ell)}$ (cf. Definition 7.551, Lemma 7.552, and Proposition 7.556),

$$\partial_{\alpha_{\text{gf}}} X^{(\lambda_{\text{UV}},\ell)} = \zeta\Big(\mathcal{N}_{\alpha_{\text{gf}}}[X]^{(\lambda_{\text{UV}},\ell)}\Big), \qquad \partial_{\alpha_{\text{gf}}} \rho_0^{(\lambda_{\text{UV}},\ell)} = \zeta\Big(\mathcal{N}_{\alpha_{\text{gf}}}[\rho_0]^{(\lambda_{\text{UV}},\ell)}\Big), \tag{7.668}$$

with some local insertions $\mathcal{N}_{\alpha_{\text{gf}}}[\cdot]$. Here we used that the UV/IR taggers are α_{gf}-independent and BRST-closed: $\partial_{\alpha_{\text{gf}}} P_x = \partial_{\alpha_{\text{gf}}} K_{\text{IR}}^{(\ell)} = 0$ and $[\zeta, P_x] = [\zeta, K_{\text{IR}}^{(\ell)}] = 0$ (Definition 7.551).

Define the band Ward functional (on $\mathcal{H}_{\text{phys}}$)

$$\mathcal{W}_a^{(\lambda_{\text{UV}},\ell)} := \nabla_\mu^{(\text{ad})} \bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu} - \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\boldsymbol{\Psi}}.$$

The scale-tagged Ward identity (7.665) states $\mathcal{W}_a^{(\lambda_{\text{UV}},\ell)} = 0$ on $\mathcal{H}_{\text{phys}}$. We show $\partial_{\alpha_{\text{gf}}} \mathcal{W}_a^{(\lambda_{\text{UV}},\ell)} = 0$ there, whence $\mathcal{W}_a^{(\lambda_{\text{UV}},\ell)}$ is α_{gf}-independent and, being zero for one value of α_{gf}, is zero for all.

LHS variation is ζ-exact. Using (7.668) with $X = \bar{J}_{a,\text{imp}}^{\mu}$ and the commutation $[\zeta, \nabla_\mu^{(\text{ad})}] = 0$,

$$\begin{aligned} \partial_{\alpha_{\text{gf}}}\Big(\nabla_\mu^{(\text{ad})} \bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu}\Big) &= \nabla_\mu^{(\text{ad})}\, \partial_{\alpha_{\text{gf}}} \bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu} \\ &= \nabla_\mu^{(\text{ad})}\, \zeta\Big(\mathcal{N}_{\alpha_{\text{gf}}}[J_{a,\text{imp}}^{\mu}]^{(\lambda_{\text{UV}},\ell)}\Big) \\ &= \zeta\Big(\nabla_\mu^{(\text{ad})} \mathcal{N}_{\alpha_{\text{gf}}}[J_{a,\text{imp}}^{\mu}]^{(\lambda_{\text{UV}},\ell)}\Big). \end{aligned}$$

Hence the entire LHS variation is a ζ-exact insertion.

RHS variation is ζ-exact in expectation. Differentiate the expectation value:

$$\partial_{\alpha_{\text{gf}}}\Big(\sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\boldsymbol{\Psi}}\Big) = \sum_k \epsilon_k\, \partial_{\alpha_{\text{gf}}} \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\boldsymbol{\Psi}}.$$

Using the band Nielsen identity for expectations (derived from (7.668) and the graded Leibniz rule),

$$\partial_{\alpha_{\text{gf}}} \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\boldsymbol{\Psi}} = \text{Tr}\Big(\rho_0^{(\lambda_{\text{UV}},\ell)}\, \partial_{\alpha_{\text{gf}}} \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})}\Big) + \text{Tr}\Big((\partial_{\alpha_{\text{gf}}} \rho_0^{(\lambda_{\text{UV}},\ell)})\, \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})}\Big) = \text{Tr}\Big(\rho_0^{(\lambda_{\text{UV}},\ell)}\, \zeta(\dots)\Big),$$

i.e. the variation is the expectation of a ζ-exact insertion (explicitly: the sum of $\zeta(\mathcal{N}_{\alpha_{\text{gf}}}[\mathcal{S}_{k,a}]^{(\lambda_{\text{UV}})})$ and $\zeta(\mathcal{N}_{\alpha_{\text{gf}}}[\rho_0]^{(\lambda_{\text{UV}},\ell)})$ reorganized by cyclicity of the (super)trace).

Cohomological vanishing on $\mathcal{H}_{\text{phys}}$. By Lemma 7.552, for any ghost-number-zero band state $\rho^{(\lambda_{\text{UV}},\ell)}$ with $\zeta(\rho^{(\lambda_{\text{UV}},\ell)}) = 0$,

$$\operatorname{Tr}\Big(\rho^{(\lambda_{\text{UV}},\ell)}\,\zeta(Y)\Big) = 0 \quad \text{on } \mathcal{H}_{\text{phys}}.$$

Therefore both the LHS and RHS variations vanish separately in the physical sector. We conclude $\partial_{\alpha_{\text{gf}}}\mathcal{W}_a^{(\lambda_{\text{UV}},\ell)} = 0$ on $\mathcal{H}_{\text{phys}}$.

Conclusion. Since $\mathcal{W}_a^{(\lambda_{\text{UV}},\ell)} = 0$ for some gauge choice implies $\partial_{\alpha_{\text{gf}}}\mathcal{W}_a^{(\lambda_{\text{UV}},\ell)} = 0$ everywhere, the identity (7.665) holds for all α_{gf} on $\mathcal{H}_{\text{phys}}$. Thus the band Ward identity is gauge-parameter independent. □

Theorem 7.570 (Non-vanishing Ward source in QIV)**.** *If at least one explicit breaking coupling is nonzero and relevant/marginal on the plateau band (QIV hypothesis), then on any certified plateau $\mathfrak{M}$ (cf. Definition 6.300)*

$$\sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\boldsymbol{\Psi}} \neq 0 \quad \textit{for some broken generator } a,$$

and the scale-tagged divergence (7.665) does not vanish on $\mathfrak{M}$.

Proof (expanded). Write the band Ward source

$$\mathcal{R}_a^{(\lambda_{\text{UV}},\ell)} := \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\boldsymbol{\Psi}}, \tag{7.669}$$

so the scale-tagged Ward identity (Definition 7.567)

$$\nabla_\mu^{(\text{ad})}\,\bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu} = \mathcal{R}_a^{(\lambda_{\text{UV}},\ell)} \quad \text{on } \mathcal{H}_{\text{phys}}. \tag{7.670}$$

By Proposition 7.568, $\mathcal{R}_a^{(\lambda_{\text{UV}},\ell)}$ transforms in the adjoint; by Proposition 7.569 and Lemma 7.552, it is gauge-parameter independent on $\mathcal{H}_{\text{phys}}$. Throughout we work uniformly on a certified plateau mask $\mathfrak{M}$ (Definition 6.300).

Step I: Contradiction hypothesis and adjoint orbit. Assume, on $\mathfrak{M}$, that

$$\mathcal{R}_a^{(\lambda_{\text{UV}},\ell)} = 0 \quad \text{for all broken generators } a. \tag{7.671}$$

Adjoint covariance (Proposition 7.568) implies that (7.671) holds for the entire adjoint orbit generated from the broken subspace; in particular, it holds for every component connected by $f_{ba}{}^c$ to a broken direction.

Step II: Consequence—band conservation of the improved current. From (7.665) and (7.671) we obtain, for all such a,

$$\nabla_\mu^{(\text{ad})}\,\bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu} = 0 \quad \text{on } \mathcal{H}_{\text{phys}} \text{ and on } \mathfrak{M}. \tag{7.672}$$

Thus each broken-component current is (band-)conserved on the plateau in the physical sector.

Step III: Variation of the band effective action. Let $\Gamma^{(\lambda_{\mathrm{UV}},\ell)}$ denote the band effective action (generating functional of 1PI graphs) obtained with the taggers $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}$; insert a spacetime-dependent test parameter $\alpha^a(x)$ coupled to the adjoint-covariant divergence. The operator Ward identity (eq. (6.293)) and band descent (Lemma 7.552 and Definition 7.567) give, to first order in α,

$$\delta_\alpha \Gamma^{(\lambda_{\mathrm{UV}},\ell)} = \int d^d x \; \alpha^a(x)\, \mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)}(x), \tag{7.673}$$

up to BRST-exact insertions and total derivatives, which do not contribute on $\mathcal{H}_{\mathrm{phys}}$. By (7.671), we would have $\delta_\alpha \Gamma^{(\lambda_{\mathrm{UV}},\ell)} = 0$ for all α^a supported on the broken subspace. Hence the band effective action would be invariant (to first order) under those broken transformations.

Step IV: Relevance/marginality forbids trivialization. QIV assumes that at least one explicit breaking operator in the deformation $\sum_k \epsilon_k \mathcal{O}_k$ is *relevant or marginal* on the plateau band and has $\epsilon_k \neq 0$. In the algebraic–renormalization framework [117], a relevant/marginal deformation that is cohomologically trivial (BRST-exact plus total derivative, i.e. a redundant coupling) does not affect Γ at first order and can be removed by a field redefinition. Conversely, if $\delta_\alpha \Gamma^{(\lambda_{\mathrm{UV}},\ell)} = 0$ for all broken α^a, then the broken-direction part of the spurion deformation would be cohomologically trivial on the band, i.e.

$$\sum_k \epsilon_k \, \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \;=\; \nabla_\mu^{(\mathrm{ad})} X_a^\mu \;+\; \zeta(Y_a) \qquad \text{(in the band theory)}. \tag{7.674}$$

But (7.674) contradicts the QIV hypothesis: a *relevant/marginal* explicit breaking on $\mathfrak{M}$ is, by definition, a non-redundant deformation in the $H^0(\hat{Q}_{\mathrm{BRST}})$ cohomology class of the band theory; it cannot be written as an improvement plus a BRST-exact term without nullifying its physical effect on Γ. Therefore our assumption (7.671) is false.

Step V: Conclusion. There exists a broken generator a such that $\mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)} \neq 0$ on $\mathfrak{M}$. By (7.665), the scale-tagged divergence $\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu}$ does not vanish on $\mathfrak{M}$. This establishes the claim. □

Corollary 7.571 (QIV vs. QI limit)**.** *Setting $\epsilon_k \to 0$ in (7.665) recovers band conservation, $\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = 0$, which is precisely the QI law-channel signature (Section 7.1).*

Proof. Start from the band Ward identity (Definition 7.567)

$$\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\boldsymbol{\Psi}} \quad \text{on } \mathcal{H}_{\mathrm{phys}}. \tag{7.675}$$

Fix a certified plateau mask $\mathfrak{M}$ (Definition 6.300). By Lemma 7.552 the band-tagged expectations on the right-hand side are well-defined and gauge-parameter independent (Proposition 7.569).

Consider the family of deformations parameterized by $\epsilon = \{\epsilon_k\}$. On $\mathfrak{M}$, plateau certification implies uniform bounds and smooth dependence of band correlators on small couplings;

hence the map $\epsilon \mapsto \langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \rangle_{\mathbf{\Psi}}$ is continuous at $\epsilon = 0$ (cf. standard locality/analyticity arguments in algebraic renormalization [117] and effective action dependence [91]). Therefore, taking the limit $\epsilon_k \to 0$ termwise in the finite (relevant/marginal) sum,

$$\lim_{\epsilon \to 0} \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} \;=\; 0 \qquad \text{uniformly on } \mathfrak{M}.$$

Passing to the limit in (7.675) yields

$$\nabla_\mu^{(\mathrm{ad})} \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} \;=\; 0 \quad \text{on } \mathcal{H}_{\mathrm{phys}} \text{ and on } \mathfrak{M}.$$

This is precisely the band conservation statement that characterizes the QI law channel (Section 7.1). The result is independent of gauge-fixing parameters (by Proposition 7.569) and stable under BRST- and Noether-improvements, which do not affect the conserved charge on $\mathcal{H}_{\mathrm{phys}}$ (Lemma 7.552). □

Intuition. This subsection pins down the symmetry frame and shows how the explicit breakings enter the *band* Ward identity in a fully covariant, BRST- and gauge-safe way. In QIV the right-hand side is nonzero on plateaus (relevant/marginal spurions), and this is exactly the seed that drives the non-healing law-visibility deficit in Theorem 7.557.

7.9.3 Cone–preserving Kernels

Goal. Instantiate the UV/IR taggers (Definition 7.551) with an explicit causal kernel family that (i) preserves microcausality (support inside $\mathsf{C}^+ \cup \mathsf{C}^-$), (ii) commutes with BRST/G, and (iii) is compatible with the spectral/tomographic constructions of Definition 7.607 and Proposition 7.609.

Definition 7.572 (Causal IR kernel family)**.** Let $v_* > 0$ be the microscopic signal speed (e.g. $v_* = c$ relativistically, or a Lieb–Robinson velocity on the lattice). For each band point $x = (\lambda_{\mathrm{UV}}, \ell)$, define the IR kernel

$$\kappa_x(t, \mathbf{r}) \;:=\; \chi_\ell(t)\, \phi_\ell\!\left(\frac{\|\mathbf{r}\|}{v_* |t| + \delta} \right),$$

with: (i) $\chi_\ell \in C_c^\infty(\mathbb{R})$, even, supported in $|t| \le \tau(\ell)$, normalized $\int \chi_\ell(t)\, dt = 1$; (ii) $\phi_\ell \in C_c^\infty([0,\infty))$, supported in $[0,1]$, nonnegative, $\phi_\ell(0) = 1$; (iii) $\delta > 0$ a small regulator (removed at the end). The associated convolution tagger on operators is $(K_{\mathrm{IR}}^{(\ell)} \mathcal{O})(x) := \int dt\, d^d\mathbf{r}\; \kappa_x(t,\mathbf{r})\; \mathcal{O}(x^0 - t, \mathbf{x} - \mathbf{r})$, and similarly for states by dual action. Take the UV projector $P_x(\lambda_{\mathrm{UV}})$ as any spectral-cutoff operator commuting with spacetime translations (e.g. a Fourier-multiplier with radial mask).

Proposition 7.573 (Cone preservation and commutation)**.** *The family $\{\kappa_x\}$ of Definition 7.572 is cone–preserving:* $\operatorname{supp} \kappa_x \subset \mathsf{C}^+ \cup \mathsf{C}^-$ *for every x. Moreover $K_{\mathrm{IR}}^{(\ell)}$ and $P_x(\lambda_{\mathrm{UV}})$ commute with BRST and G actions:* $[\zeta, K_{\mathrm{IR}}^{(\ell)}] = [\zeta, P_x] = [\delta_a, K_{\mathrm{IR}}^{(\ell)}] = [\delta_a, P_x] = 0$.

Proof. (A) Cone preservation. By Definition 7.572, each kernel is constructed with a finite time aperture $\tau(\ell)$ and a finite propagation speed bound $v_*(x)$ (from strong hyperbolicity and the principal symbol; cf. Definition 7.535), together with a harmless thickness $\delta \geq 0$. Concretely,

$$\kappa_x(t,\mathbf{r}) = 0 \quad \text{unless} \quad |t| \leq \tau(\ell) \ \text{ and } \ \|\mathbf{r}\| \leq v_*(x)\,|t| + \delta.$$

Hence $\operatorname{supp}\kappa_x \subset \mathsf{C}^+ \cup \mathsf{C}^-$ by definition of the thickened forward/backward cones $\mathsf{C}^\pm$ at x. This establishes cone preservation.

(B) Representation of the taggers. Both taggers are linear, continuous maps on operator–valued distributions obtained by c–number kernels/multipliers:

$$(K_{\mathrm{IR}}^{(\ell)}\mathcal{O})(y) = \int d^d z\ \kappa_x(y-z)\,\mathcal{O}(z), \tag{7.676}$$

$$(P_x(\lambda_{\mathrm{UV}})\mathcal{O})\widehat{\ }(p) = \chi_x(\lambda_{\mathrm{UV}},p)\ \widehat{\mathcal{O}}(p), \tag{7.677}$$

where κ_x is as above and χ_x is a smooth, compactly supported (or rapidly decaying) UV window around $|p| \lesssim \lambda_{\mathrm{UV}}$ fixed at x. Equivalently, P_x can be written as a convolution with a c–number kernel p_x obtained by inverse Fourier transform of χ_x.

(C) Commutation with BRST. Let ζ be the BRST differential acting as a graded derivation on the field/operator algebra, with $[\zeta,\partial_\mu]=0$ and ζ annihilating c–number functions. Using (7.676) and linearity,

$$\zeta\Big(K_{\mathrm{IR}}^{(\ell)}\mathcal{O}\Big)(y) = \zeta\Big(\int d^d z\ \kappa_x(y-z)\,\mathcal{O}(z)\Big) = \int d^d z\ \kappa_x(y-z)\,\zeta\mathcal{O}(z) = (K_{\mathrm{IR}}^{(\ell)}\,\zeta\mathcal{O})(y),$$

so $[\zeta, K_{\mathrm{IR}}^{(\ell)}]=0$. In momentum space,

$$\zeta(P_x\mathcal{O})\widehat{\ }(p) = \zeta\Big(\chi_x(\lambda_{\mathrm{UV}},p)\,\widehat{\mathcal{O}}(p)\Big) = \chi_x(\lambda_{\mathrm{UV}},p)\,\zeta\widehat{\mathcal{O}}(p) = (P_x\,\zeta\mathcal{O})\widehat{\ }(p),$$

hence $[\zeta,P_x]=0$. No domain subtleties arise on certified plateaus since both taggers are bounded on the Banach spaces used there, and ζ is closable on the same domain (standard BRST functional setting).

(D) Commutation with the G–action. Let δ_a denote the infinitesimal G–action (global/internal), acting fibrewise on field indices and as a derivation on products; it commutes with spacetime translations/derivatives and does not act on c–number kernels. Then, using (7.676),

$$\delta_a\Big(K_{\mathrm{IR}}^{(\ell)}\mathcal{O}\Big)(y) = \int d^d z\ \kappa_x(y-z)\,\delta_a\mathcal{O}(z) = (K_{\mathrm{IR}}^{(\ell)}\,\delta_a\mathcal{O})(y),$$

so $[\delta_a, K_{\mathrm{IR}}^{(\ell)}]=0$. Likewise from (7.677),

$$\delta_a(P_x\mathcal{O})\widehat{\ }(p) = \chi_x(\lambda_{\mathrm{UV}},p)\,\delta_a\widehat{\mathcal{O}}(p) = (P_x\,\delta_a\mathcal{O})\widehat{\ }(p),$$

so $[\delta_a,P_x]=0$. If one realises δ_a as an inner derivation $\delta_a(\cdot)=i[Q_a,\cdot]$ with Q_a the conserved charge, the same conclusion follows since $K_{\mathrm{IR}}^{(\ell)}$ and P_x are c–number maps on spacetime arguments and hence commute with taking commutators in field space: $[Q_a, K_{\mathrm{IR}}^{(\ell)}\mathcal{O}] = K_{\mathrm{IR}}^{(\ell)}[Q_a,\mathcal{O}]$, and similarly for P_x.

Combining (A)–(D) gives the stated cone support for κ_x and the commutators $[\zeta, K_{\mathrm{IR}}^{(\ell)}] = [\zeta,P_x] = [\delta_a, K_{\mathrm{IR}}^{(\ell)}] = [\delta_a,P_x] = 0$, completing the proof. □

Corollary 7.574 (Non-signalling after band descent)**.** *If the microscopic theory is microcausal, then for spacelike–separated regions A, B, $\langle[\,\bar{J}^{(x)\mu}_{a,\mathrm{imp}}(A),\,\mathcal{W}^{(x)}(B)\,]\rangle_{\mathbf{\Psi}} = 0$ for all certified $x \in \mathfrak{P}$ (Definition 6.300).*

Proof. Setup. Let $C^{\mu}_{a}(y,z) := \Big\langle\,[\,\bar{J}^{\mu}_{a,\mathrm{imp}}(y),\,\mathcal{W}(z)\,]\,\Big\rangle_{\mathbf{\Psi}}$ denote the microscopic commutator bi–distribution. Microcausality means

$$\operatorname{supp} C^{\mu}_{a} \subset \{(y,z) \in \mathbb{R}^{d} \times \mathbb{R}^{d} :\ (y-z) \in \mathsf{C}^{+} \cup \mathsf{C}^{-}\}.$$

Band descent acts as the c–number maps $K^{(\ell)}_{\mathrm{IR}}$ and $P_x(\lambda_{\mathrm{UV}})$ (Definition 7.572) on operator–valued distributions (convolution in position or multiplication in momentum, cf. Proposition 7.573). If f_A, g_B are test functions supported in A, B respectively, then

$$\bar{J}^{(x)\mu}_{a,\mathrm{imp}}(A) = \bar{J}^{\mu}_{a,\mathrm{imp}}\Big((K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} f_A\Big), \qquad \mathcal{W}^{(x)}(B) = \mathcal{W}\Big((K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} g_B\Big),$$

where $(\cdot)^{\dagger}$ is the transpose action on test functions. Writing κ_x for the IR kernel and χ_x for the UV window, one has $(K^{(\ell)}_{\mathrm{IR}})^{\dagger} f_A = f_A * \tilde{\kappa}_x$ with $\tilde{\kappa}_x(t,\mathbf{r}) = \kappa_x(-t,-\mathbf{r})$, and $(P_x)^{\dagger}$ acts by multiplication with χ_x in momentum space.

Step 1: Cone preservation under band descent. By Proposition 7.573, $\operatorname{supp}\kappa_x \subset \mathsf{C}^{+} \cup \mathsf{C}^{-}$ and the taggers commute with internal actions. Hence the *effective* test functions after descent satisfy

$$\operatorname{supp}\Big((K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} f_A\Big) \subset A + \operatorname{supp}\kappa_x, \qquad \operatorname{supp}\Big((K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} g_B\Big) \subset B + \operatorname{supp}\kappa_x,$$

where $S + T := \{s + t :\ s \in S,\ t \in T\}$ is the Minkowski sum.

Step 2: Plateau non–overlap margin. By certification (Definition 6.300) one chooses the IR aperture $\tau(\ell)$ and speed bound $v_*(x)$ (from strong hyperbolicity, Definition 7.535) so that the *thickened supports*

$$A^{\sharp} := A + \operatorname{supp}\kappa_x, \qquad B^{\sharp} := B + \operatorname{supp}\kappa_x$$

remain spacelike–separated: $(y-z) \notin \mathsf{C}^{+} \cup \mathsf{C}^{-}$ for all $y \in A^{\sharp}$, $z \in B^{\sharp}$. This is exactly the "non–signalling margin" encoded in the plateau acceptance (finite time aperture $\tau(\ell)$ and cone thickness δ chosen below the region–separation buffer).

Step 3: Vanishing of the descended commutator. Using the distributional pairing and Fubini,

$$\begin{aligned}\Big\langle\,[\,\bar{J}^{(x)\mu}_{a,\mathrm{imp}}(A),\,\mathcal{W}^{(x)}(B)\,]\,\Big\rangle_{\mathbf{\Psi}} &= \Big\langle\, C^{\mu}_{a},\ (K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} f_A \ \otimes\ (K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} g_B \,\Big\rangle \\ &= \int dy\, dz\ C^{\mu}_{a}(y,z)\ \Big((K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} f_A\Big)(y)\ \Big((K^{(\ell)}_{\mathrm{IR}}P_x)^{\dagger} g_B\Big)(z).\end{aligned}$$

The integrand has support inside

$$\{(y,z) :\ (y-z) \in \mathsf{C}^{+} \cup \mathsf{C}^{-}\}\ \cap\ \Big(A^{\sharp} \times B^{\sharp}\Big),$$

which is empty by the plateau non–overlap from Step 2. Therefore the integral vanishes: $\langle[\,\bar{J}^{(x)\mu}_{a,\mathrm{imp}}(A),\,\mathcal{W}^{(x)}(B)\,]\rangle_{\mathbf{\Psi}} = 0$.

Remarks. (i) The replacement of ∂_μ by the adjoint covariant divergence in $\bar{J}^{(x)\mu}_{a,\mathrm{imp}}$ does not affect support since the connection is a c–number background on spacetime indices. (ii) Commutation $[\zeta, K^{(\ell)}_{\mathrm{IR}}] = [\delta_a, K^{(\ell)}_{\mathrm{IR}}] = [\zeta, P_x] = [\delta_a, P_x] = 0$ (Proposition 7.573) ensures the BRST/G structure is unchanged by descent and does not obstruct microcausality.

This establishes non–signalling of the descended observables for all certified $x \in \mathfrak{P}$. □

Lemma 7.575 (Frequency response and kernel floor)**.** *Let $\widehat{\kappa}_x(\omega, \mathbf{k})$ be the Fourier transform of κ_x. Then $\widehat{\kappa}_x$ is C^∞ in $(\omega, \mathbf{k})$, real–valued and even in ω. Moreover, for any $\omega_0 > 0$ sufficiently small there exists $\kappa_{\mathrm{spec}}(x) > 0$ such that*

$$\mathsf{K}_{\mathrm{spec}}(x; \omega) \;\geq\; \kappa_{\mathrm{spec}}(x) \qquad \text{for } |\omega| \leq \omega_0,$$

with $\mathsf{K}_{\mathrm{spec}}$ the tomography kernel of Definition 7.607.

Proof. Structure of κ_x and smoothness. By Definition 7.572, the IR tagger uses a causal, compactly supported C^∞ kernel which, in local coordinates at x, factors as

$$\kappa_x(t, \mathbf{r}) \;=\; \chi_\ell(t)\, \phi_\ell(\mathbf{r}),$$

with $\chi_\ell \in C^\infty_c(\mathbb{R})$ an even time window ($\chi_\ell(t) = \chi_\ell(-t)$, real, nonnegative) and $\phi_\ell \in C^\infty_c(\mathbb{R}^{d-1})$ a real, radially symmetric spatial window. Hence

$$\widehat{\kappa}_x(\omega, \mathbf{k}) \;=\; \widehat{\chi}_\ell(\omega)\, \widehat{\phi}_\ell(\mathbf{k}),$$

and both factors are entire (Paley–Wiener), thus C^∞ in all variables. Because χ_ℓ is real and even, $\widehat{\chi}_\ell$ is real and even in ω; because ϕ_ℓ is real and even (radial), $\widehat{\phi}_\ell$ is real and even in $\mathbf{k}$. Therefore $\widehat{\kappa}_x$ is smooth and real–even in ω.

Positivity at zero frequency. Since $\chi_\ell \geq 0$ and not identically zero, $\widehat{\chi}_\ell(0) = \int_{\mathbb{R}} \chi_\ell(t)\, dt > 0$. By construction, the tomography kernel of Definition 7.607 is a positive quadratic functional of $\widehat{\kappa}_x$ of the form

$$\mathsf{K}_{\mathrm{spec}}(x; \omega) \;=\; \int_{\mathbb{R}^{d-1}} W_x(\mathbf{k}) \left|\widehat{\kappa}_x(\omega, \mathbf{k})\right|^2 d\mathbf{k} \;=\; \left|\widehat{\chi}_\ell(\omega)\right|^2 \int_{\mathbb{R}^{d-1}} W_x(\mathbf{k}) \left|\widehat{\phi}_\ell(\mathbf{k})\right|^2 d\mathbf{k}, \tag{7.678}$$

where $W_x(\mathbf{k}) \geq 0$ is the channel weight specified in Definition 7.607 (it encodes the T–odd projection and normalization). By design, W_x is not a.e. zero and has positive mass on some compact set $A_x \subset \mathbb{R}^{d-1}$; since $\widehat{\phi}_\ell$ is continuous and not identically zero, there exists a compact A_x with

$$c_x \;:=\; \int_{A_x} W_x(\mathbf{k}) \left|\widehat{\phi}_\ell(\mathbf{k})\right|^2 d\mathbf{k} \;>\; 0.$$

Therefore

$$\mathsf{K}_{\mathrm{spec}}(x; 0) \;=\; \left|\widehat{\chi}_\ell(0)\right|^2 \int_{\mathbb{R}^{d-1}} W_x(\mathbf{k}) \left|\widehat{\phi}_\ell(\mathbf{k})\right|^2 d\mathbf{k} \;\geq\; \left|\widehat{\chi}_\ell(0)\right|^2 c_x \;>\; 0.$$

Continuity and a uniform floor near $\omega = 0$. The map $\omega \mapsto \mathsf{K}_{\mathrm{spec}}(x; \omega)$ is continuous: indeed, $\widehat{\chi}_\ell$ is continuous and $W_x(\mathbf{k})|\widehat{\phi}_\ell(\mathbf{k})|^2$ is integrable on $\mathbb{R}^{d-1}$, so (7.678) is a continuous composition and dominated-convergence applies. Hence there exists $\omega_0 > 0$ such that

$$\left|\widehat{\chi}_\ell(\omega)\right|^2 \;\geq\; \tfrac{1}{2} \left|\widehat{\chi}_\ell(0)\right|^2 \qquad \text{for all } |\omega| \leq \omega_0.$$

Combining with (7.678) and the definition of c_x,

$$\mathsf{K}_{\mathrm{spec}}(x;\omega) \;\geq\; \tfrac{1}{2}\left|\widehat{\chi}_\ell(0)\right|^2 c_x \;=:\; \kappa_{\mathrm{spec}}(x) \;>\; 0 \qquad \text{for all } |\omega| \leq \omega_0.$$

Remarks on invariances. Because κ_x is a c–number kernel and the taggers commute with BRST/G (Proposition 7.573), the bound is taken on the same physical sector $\mathcal{H}_{\mathrm{phys}}$ and is unaffected by gauge-parameter choices (Nielsen robustness).

This proves the existence of a strictly positive low–frequency kernel floor $\kappa_{\mathrm{spec}}(x)$. □

Definition 7.576 (One–time numerical verification (accept/reject))**.** On the working spacetime grid, precompute κ_x and declare a tolerance $\epsilon_{\mathrm{cone}} = 10^{-12}$ (floating–point floor). Accept the kernel family if

$$\max_{(t,\mathbf{r})\notin \mathsf{C}^{\pm}} \; |\kappa_x(t,\mathbf{r})| \;\leq\; \epsilon_{\mathrm{cone}} \quad \text{for all } x \in \mathfrak{P},$$

and if the discrete Fourier sample of $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ satisfies the kernel–floor inequality of Lemma 7.575 with a discretization slack δ_{disc} as in Proposition 7.602. Re-run only when $\tau(\ell)$ or the spatial stencil changes.

Notes. (i) The time–only choice $\phi_\ell \equiv \delta(\mathbf{r})$ is trivially cone–preserving and may be used for baseline audits. (ii) For lattice models, replace v_* by a compatible Lieb–Robinson velocity; proofs are unchanged. (iii) All statements are BRST/Nielsen safe by Lemma 7.552 and Proposition 7.556.

7.9.4 Visibilities (Primary Diagnostics)

Definition 7.577 (Plateau-wise primary diagnostics)**.** Let $\mathfrak{P} \subset \{(\lambda_{\mathrm{UV}}, \ell)\}$ be a certified plateau mask in the sense of Definition 6.300. On $\mathfrak{P}$ we define:

1. *Persistent law-deficit:* there exists $\delta_\star \in (0,1)$ such that
$$\left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\leq\; 1-\delta_\star \qquad \forall\,(\lambda_{\mathrm{UV}},\ell) \in \mathfrak{P}.$$
2. *Unique-vacuum state channel:* for any volume sequence $V \to \infty$,
$$\lim_{V\to\infty} \left|\Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)}(V)\right| \;=\; 1 \qquad \text{uniformly on } \mathfrak{P}.$$

Here $\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$ are the holosymmetric visibilities with UV/IR tags as in Definitions 6.275 and 7.551, and expectations are taken on $\mathcal{H}_{\mathrm{phys}}$ (BRST/Nielsen-safe by Lemma 7.552 and Proposition 7.556).

Lemma 7.578 (From non-vanishing Ward source to a positive law gap at a point)**.** *Fix $(\lambda_{\mathrm{UV}},\ell) \in \mathfrak{P}$. If the band Ward source*

$$\mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)} := \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}}$$

is nonzero for some broken generator a (cf. Theorem 7.570), then there exists $c_\bullet(\{\epsilon_k\},\lambda_{\mathrm{UV}},\ell) > 0$ such that

$$1 - \left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\geq\; c_\bullet(\{\epsilon_k\},\lambda_{\mathrm{UV}},\ell).$$

Proof (expanded). **1) Channel decomposition and the spectral (T-odd) branch.** By the holosymmetric construction, the law visibility at the band point $(\lambda_{\mathrm{UV}}, \ell)$ is the tagged overlap of branch unitaries traced against the tagged state, $\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)} = \mathrm{Tr}\big[(U_B^{(\lambda_{\mathrm{UV}},\ell)})^\dagger U_A^{(\lambda_{\mathrm{UV}},\ell)}\, \rho_0^{(\lambda_{\mathrm{UV}},\ell)}\big]$ (Definitions 6.275 and 7.551). Insert the triadic channel projectors and use Proposition 7.555 to write

$$\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)} = \Lambda_{\mathrm{law}}^{(\mathrm{vac};\lambda_{\mathrm{UV}},\ell)} + \Lambda_{\mathrm{law}}^{(\mathrm{corr};\lambda_{\mathrm{UV}},\ell)} + \Lambda_{\mathrm{law}}^{(\mathrm{spec};\lambda_{\mathrm{UV}},\ell)}.$$

By construction (holosymmetric/T-parity split), the *spectral* branch is T-odd and admits a Kubo-type spectral representation

$$-\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec};\lambda_{\mathrm{UV}},\ell)} = \int_{\mathbb{R}} d\omega\; \mathsf{K}_{\mathrm{spec}}^{(\lambda_{\mathrm{UV}},\ell)}(\omega)\, \mathsf{S}_a^{(\lambda_{\mathrm{UV}},\ell)}(\omega), \tag{7.679}$$

where $\mathsf{K}_{\mathrm{spec}}^{(\lambda_{\mathrm{UV}},\ell)}(\omega) \geq 0$ is a positive kernel determined by the UV/IR taggers (commuting with BRST and G by Definition 7.551) and $\mathsf{S}_a^{(\lambda_{\mathrm{UV}},\ell)}(\omega)$ is the spectral density associated with the adjoint-covariant divergence of the improved current along a broken direction a (defined cohomologically on $\mathcal{H}_{\mathrm{phys}}$ by Lemma 7.552).[17]

2) Injecting the Ward identity. On $\mathcal{H}_{\mathrm{phys}}$, the scale-tagged Ward identity reads

$$\nabla_\mu^{(\mathrm{ad})}\, \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = \mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)} \qquad \text{(Definition 7.567)}. \tag{7.680}$$

A nonzero $\mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)}$ (for some broken a) implies that the T-odd two-point function of the divergence has a non-vanishing zero-frequency component: in the spectral language, $\mathsf{S}_a^{(\lambda_{\mathrm{UV}},\ell)}(\omega)$ carries a strictly positive weight in any neighborhood of $\omega = 0$.This uses adjoint covariance (Proposition 7.568) and the fact that BRST-exact/improvement pieces do not contribute on $\mathcal{H}_{\mathrm{phys}}$ (Lemma 7.552).

3) Positivity of the kernel on a certified band point. By the certification of $(\lambda_{\mathrm{UV}}, \ell) \in \mathfrak{P}$ (Definition 6.300), the UV/IR taggers fix the bandwidth and coarse-graining so that the kernel $\mathsf{K}_{\mathrm{spec}}^{(\lambda_{\mathrm{UV}},\ell)}(\omega)$ is continuous and admits a strictly positive lower bound on a compact neighborhood of $\omega = 0$:

$$\exists\, \omega_0 > 0,\ \kappa_{\mathrm{spec}}(\lambda_{\mathrm{UV}}, \ell) > 0 \quad \text{s.t.} \quad \mathsf{K}_{\mathrm{spec}}^{(\lambda_{\mathrm{UV}},\ell)}(\omega) \;\geq\; \kappa_{\mathrm{spec}}(\lambda_{\mathrm{UV}}, \ell) \quad \forall\, \omega \in [-\omega_0, \omega_0].$$

(This follows from the scale-aware setup of Section 6.12 and the commutation/regularity properties of Definition 7.551.)

4) Lower-bounding the modulus deficit. Since $|\Lambda_{\mathrm{law}}| \leq \mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{vac})} + \mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{corr})} + \mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec})}$ and the first two branches are T-even (do not contribute negatively to the real part at unity normalization), we have

$$1 - \left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\geq\; -\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec};\lambda_{\mathrm{UV}},\ell)}.$$

Combining with (7.679) and the kernel bound gives

$$1 - \left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\geq\; \kappa_{\mathrm{spec}}(\lambda_{\mathrm{UV}}, \ell) \int_{-\omega_0}^{\omega_0} d\omega\; \mathsf{S}_a^{(\lambda_{\mathrm{UV}},\ell)}(\omega).$$

[17] Any broken direction suffices for the lower bound below; we suppress the index a when clear.

By Step 2, the integral on the right is strictly positive whenever $\mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)} \neq 0$; denote it by $\sigma_a^{(\lambda_{\mathrm{UV}},\ell)} > 0$, a continuous function of the couplings $\{\epsilon_k\}$ at fixed band point (gauge-parameter independent by Proposition 7.569). Therefore

$$1 - \left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\geq\; \kappa_{\mathrm{spec}}(\lambda_{\mathrm{UV}},\ell)\,\sigma_a^{(\lambda_{\mathrm{UV}},\ell)} \;:=\; c_\bullet(\{\epsilon_k\},\lambda_{\mathrm{UV}},\ell) \;>\; 0.$$

5) Cohomological and gauge independence. All steps above are performed on $\mathcal{H}_{\mathrm{phys}}$; BRST-exact and Noether-improvement pieces drop out (Lemma 7.552), and the bound is independent of gauge-fixing parameters (Proposition 7.569). Adjoint covariance ensures that choosing any broken generator a with $\mathcal{R}_a^{(\lambda_{\mathrm{UV}},\ell)} \neq 0$ yields the same conclusion (Proposition 7.568).

This proves the claim with the stated, strictly positive constant $c_\bullet(\{\epsilon_k\},\lambda_{\mathrm{UV}},\ell)$. □

Lemma 7.579 (Plateau uniformization)**.** *If a function $f(\lambda_{\mathrm{UV}},\ell)$ obeys $|f(x)-f(y)| \leq \eta_{\mathfrak{P}}$ for all $x,y \in \mathfrak{P}$ (slope/curvature/oscillation bounds of Definition 6.300), and $f(x_0) \geq c_0 > 0$ for some $x_0 \in \mathfrak{P}$, then*

$$\inf_{x\in\mathfrak{P}} f(x) \;\geq\; c_0 - \eta_{\mathfrak{P}}.$$

Proof (expanded). By the plateau certification criteria (Definition 6.300, within the scale-aware scheme of Section 6.12), the mask $\mathfrak{P}$ enforces a uniform oscillation bound

$$\mathrm{osc}_{\mathfrak{P}}(f) := \sup_{x,y\in\mathfrak{P}} |f(x)-f(y)| \;\leq\; \eta_{\mathfrak{P}}, \tag{7.681}$$

where $\eta_{\mathfrak{P}} \geq 0$ is the certified tolerance determined by the slope/curvature tests on the $(\lambda_{\mathrm{UV}},\ell)$-grid.

Fix any $x \in \mathfrak{P}$. Apply the triangle inequality with the reference point $x_0 \in \mathfrak{P}$:

$$f(x) \;=\; f(x_0) \;-\; \big(f(x_0)-f(x)\big) \;\geq\; f(x_0) \;-\; |f(x_0)-f(x)| \;\geq\; c_0 \;-\; \mathrm{osc}_{\mathfrak{P}}(f).$$

Using (7.681) gives

$$f(x) \;\geq\; c_0 - \eta_{\mathfrak{P}} \qquad \forall\, x \in \mathfrak{P}.$$

Taking the infimum over $x \in \mathfrak{P}$ proves the claim: $\inf_{x\in\mathfrak{P}} f(x) \geq c_0 - \eta_{\mathfrak{P}}$.

Remarks. (i) If f is a BRST/Nielsen-safe observable built from band visibilities (e.g. $f = 1 - |\Lambda_{\mathrm{law}}|$), the bound is gauge-parameter independent by Proposition 7.556, and the band descent used to define f is valid on $\mathcal{H}_{\mathrm{phys}}$ by Lemma 7.552. (ii) When $c_0 > \eta_{\mathfrak{P}}$ the lemma guarantees a strictly positive uniform lower bound on $\mathfrak{P}$. □

Theorem 7.580 (Primary QIV visibility diagnostics on certified plateaus)**.** *Assume the QIV hypotheses (nonzero relevant/marginal explicit breakings on the band) and work on a certified plateau $\mathfrak{P}$. Then:*

1. *(*Persistent law-deficit*) There exists $\delta_\star \in (0,1)$ such that*

$$\left|\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}\right| \;\leq\; 1-\delta_\star \qquad \forall\,(\lambda_{\mathrm{UV}},\ell) \in \mathfrak{P}.$$

*2. (*Unique-vacuum state channel*) Uniformly on* $\mathfrak{P}$*,*

$$\lim_{V\to\infty} \left|\Lambda_{\text{state}}^{(\lambda_{\text{UV}},\ell)}(V)\right| \;=\; 1.$$

Proof (expanded). We recall (i) the holosymmetric visibilities with UV/IR tags (Definitions 6.275 and 7.551), (ii) the band Ward identity (Definition 7.567), (iii) adjoint covariance of the band Ward identity (Proposition 7.568), (iv) gauge-parameter independence on $\mathcal{H}_{\text{phys}}$ (Proposition 7.569), and (v) the descent and cohomological properties on $\mathcal{H}_{\text{phys}}$ (Lemma 7.552).

(1) Law channel: existence of a uniform deficit on $\mathfrak{P}$. *Step 1a (Pointwise positive gap).* By Theorem 7.570, on any certified plateau $\mathfrak{P}$ there exists a broken generator a and a band point $x_0 = (\lambda_{\text{UV}}, \ell) \in \mathfrak{P}$ such that the band Ward source $\mathcal{R}_a^{(\lambda_{\text{UV}},\ell)} = \sum_k \epsilon_k \langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \rangle_{\Psi}$ is nonzero. Then Lemma 7.578 yields a *pointwise* strictly positive modulus deficit,

$$1 - \left|\Lambda_{\text{law}}^{(\lambda_{\text{UV}},\ell)}\right| \;\geq\; c_\bullet(\{\epsilon_k\}, \lambda_{\text{UV}}, \ell) \;:=\; c_0 \;>0 \qquad \text{at } x_0 \in \mathfrak{P},$$

with c_0 depending continuously on the explicit couplings and the band point, and independent of the gauge-fixing parameters by Proposition 7.569.

Step 1b (Uniformization over the plateau). By certification (Definition 6.300 in the scale-aware scheme of Section 6.12), the law visibility varies slowly on $\mathfrak{P}$:

$$\sup_{x,y\in\mathfrak{P}} \left|\Lambda_{\text{law}}(x) - \Lambda_{\text{law}}(y)\right| \;\leq\; \eta_{\mathfrak{P}}.$$

Applying Lemma 7.579 to $f(x) := 1 - |\Lambda_{\text{law}}(x)|$ with the single-point lower bound $f(x_0) \geq c_0$ gives

$$\inf_{x\in\mathfrak{P}} \left(1 - |\Lambda_{\text{law}}(x)|\right) \;\geq\; c_0 - \eta_{\mathfrak{P}}.$$

Since $\eta_{\mathfrak{P}}$ is a certification tolerance, we may (if needed) tighten the mask $\mathfrak{P}$ so that $\eta_{\mathfrak{P}} < \frac{1}{2}c_0$. Define

$$\delta_\star \;:=\; \tfrac{1}{2}c_0 \;\in (0,1).$$

Then for all $x \in \mathfrak{P}$,

$$1 - \left|\Lambda_{\text{law}}(x)\right| \;\geq\; \delta_\star \quad\Longleftrightarrow\quad \left|\Lambda_{\text{law}}(x)\right| \;\leq\; 1 - \delta_\star.$$

This proves the *persistent law-deficit* uniformly on $\mathfrak{P}$. Gauge-parameter independence follows from Proposition 7.569, and insensitivity to BRST/improvement trivialities from Lemma 7.552.

(2) State channel: unique vacuum $\Rightarrow |\Lambda_{\text{state}}| \to 1$ uniformly on $\mathfrak{P}$. *Step 2a (Uniqueness and mass gap on the band).* In QIV, explicit breakings select a unique vacuum (no vacuum manifold), so there are *no exact NG modes*; the would-be NG excitations are pseudo-NG with GMOR-type masses controlled by the spurions (see the Ward→GMOR discussion in Section 7.9 and the standard references [94, 91, 112]). On the band, the mass/mixing ledger built from the scale-tagged Hessian (cf. the "Mass-matrix & mixing ledger" step in Section 7.9) shows that all would-be NG directions acquire positive masses $m_\pi^2(\lambda_{\text{UV}}, \ell) > 0$ for $\epsilon_k \neq 0$.

Because $\mathfrak{P}$ is a finite (or compact) mask in the discretized $(\lambda_{\mathrm{UV}}, \ell)$-grid and the ledger depends continuously on parameters, there exists a *uniform* lower bound

$$m_{\min}^2 \;:=\; \inf_{x\in\mathfrak{P}} \; m_\pi^2(x) \;>\; 0. \tag{7.682}$$

Hence the correlation length is uniformly bounded: $\xi_{\max} := \sup_{x\in\mathfrak{P}} \xi(x) = \sup_x m_\pi(x)^{-1} < \infty$.

Step 2b (Exponential clustering and branch preparation). Let $|\Omega_1(x)\rangle\,, |\Omega_2(x)\rangle$ be the two branch-prepared states used in the visibility definition (Definition 6.275), constructed by admissible boundary conditions that differ only in a boundary layer. For a gapped, local theory with correlation length $\xi(x)$, the cluster property implies exponential decay of connected correlators on scales $\gtrsim \xi(x)$ (see, e.g., [91] for continuum arguments). Therefore boundary-induced differences are confined to an $O(\xi(x))$-thick shell near the boundary. If the system volume is $V = L^d$, then standard estimates (trace-norm/fidelity or Lieb–Robinson–type bounds in the lattice regularization) give, for some $C > 0$ independent of L,

$$\big\|\Omega_2(x) - \Omega_1(x)\big\| \;\le\; C\,\frac{\mathrm{Area}(\partial\Lambda)}{V}\, e^{-L/\xi(x)} \;=\; O\Big(e^{-L/\xi(x)}\Big)\,. \tag{7.683}$$

For normalized pure states, the overlap satisfies $1 - |\,\langle\Omega_2\rangle\,\Omega_1|\le \tfrac{1}{2}\|\Omega_2 - \Omega_1\|^2$, hence, inserting (7.683),

$$1 - \Big|\Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)}(V)\Big| = 1 - \Big|\,\langle\Omega_2(x)\rangle\,\Omega_1(x)\Big| \;\le\; C'\,e^{-2L/\xi(x)} \;\xrightarrow{L\to\infty}\; 0. \tag{7.684}$$

Step 2c (Uniformity on $\mathfrak{P}$). By (7.682), $\xi(x) \le \xi_{\max}$ for all $x \in \mathfrak{P}$. Therefore (7.684) is uniform on $\mathfrak{P}$:

$$\sup_{x\in\mathfrak{P}} \Big(1 - \Big|\Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)}(V)\Big|\Big) \;\le\; C''\,e^{-2L/\xi_{\max}} \;\xrightarrow{L\to\infty}\; 0,$$

which proves $\lim_{V\to\infty} |\Lambda_{\mathrm{state}}^{(\lambda_{\mathrm{UV}},\ell)}(V)| = 1$ uniformly on the plateau. As before, gauge-parameter independence and cohomological robustness follow from Proposition 7.556 and Lemma 7.552.

Conclusion. Steps (1a–1b) establish a *uniform* law-visibility deficit with some $\delta_\star \in (0,1)$; Steps (2a–2c) establish the *uniform* large-volume convergence of the state visibility to 1. Both statements hold on $\mathcal{H}_{\mathrm{phys}}$, are adjoint-covariant (Proposition 7.568), and are stable under BRST/improvement ambiguities (Lemma 7.552). This completes the proof. □

Corollary 7.581 (Channel additivity and robustness)**.** *With the triadic decomposition of Proposition 7.555,*

$$\Lambda_\bullet^{(\lambda_{\mathrm{UV}},\ell)} = \sum_{\alpha\in\{\mathrm{corr},\mathrm{vac},\mathrm{spec}\}} \Lambda_\bullet^{(\alpha;\lambda_{\mathrm{UV}},\ell)}, \qquad \bullet \in \{\mathrm{law},\mathrm{state}\},$$

the law-deficit lower bound of Theorem 7.580 is saturated (up to certified plateau tolerances) by the spectral (T-odd) contribution, while the state channel's approach to unity is saturated by the vacuum piece; both statements are uniform on $\mathfrak{P}$ and invariant under BRST- and Noether-improvements on $\mathcal{H}_{\mathrm{phys}}$.

Proof (expanded). We use: (i) channel additivity and orthogonality (Proposition 7.555); (ii) band descent and BRST/Nielsen safety (Lemma 7.552 and Proposition 7.556); (iii) the QIV law-deficit and state-limit established on certified plateaus (Theorem 7.580); (iv) plateau regularity (Definition 6.300); and (v) the scale-aware setup (Section 6.12).

(A) Law channel: deficit is (plateau-)saturated by the spectral branch. At a fixed band point $x = (\lambda_{\mathrm{UV}}, \ell) \in \mathfrak{P}$, decompose

$$\Lambda_{\mathrm{law}}(x) = \Lambda_{\mathrm{law}}^{(\mathrm{vac})}(x) + \Lambda_{\mathrm{law}}^{(\mathrm{corr})}(x) + \Lambda_{\mathrm{law}}^{(\mathrm{spec})}(x).$$

By construction of the holosymmetric visibilities, the *spectral* piece is T-odd, while the *vacuum* and *correction* pieces are T-even (they come from equal-time, symmetric correlators that do not contribute negatively to the real part at unity normalization). Therefore

$$1 - |\Lambda_{\mathrm{law}}(x)| \;\geq\; -\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec})}(x). \tag{7.685}$$

The spectral contribution admits a positive-kernel representation (Kubo-type) at the band point (cf. the proof of Lemma 7.578):

$$-\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec})}(x) = \int_{-\omega_0}^{\omega_0} d\omega\; \mathsf{K}_{\mathrm{spec}}(x;\omega)\, \mathsf{S}_a(x;\omega),$$

with $\mathsf{K}_{\mathrm{spec}}(x;\omega) \geq \kappa_{\mathrm{spec}}(x) > 0$ on a compact window and S_a the spectral density of the adjoint-covariant divergence for a broken direction a. If the Ward source $\mathcal{R}_a(x)$ is nonzero, then the integral is strictly positive (Lemma 7.578).

On a certified plateau $\mathfrak{P}$, oscillation bounds ensure that the *T-even* sum $\Lambda_{\mathrm{law}}^{(\mathrm{vac})} + \Lambda_{\mathrm{law}}^{(\mathrm{corr})}$ stays within $\eta_{\mathfrak{P}}$ of its x_0-value where the bound is attained. Hence,

$$1 - |\Lambda_{\mathrm{law}}(x)| \;=\; -\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec})}(x) \;\pm\; O(\eta_{\mathfrak{P}}) \qquad \text{uniformly in } x \in \mathfrak{P}, \tag{7.686}$$

where the $\pm O(\eta_{\mathfrak{P}})$ captures the certified variation of the T-even branches (Definition 6.300). Combining (7.685)–(7.686) with Theorem 7.580 yields that the *lower bound* for the law-deficit is provided by the spectral branch and is *saturated up to* $O(\eta_{\mathfrak{P}})$.

Cohomological robustness: by Lemma 7.552, BRST-exact and Noether-improvement terms do not contribute on $\mathcal{H}_{\mathrm{phys}}$; thus both the bound and its (plateau) saturation are invariant under such redefinitions. Gauge-parameter independence is guaranteed by Proposition 7.556.

(B) State channel: convergence to unity is saturated by the vacuum branch. Decompose similarly,

$$\Lambda_{\mathrm{state}}(x;V) = \Lambda_{\mathrm{state}}^{(\mathrm{vac})}(x;V) + \Lambda_{\mathrm{state}}^{(\mathrm{corr})}(x;V) + \Lambda_{\mathrm{state}}^{(\mathrm{spec})}(x;V).$$

In QIV there is a *unique* vacuum (no exact NG directions); the would-be NG modes are pseudo-NG and gapped on the band (mass/mixing ledger, cf. Section 7.9), yielding a uniform correlation-length bound on $\mathfrak{P}$ (see the proof of Theorem 7.580). Standard clustering/exponential-decay arguments then imply that, as $V \to \infty$,

$$\Lambda_{\mathrm{state}}^{(\mathrm{corr})}(x;V) \;\to\; 0, \qquad \Lambda_{\mathrm{state}}^{(\mathrm{spec})}(x;V) \;\to\; 0, \qquad \text{uniformly in } x \in \mathfrak{P}, \tag{7.687}$$

while the vacuum branch converges to unity,

$$\Lambda_{\mathrm{state}}^{(\mathrm{vac})}(x;V) \;\to\; 1 \qquad \text{uniformly in } x \in \mathfrak{P}. \tag{7.688}$$

Thus

$$\lim_{V\to\infty}\; \Lambda_{\mathrm{state}}(x;V) = \lim_{V\to\infty}\; \Lambda_{\mathrm{state}}^{(\mathrm{vac})}(x;V) = 1 \quad \text{uniformly on } \mathfrak{P},$$

which is precisely the statement that the approach to unity is *saturated* by the vacuum piece. As before, BRST/improvement invariance follows from Lemma 7.552, and gauge-parameter independence from Proposition 7.556.

Conclusion. The channel-additive structure (Proposition 7.555) together with the QIV plateau diagnostics (Theorem 7.580) implies: (i) the law-channel deficit originates from—and, up to certified tolerances, is saturated by—the spectral (T-odd) branch; (ii) the state-channel limit to unity is saturated by the vacuum branch; in both cases uniformly on $\mathfrak{P}$ and stable under BRST- and Noether-improvements on $\mathcal{H}_{\text{phys}}$. □

7.9.5 State–visibility guardrail (no SSB / no decoherence of vacua)

Definition 7.582 (State–visibility guardrail and acceptance)**.** Let $\mathfrak{P}$ be a certified plateau mask (Definition 6.300) in the scale-aware setup (Section 6.12). The *state visibility* at a band point $x = (\lambda_{\text{UV}}, \ell)$ and finite volume $V = L^d$ is

$$\Lambda_{\text{state}}(x; V) := \langle \Omega_2^{(\lambda_{\text{UV}},\ell)}(V) \rangle \, \Omega_1^{(\lambda_{\text{UV}},\ell)}(V),$$

with branch states prepared as in Definitions 6.275 and 7.551. We say the state channel *passes the guardrail* on $\mathfrak{P}$ if there exists a tolerance function $\varepsilon_{\mathfrak{P}}(L) \downarrow 0$ such that

$$1 - |\Lambda_{\text{state}}(x; V)| \;\le\; \varepsilon_{\mathfrak{P}}(L) \qquad \text{for all } x \in \mathfrak{P}.$$

Two canonical acceptance envelopes are allowed:

1. *Exponential (gapped case):* $\varepsilon_{\mathfrak{P}}(L) = C\, e^{-L/\xi_{\max}}$ for some $C, \xi_{\max} > 0$ independent of $x \in \mathfrak{P}$.
2. *Power-law (critical but non-SSB case):* $\varepsilon_{\mathfrak{P}}(L) = C\, L^{-\gamma}$ for some $\gamma > 0$ independent of $x \in \mathfrak{P}$.

Gauge-parameter independence of Λ_{state} on $\mathcal{H}_{\text{phys}}$ is guaranteed by Proposition 7.556, and the band descent is BRST-safe by Lemma 7.552.

Lemma 7.583 (Fidelity and trace-distance control for band-prepared branches)**.** *For normalized branch states at $x \in \mathfrak{P}$ and volume V,*

$$1 - |\Lambda_{\text{state}}(x; V)| \;\le\; \tfrac{1}{2} \big\| \rho_2(x; V) - \rho_1(x; V) \big\|_1,$$

where ρ_i are the corresponding band-reduced density operators. The right-hand side is BRST/Nielsen safe on $\mathcal{H}_{\text{phys}}$ by Lemma 7.552 and Proposition 7.556.

Proof. Step 1: Band descent and reduced states. Let Φ_x denote the (UV/IR) band-preparation channel at x (the composition of $P_x(\lambda_{\text{UV}})$, $K_{\text{IR}}^{(\ell)}$, and the restriction to the finite volume V). Then Φ_x is a completely positive, trace-preserving (CPTP) map on density operators, and the band-reduced states are

$$\rho_i(x; V) \;:=\; \Phi_x\Big(|\Psi_i\rangle\langle\Psi_i| \Big), \qquad i = 1, 2,$$

for normalized branch vectors $|\Psi_i\rangle$ on the underlying Hilbert space. By Proposition 7.573, Φ_x commutes with BRST/G actions and is well defined on certified plateaus.

Step 2: Choice of branch overlap as Uhlmann amplitude. By Uhlmann's theorem, for any ρ_1, ρ_2 there exist purifications $|\varphi_i\rangle$ on a system+ancilla space such that

$$\left|\langle\varphi_2|\varphi_1\rangle\right| \;=\; \sqrt{F(\rho_1,\rho_2)}\,, \qquad \text{(Uhlmann fidelity) [385, 386].}$$

In the present setting we realise purifications canonically via a Stinespring dilation of Φ_x: $\rho_i = \mathrm{Tr}_E\big(U_x\,|\Psi_i\rangle\langle\Psi_i|\otimes|0\rangle\langle 0|\,U_x^\dagger\big)$. The freedom $|\varphi_i\rangle \mapsto (\mathbf{1}\otimes U_i)|\varphi_i\rangle$ on the ancilla allows us to *fix the relative ancilla gauge* so that the overlap equals the Uhlmann amplitude. We *define* the (post–band) state overlap as

$$|\Lambda_{\mathrm{state}}(x;V)| \;:=\; \sqrt{F\big(\rho_1(x;V),\rho_2(x;V)\big)}.$$

This convention matches the pure–state case (then ρ_i are pure and $|\Lambda_{\mathrm{state}}| = |\langle\Psi_2|\Psi_1\rangle|$) and is invariant under physically irrelevant ancilla unitaries.

Step 3: Fuchs–van de Graaf (FvdG) inequality. The FvdG bounds relate trace distance $D(\rho_1,\rho_2) := \frac{1}{2}\|\rho_1-\rho_2\|_1$ and fidelity [388]:

$$1-\sqrt{F(\rho_1,\rho_2)} \;\le\; D(\rho_1,\rho_2) \;\le\; \sqrt{1-F(\rho_1,\rho_2)}.$$

Applying the left-hand inequality with $\rho_i = \rho_i(x;V)$ and using the definition in Step 2 yields

$$1-|\Lambda_{\mathrm{state}}(x;V)| \;=\; 1-\sqrt{F(\rho_1,\rho_2)} \;\le\; \tfrac{1}{2}\,\|\rho_2-\rho_1\|_1,$$

which is the desired inequality.

Step 4: BRST/Nielsen safety. On $\mathcal{H}_{\mathrm{phys}}$, BRST-exact deformations do not change physical matrix elements, and gauge-parameter variations are Nielsen-trivial (Lemma 7.552 and Proposition 7.556). Since trace distance is invariant under unitary conjugations and *contractive* under CPTP maps, and since Φ_x commutes with BRST/G (Proposition 7.573), the quantity $\|\rho_2-\rho_1\|_1$ is gauge-parameter independent on certified plateaus. Hence the right-hand side is BRST/Nielsen safe.

This completes the proof. □

Lemma 7.584 (Boundary sensitivity bound (gapped case))**.** *Assume at $x\in\mathfrak{P}$ the band Hessian has a positive spectral gap $m_{\min}(x)>0$ in the would-be NG sector (no exact NG). Then there exist constants $C(x),\xi(x)<\infty$ such that for branch preparations differing only on a boundary layer of width $O(1)$,*

$$\Big\|\rho_2(x;V)-\rho_1(x;V)\Big\|_1 \;\le\; C(x)\,e^{-L/\xi(x)}.$$

If $\inf_{x\in\mathfrak{P}} m_{\min}(x)>0$, then $\sup_{x\in\mathfrak{P}}\xi(x) =: \xi_{\max}<\infty$ and $\sup_{x\in\mathfrak{P}} C(x) =: C<\infty$.

Proof. Setting and notation. Let V be a region of linear size L and let the two preparations differ only on a boundary layer S_{bdy} of thickness $O(1)$ adjacent to ∂V. Denote by Φ_x the band-preparation channel at x (composition of $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$, and restriction to V), so $\rho_i(x;V) = \Phi_x(|\Psi_i\rangle\langle\Psi_i|)$. By Proposition 7.573, Φ_x is CPTP, commutes with BRST/G, and is quasi-local (cone-preserving).

Step 1: Linear-response representation of the difference. Connect the two boundary preparations by a path of boundary couplings $\{\mathcal{B}_s\}_{s\in[0,1]}$ supported on S_{bdy}, with $\mathcal{B}_0$ and $\mathcal{B}_1$ realizing the two choices. For any observable A supported in the deep interior V_{in} (distance $\gtrsim L$ from the boundary), the Gâteaux derivative of the band-expectation is given by the Kubo/Duhamel formula at x:

$$\frac{d}{ds}\,\mathrm{Tr}\big[A\,\rho_s(x;V)\big] = \int_{S_{\mathrm{bdy}}} d\Sigma \int_0^1 dt\,\Big\langle A^{(x)}\;;\;\mathcal{J}_s^{(x)}(t)\Big\rangle_c\,, \tag{7.689}$$

where $\rho_s(x;V) := \Phi_x(\rho_s)$, $\mathcal{J}_s$ is the boundary insertion local current (a linear functional of $\dot{\mathcal{B}}_s$), $A^{(x)}$ and $\mathcal{J}_s^{(x)}$ denote their band-descended versions, and $\langle\cdot;\cdot\rangle_c$ is the connected correlator on $\mathcal{H}_{\mathrm{phys}}$. The representation (7.689) follows from standard linear-response plus the fact that Φ_x is linear and commutes with BRST/G (Proposition 7.573); non–signalling of descended operators is guaranteed by Corollary 7.574.

Step 2: Exponential clustering. The spectral gap $m_{\min}(x) > 0$ for the (band) Hessian implies exponential clustering of connected correlators with correlation length $\xi(x) \sim m_{\min}(x)^{-1}$:

$$\Big|\langle A^{(x)}\;;\;\mathcal{J}_s^{(x)}(t)\rangle_c\Big| \;\le\; C_0(x)\,\|A\|\,\|\mathcal{J}_s\|\,e^{-\mathrm{dist}(V_{\mathrm{in}},S_{\mathrm{bdy}})/\xi(x)} \;\le\; C_0(x)\,\|A\|\,\|\mathcal{J}_s\|\,e^{-L/\xi(x)}. \tag{7.690}$$

Here $C_0(x)$ absorbs local norms and the finite time aperture coming from the IR tagger, and we used that band descent preserves locality and does not increase operator norm up to a finite factor on certified plateaus (Definition 6.300).

Step 3: From response to trace distance. Integrating (7.689) in $s \in [0,1]$ and $t \in [0,1]$, using (7.690), and the fact that the boundary layer has $O(1)$ thickness and $O(L^{d-2})$ area (absorbed into constants for fixed geometry), we obtain

$$\Big|\,\mathrm{Tr}\Big[A\;(\rho_2(x;V) - \rho_1(x;V))\Big]\Big| \;\le\; C_1(x)\,\|A\|\,e^{-L/\xi(x)}.$$

Taking the supremum over $\|A\| \le 1$ (the dual characterization of the trace norm) yields

$$\big\|\rho_2(x;V) - \rho_1(x;V)\big\|_1 \;\le\; C(x)\,e^{-L/\xi(x)}\,,$$

with $C(x)$ finite for each fixed x.

Step 4: Uniformity on $\mathfrak{P}$. If $\inf_{x\in\mathfrak{P}} m_{\min}(x) > 0$, continuity of the band spectrum and kernels on the certified plateau (compactness of the mask, Definition 6.300) implies $x \mapsto \xi(x)$ and $x \mapsto C(x)$ are bounded on $\mathfrak{P}$. Set $\xi_{\max} := \sup_{x\in\mathfrak{P}} \xi(x) < \infty$ and $C := \sup_{x\in\mathfrak{P}} C(x) < \infty$.

This proves the claim. □

Lemma 7.585 (Boundary sensitivity bound (critical but non-SSB case))**.** *If the band theory at $x \in \mathfrak{P}$ is gapless but has a unique vacuum (no SSB) and finite dynamic exponent $z < \infty$, then for boundary-layer preparations as above there exist $C(x), \gamma(x) > 0$ such that*

$$\big\|\rho_2(x;V) - \rho_1(x;V)\big\|_1 \;\le\; C(x)\,L^{-\gamma(x)}.$$

If critical exponents vary continuously on $\mathfrak{P}$, we may take $C := \sup_{x\in\mathfrak{P}} C(x) < \infty$ and $\gamma := \inf_{x\in\mathfrak{P}} \gamma(x) > 0$.

Proof. Step 1: Linear-response as in the gapped case. With the same setup and notation as in Lemma 7.584, the difference of band-reduced states against a bulk observable A supported in V_{in} admits the linear-response representation (7.689). The only change is the *clustering estimate* appropriate to criticality.

Step 2: Power-law clustering without SSB. At a critical point with unique vacuum and finite $z < \infty$, connected correlators decay as a *power law* set by scaling dimensions. Denote by $\Delta_A(x)$ the (band) scaling dimension of the bulk representative of A and by $\Delta_{\mathrm{b}}(x)$ the boundary scaling dimension of the insertion represented by $\mathcal{J}_s$.[18] Then there exists $\gamma(x) > 0$ such that for separations $r \equiv \mathrm{dist}(V_{\mathrm{in}}, S_{\mathrm{bdy}}) \sim L$,

$$\left|\langle A^{(x)} \,;\, \mathcal{J}_s^{(x)}(t)\rangle_c\right| \;\le\; C_0(x)\,\|A\|\,\|\mathcal{J}_s\|\,r^{-\gamma(x)}\,, \qquad \gamma(x) \;:=\; \Delta_A(x)+\Delta_{\mathrm{b}}(x)-d_{\mathrm{eff}}(x), \tag{7.691}$$

with $d_{\mathrm{eff}}(x) = d - 1 + z(x)$ the effective (boundary + time) scaling dimension. The bound (7.691) is the standard boundary-to-bulk decay from scale invariance in the absence of spontaneous order.

Step 3: Integration and trace-distance bound. Integrating (7.689) over $s \in [0,1]$, $t \in [0,1]$, and the boundary layer (whose thickness is $O(1)$) and using (7.691) with $r \sim L$ yields

$$\left|\,\mathrm{Tr}\Big[A\;(\rho_2(x;V)-\rho_1(x;V))\Big]\right| \;\le\; C_1(x)\,\|A\|\,L^{-\gamma(x)}.$$

Taking the supremum over $\|A\| \le 1$ gives

$$\Big\|\rho_2(x;V)-\rho_1(x;V)\Big\|_1 \;\le\; C(x)\,L^{-\gamma(x)}\,,$$

with $C(x)$ finite.

Step 4: Uniformity on $\mathfrak{P}$. On certified plateaus the critical data $(z, \Delta_A, \Delta_{\mathrm{b}})$ vary continuously (scale-aware regularity), hence $x \mapsto \gamma(x)$ and $x \mapsto C(x)$ are continuous. If $\inf_{x\in\mathfrak{P}}\gamma(x) > 0$, then setting $\gamma := \inf_{x\in\mathfrak{P}}\gamma(x)$ and $C := \sup_{x\in\mathfrak{P}} C(x)$ yields the uniform bound claimed.

This completes the proof. □

Remark 7.586. (i) The linear-response step is legitimate because the two preparations differ only by boundary terms of finite norm; the band-preparation channel is linear and CPTP, and commutes with BRST/G (Proposition 7.573). (ii) In the gapped case, (7.690) is the standard exponential clustering with correlation length $\xi(x) \propto m_{\min}(x)^{-1}$; in the critical case, (7.691) encodes boundary-to-bulk decay from scaling, with $\gamma(x)>0$ ensured by "no SSB." (iii) Non–signalling after band descent (Corollary 7.574) rules out contamination from outside the causal cones of the boundary layer.

Proposition 7.587 (Guardrail acceptance from boundary sensitivity)**.** *Under the hypotheses of Lemma 7.584 (gapped) or Lemma 7.585 (gapless non-SSB), the guardrail in Definition 7.582 holds with the corresponding envelope $\varepsilon_{\mathfrak{P}}(L)$, uniformly on $\mathfrak{P}$.*

[18] In the relativistic case $z = 1$, these are the usual CFT dimensions; for general finite z, replace time with $x^0 \sim r^{\,z}$ in the anisotropic scaling.

Proof. Step 1: From boundary sensitivity to a trace–distance envelope. In the gapped case (Lemma 7.584) there exist $C(x), \xi(x) < \infty$ such that

$$\left\|\rho_2(x;V) - \rho_1(x;V)\right\|_1 \;\le\; C(x)\, e^{-L/\xi(x)}.$$

If $\inf_{x\in\mathfrak{P}} m_{\min}(x) > 0$, continuity on the certified plateau (Definition 6.300) yields uniform bounds $\xi_{\max} := \sup_{x\in\mathfrak{P}} \xi(x) < \infty$ and $C := \sup_{x\in\mathfrak{P}} C(x) < \infty$, so

$$\sup_{x\in\mathfrak{P}} \left\|\rho_2(x;V) - \rho_1(x;V)\right\|_1 \;\le\; C\, e^{-L/\xi_{\max}}.$$

In the gapless non-SSB case (Lemma 7.585) there are $C(x), \gamma(x) > 0$ with $\|\rho_2(x;V) - \rho_1(x;V)\|_1 \le C(x)\, L^{-\gamma(x)}$. Assuming the scale data vary continuously on $\mathfrak{P}$, define $C := \sup_{x\in\mathfrak{P}} C(x) < \infty$ and $\gamma := \inf_{x\in\mathfrak{P}} \gamma(x) > 0$, hence

$$\sup_{x\in\mathfrak{P}} \left\|\rho_2(x;V) - \rho_1(x;V)\right\|_1 \;\le\; C\, L^{-\gamma}.$$

Step 2: From trace distance to the state guardrail. By the Fuchs–van de Graaf inequality (cf. Lemma 7.583),

$$1 - |\Lambda_{\text{state}}(x;V)| \;\le\; \tfrac{1}{2}\left\|\rho_2(x;V) - \rho_1(x;V)\right\|_1.$$

Taking the supremum over $x \in \mathfrak{P}$ and using the envelopes from Step 1 gives, uniformly on $\mathfrak{P}$,

$$\sup_{x\in\mathfrak{P}} \left(1 - |\Lambda_{\text{state}}(x;V)|\right) \;\le\; \begin{cases} \dfrac{C}{2}\, e^{-L/\xi_{\max}}, & \text{(gapped case)},\\[2ex] \dfrac{C}{2}\, L^{-\gamma}, & \text{(gapless non-SSB case)}. \end{cases}$$

Thus the guardrail of Definition 7.582 holds with $\varepsilon_{\mathfrak{P}}(L) = \frac{C}{2} e^{-L/\xi_{\max}}$ in the gapped case, or $\varepsilon_{\mathfrak{P}}(L) = \frac{C}{2} L^{-\gamma}$ in the critical non-SSB case. The constants are plateau–uniform by construction, completing the proof. □

Lemma 7.588 (Plateau uniformization for the state channel)**.** *Suppose for some $x_0 \in \mathfrak{P}$ and volume V we have $1 - |\Lambda_{\text{state}}(x_0;V)| \le \varepsilon_{\mathfrak{P}}(L)$, and the oscillation bound of Definition 6.300 holds for $\Lambda_{\text{state}}(\cdot;V)$. Then*

$$\sup_{x\in\mathfrak{P}} \left(1 - |\Lambda_{\text{state}}(x;V)|\right) \;\le\; \varepsilon_{\mathfrak{P}}(L) + \eta_{\mathfrak{P}}.$$

Proof. Let $f(x) := 1 - |\Lambda_{\text{state}}(x;V)| \ge 0$. The plateau oscillation bound from Definition 6.300 asserts that

$$\sup_{x,y\in\mathfrak{P}} |f(x) - f(y)| \;\le\; \eta_{\mathfrak{P}}.$$

Fix $x_0 \in \mathfrak{P}$ with $f(x_0) \le \varepsilon_{\mathfrak{P}}(L)$. Then for any $x \in \mathfrak{P}$,

$$f(x) \;\le\; f(x_0) + |f(x) - f(x_0)| \;\le\; \varepsilon_{\mathfrak{P}}(L) + \eta_{\mathfrak{P}}.$$

Taking the supremum over $x \in \mathfrak{P}$ yields the claim. Equivalently, this is the direct application of Lemma 7.579 with baseline point x_0 and envelope $\varepsilon_{\mathfrak{P}}(L)$. □

Theorem 7.589 (State–visibility guardrail: no decoherence of vacua)**.** *Assume (i) unique vacuum (no SSB) on the band for all $x \in \mathfrak{P}$, and (ii) either a uniform mass gap on $\mathfrak{P}$ or a critical but non-SSB regime with continuous exponents on $\mathfrak{P}$. Then the state channel passes the guardrail of Definition 7.582: uniformly on $\mathfrak{P}$,*

$$\lim_{V\to\infty} \; |\Lambda_{\text{state}}(x;V)| \;=\; 1.$$

If instead there exists a subsequence of volumes for which $|\Lambda_{\text{state}}(x;V)|$ exhibits a systematic decay bounded below by a positive constant independent of L on any refined mask, the system drifts toward QII (SSB-induced orthogonalization) and the guardrail fails.

Proof. Step 1: Uniform envelope from boundary sensitivity. For the gapped case, Lemma 7.584 yields $\|\rho_2(x;V) - \rho_1(x;V)\|_1 \le C(x)\, e^{-L/\xi(x)}$ whenever the two branch preparations differ only on an $O(1)$ boundary layer; assuming a plateau–uniform gap, we get the uniform bound $\sup_{x\in\mathfrak{P}} \|\rho_2 - \rho_1\|_1 \le C\, e^{-L/\xi_{\max}}$. For the gapless but non-SSB case, Lemma 7.585 gives $\sup_{x\in\mathfrak{P}} \|\rho_2 - \rho_1\|_1 \le C\, L^{-\gamma}$ for some $C < \infty$ and $\gamma > 0$ depending only on $\mathfrak{P}$.

Step 2: From trace distance to state visibility. By the Fuchs–van de Graaf bound (Lemma 7.583),

$$1 - |\Lambda_{\text{state}}(x;V)| \;\le\; \tfrac{1}{2}\, \|\rho_2(x;V) - \rho_1(x;V)\|_1.$$

Taking the supremum over $x \in \mathfrak{P}$ and using Step 1 gives, uniformly on $\mathfrak{P}$,

$$\sup_{x\in\mathfrak{P}} \big(1 - |\Lambda_{\text{state}}(x;V)|\big) \;\le\; \begin{cases} \frac{C}{2}\, e^{-L/\xi_{\max}}, & \text{(gapped)}, \\ \frac{C}{2}\, L^{-\gamma}, & \text{(critical, non-SSB)}. \end{cases}$$

Equivalently, the guardrail of Definition 7.582 holds with a decaying envelope $\varepsilon_{\mathfrak{P}}(L)$; this is exactly Proposition 7.587. Hence $\lim_{V\to\infty} \sup_{x\in\mathfrak{P}} (1 - |\Lambda_{\text{state}}(x;V)|) = 0$, which implies the stated uniform limit $|\Lambda_{\text{state}}(x;V)| \to 1$ on $\mathfrak{P}$.

Step 3: Plateau uniformization (optional sharpening). If one has a baseline point $x_0 \in \mathfrak{P}$ with $1 - |\Lambda_{\text{state}}(x_0;V)| \le \varepsilon_{\mathfrak{P}}(L)$, the plateau oscillation bound (Definition 6.300) and Lemma 7.588 give $\sup_{x\in\mathfrak{P}} (1 - |\Lambda_{\text{state}}(x;V)|) \le \varepsilon_{\mathfrak{P}}(L) + \eta_{\mathfrak{P}}$, which also tends to 0 as $L \to \infty$.

Step 4: Contrapositive / failure mode implies drift to QII. Suppose there exists a subsequence V_n and a mask refinement sequence (staying certified) such that, for some $x^* \in \mathfrak{P}$ and all large n,

$$1 - |\Lambda_{\text{state}}(x^*;V_n)| \;\ge\; \delta_\star > 0,$$

with $\delta_\star$ independent of L_n. Then by Lemma 7.583, $\|\rho_2(x^*;V_n) - \rho_1(x^*;V_n)\|_1 \ge 2\delta_\star$ for all large n. This contradicts the envelopes of Step 1 unless at least one hypothesis of the theorem fails. If the certified plateau remains valid, the only possible failure is the uniqueness of the vacuum: persistent, volume–independent distinguishability of boundary-layer preparations signals the emergence of multiple orthogonal vacua (spontaneous symmetry breaking). In the quadrant language, this is precisely the QII drift (state orthogonalization in the thermodynamic limit). Therefore, sustained decay of $|\Lambda_{\text{state}}|$ bounded away from zero along a refined certified sequence is a witness of QII onset and the guardrail fails.

Step 5: BRST/Nielsen safety. All steps above are taken in the physical sector $\mathcal{H}_{\text{phys}}$; the band-preparation channel commutes with BRST/G actions (Proposition 7.573), non–signalling after band descent holds (Corollary 7.574), and the trace-distance and visibility statements are gauge-parameter independent by Lemmas 7.552 and 7.583 and Proposition 7.556.

This completes the proof. □

Corollary 7.590 (Operational test (log–lin / log–log slopes))**.** *Given measurements of* $1 - |\Lambda_{\text{state}}(x; V)|$ *at increasing* L*:*

(i) Gapped case. *On any certified volume-window, a linear fit in* log–lin *scale has slope* $\le -1/\xi_{\max}$ *within tolerance; failure flags guardrail violation.*

(ii) Critical non-SSB case. *On any certified volume-window, a linear fit in* log–log *scale has slope* $\le -\gamma$ *within tolerance; failure flags guardrail violation.*

Both tests are BRST/Nielsen safe on $\mathcal{H}_{\text{phys}}$ *(Lemma 7.552 and Proposition 7.556) and should be applied uniformly over* $x \in \mathfrak{P}$ *with Lemma 7.588.*

Proof. Preliminaries (uniform envelope and uniformization). By Proposition 7.587, there exists a decaying envelope $\varepsilon_{\mathfrak{P}}(L)$ such that, uniformly on $x \in \mathfrak{P}$,

$$1 - |\Lambda_{\text{state}}(x; V)| \;\le\; \varepsilon_{\mathfrak{P}}(L). \tag{7.692}$$

Moreover, with the plateau oscillation bound (Definition 6.300) and Lemma 7.588, replacing x by the $\sup_{x\in\mathfrak{P}}$ only adds at most $\eta_{\mathfrak{P}}$:

$$y(L) \;:=\; \sup_{x\in\mathfrak{P}} \Big(1 - |\Lambda_{\text{state}}(x; V)|\Big) \;\le\; \varepsilon_{\mathfrak{P}}(L) + \eta_{\mathfrak{P}}. \tag{7.693}$$

We call a *certified volume-window* any interval $[L_{\min}, L_{\max}]$ on which

$$\frac{\eta_{\mathfrak{P}}}{\varepsilon_{\mathfrak{P}}(L)} \;\le\; \tau \quad \text{for all } L \in [L_{\min}, L_{\max}], \tag{7.694}$$

with a chosen tolerance parameter $0 < \tau < 1$ (so the envelope dominates the oscillation floor).

(i) Gapped case: log–lin slope. Here $\varepsilon_{\mathfrak{P}}(L) = \frac{C}{2}\, e^{-L/\xi_{\max}}$ (Proposition 7.587). Using (7.693),

$$\log y(L) \;\le\; \log \varepsilon_{\mathfrak{P}}(L) + \log\Big(1 + \frac{\eta_{\mathfrak{P}}}{\varepsilon_{\mathfrak{P}}(L)}\Big) = \log\Big(\tfrac{C}{2}\Big) - \frac{L}{\xi_{\max}} + \log\Big(1 + r(L)\Big),$$

with $r(L) := \eta_{\mathfrak{P}}/\varepsilon_{\mathfrak{P}}(L)$. On a certified window (7.694), $r(L) \le \tau$ and thus

$$\frac{\log y(L_2) - \log y(L_1)}{L_2 - L_1} \;\le\; -\frac{1}{\xi_{\max}} + \frac{\log(1 + r(L_2)) - \log(1 + r(L_1))}{L_2 - L_1} \;\le\; -\frac{1}{\xi_{\max}} + \frac{\log(1+\tau)}{L_2 - L_1}.$$

Therefore every *secant* slope on $[L_{\min}, L_{\max}]$ is $\le -1/\xi_{\max} + \delta_{\text{lin}}$ with

$$\delta_{\text{lin}} \;:=\; \frac{\log(1+\tau)}{L_{\max} - L_{\min}}.$$

Since the least-squares slope of a line fitted to $(L_i, \log y(L_i))$ is bounded above by the maximum secant slope on the fitting interval, the fitted slope is also $\le -1/\xi_{\max} + \delta_{\text{lin}}$. Choosing τ (how far above the oscillation floor we stay) and the window width $L_{\max} - L_{\min}$ fixes the *tolerance* δ_{lin}. If the fitted slope exceeds $-1/\xi_{\max} + \delta_{\text{lin}}$, then (7.693)–(7.694) cannot simultaneously hold, flagging a guardrail violation.

(ii) Critical non-SSB case: log–log slope. Here $\varepsilon_{\mathfrak{P}}(L) = \frac{C}{2} L^{-\gamma}$ (Proposition 7.587). With $X = \log L$,

$$\log y(L) \;\le\; \log \varepsilon_{\mathfrak{P}}(L) + \log\Big(1 + r(L)\Big) = \log\left(\tfrac{C}{2}\right) - \gamma \log L + \log\Big(1 + r(L)\Big),$$

again with $r(L) = \eta_{\mathfrak{P}}/\varepsilon_{\mathfrak{P}}(L)$. On a certified window (7.694), $r(L) \le \tau$, so for any $L_1 < L_2$,

$$\frac{\log y(L_2) - \log y(L_1)}{\log L_2 - \log L_1} \;\le\; -\gamma \;+\; \frac{\log(1 + r(L_2)) - \log(1 + r(L_1))}{\log L_2 - \log L_1} \;\le\; -\gamma \;+\; \frac{\log(1+\tau)}{\log(L_2/L_1)}.$$

Thus every *log–log* secant slope on $[L_{\min}, L_{\max}]$ is $\le -\gamma + \delta_{\log}$ with

$$\delta_{\log} \;:=\; \frac{\log(1+\tau)}{\log(L_{\max}/L_{\min})}.$$

As before, the least-squares slope in $(\log L, \log y)$ is bounded above by the maximal secant slope, so the fitted slope is $\le -\gamma + \delta_{\log}$. If the fitted slope is larger than $-\gamma + \delta_{\log}$, the guardrail is violated on that window.

BRST/Nielsen safety and uniformity. All quantities are computed from band-descended, BRST-closed observables on $\mathcal{H}_{\text{phys}}$, and the preparation/measurement maps commute with BRST/G (Proposition 7.573), hence the tests are gauge-parameter independent (Lemma 7.552 and Proposition 7.556). Applying Lemma 7.588 ensures the analysis holds uniformly over $x \in \mathfrak{P}$ (the measured series can be pooled or tested pointwise with the same tolerance).

This proves both operational tests. □

7.9.6 State–visibility Envelope Selection, CIs, and Fallback Protocol

Context. On a certified plateau $\mathfrak{P}$ (Definition 6.300) the state channel must *not* exhibit thermodynamic orthogonality (QII signature). The guardrail (Definition 7.582 and Theorem 7.589) admits two acceptance envelopes, motivated by Lemmas 7.584 and 7.585: (i) exponential (gapped) and (ii) power–law (critical, non–SSB). We formalize the model selection per band point x, estimate $(\xi(x), \gamma(x))$ with CIs, aggregate to $(\xi_{\max}, \gamma)$ on $\mathfrak{P}$, and specify a fallback rule.

Definition 7.591 (Volume series and two candidate envelopes)**.** At $x = (\lambda_{\text{UV}}, \ell) \in \mathfrak{P}$, measure

$$D_x(L_n) \;:=\; 1 - |\Lambda_{\text{state}}(x; V_n)|, \qquad V_n = L_n^d, \quad n = 1, \dots, N,$$

with $L_{n+1}/L_n = r > 1$ fixed on the plateau window, and weights $w_n > 0$ from readout uncertainties. Fit the two candidate models:

$$\text{(Exp)} \quad D_x(L) \;=\; C_x\, e^{-L/\xi(x)}\,(1 + \varepsilon_L), \tag{7.695}$$

$$\text{(Pow)} \quad D_x(L) \;=\; C_x\, L^{-\gamma(x)}\,(1 + \varepsilon_L), \tag{7.696}$$

where ε_L is a small model error controlled by Lemmas 7.584 and 7.585.

Proposition 7.592 (WLS estimators and confidence intervals)**.** *Apply weighted least squares (WLS) in the linearized coordinates.*
Exponential (gapped): *log–lin regression* $y_n := \log D_x(L_n) = \alpha_x - L_n/\xi(x) + \eta_n$ *with weights* w_n*. Then* $\widehat{\xi}(x) = -1/\widehat{s}_E$ *where* $\widehat{s}_E$ *is the fitted slope; obtain* $\mathrm{CI}_{1-\beta}(\xi(x))$ *by the delta–method from the slope CI.*
Power–law (critical non-SSB): *log–log regression* $y_n := \log D_x(L_n) = \alpha_x - \gamma(x)\log L_n + \eta_n$ *with weights* w_n*; slope gives* $\widehat{\gamma}(x)$ *and its CI.*

Both fits are BRST/Nielsen safe on $\mathcal{H}_{\mathrm{phys}}$ *by Lemma 7.552 and Proposition 7.556.*

Proof. Setup and notation. For a fixed $x \in \mathfrak{P}$, let $D_x(L_n) > 0$ denote the measured state–deficit at linear size L_n (e.g. $D_x(L_n) = 1 - |\Lambda_{\mathrm{state}}(x; V_n)|$ on a certified mask). Define the linear models

$$y_n \equiv \log D_x(L_n) = \alpha_x + s\, X_n + \eta_n, \qquad X_n = \begin{cases} L_n & \text{(exponential)}, \\ \log L_n & \text{(power–law)}, \end{cases}$$

with $\mathbb{E}[\eta_n \mid X_n] = 0$ and $\mathrm{Var}(\eta_n \mid X_n) \propto w_n^{-1}$ (the proportionality can be absorbed into the scale of w_n). Let $W = \mathrm{diag}(w_1, \dots, w_N)$ and $X = \begin{bmatrix} \mathbf{1} & \mathbf{X} \end{bmatrix}$ with $\mathbf{X} = (X_1, \dots, X_N)^\top$.

WLS estimator and its variance. The WLS estimator $\widehat{\beta} = (\widehat{\alpha}, \widehat{s})^\top$ solves

$$\widehat{\beta} = (X^\top W X)^{-1} X^\top W\, \mathbf{y},$$

so the slope has the familiar centered form

$$\widehat{s} = \frac{\sum_n w_n (X_n - \bar{X}_w)(y_n - \bar{y}_w)}{\sum_n w_n (X_n - \bar{X}_w)^2}, \qquad \bar{X}_w = \frac{\sum_n w_n X_n}{\sum_n w_n}, \quad \bar{y}_w = \frac{\sum_n w_n y_n}{\sum_n w_n}.$$

If $w_n \propto \mathrm{Var}(\eta_n)^{-1}$ (well-specified WLS), then

$$\mathrm{Var}(\widehat{s} \mid X) = \sigma^2 \Big(\sum_n w_n (X_n - \bar{X}_w)^2 \Big)^{-1},$$
$$\widehat{\sigma}^2 := \frac{\sum_n w_n \widehat{\eta}_n^2}{N - 2}.$$

and an approximate $(1-\beta)$ slope–CI is $\widehat{s} \pm t_{N-2,\,1-\beta/2}\ \widehat{\mathrm{se}}(\widehat{s})$, with $\widehat{\mathrm{se}}(\widehat{s}) = \widehat{\sigma}\left(\sum_n w_n (X_n - \bar{X}_w)^2\right)^{-1/2}$. If the weights are only approximate, use the usual WLS *sandwich* (HC) covariance:

$$\widehat{\mathrm{Var}}(\widehat{\beta}) = (X^\top W X)^{-1} \Big(\sum_n w_n^2\, \widehat{\eta}_n^2\, x_n x_n^\top \Big) (X^\top W X)^{-1},$$
$$\text{where } x_n = (1, X_n)^\top,$$

and read off $\widehat{\mathrm{Var}}(\widehat{s})$ from the $(2,2)$ entry.

Exponential case: estimator for $\xi(x)$. Here $s = s_E = -1/\xi(x) < 0$. Define $g(s) := -1/s$ so that $\xi(x) = g(s_E)$. By asymptotic normality of $\widehat{s}$ (linear model with fixed design and

standard regularity), the *delta–method* gives

$$\widehat{\xi}(x) = g(\widehat{s}) = -\frac{1}{\widehat{s}},$$
$$\widehat{\mathrm{Var}}\big(\widehat{\xi}(x)\big) \approx \big(g'(\widehat{s})\big)^2\, \widehat{\mathrm{Var}}(\widehat{s}) = \frac{\widehat{\mathrm{Var}}(\widehat{s})}{\widehat{s}^{\,4}}.$$

Thus an approximate $(1-\beta)$ CI is

$$\mathrm{CI}_{1-\beta}\big(\xi(x)\big) \;:\; \widehat{\xi}(x) \;\pm\; z_{1-\beta/2}\,\frac{\widehat{\mathrm{se}}(\widehat{s})}{|\widehat{s}|^2},$$

with $z_{1-\beta/2}$ (or replace by $t_{N-2,1-\beta/2}$). Because g is monotone on $(-\infty,0)$, one may equivalently *transform the slope–CI* endpoints: if $[\widehat{s}_-,\widehat{s}_+]$ is the $(1-\beta)$ CI for s with $\widehat{s}_- < \widehat{s}_+ < 0$, then

$$\mathrm{CI}_{1-\beta}\big(\xi(x)\big) \;=\; \Big[-\frac{1}{\widehat{s}_+},\; -\frac{1}{\widehat{s}_-}\Big],$$

which is first–order equivalent to the delta–method CI. (If a fitted slope is nonnegative on a window, this violates the guardrail; cf. Corollary 7.590.)

Power–law case: estimator for $\gamma(x)$. Here $s = s_P = -\gamma(x)$. Hence $\widehat{\gamma}(x) = -\widehat{s}$, and the slope–CI $\widehat{s} \pm z_{1-\beta/2}\,\widehat{\mathrm{se}}(\widehat{s})$ maps to

$$\mathrm{CI}_{1-\beta}\big(\gamma(x)\big) \;:\; -\widehat{s} \;\mp\; z_{1-\beta/2}\,\widehat{\mathrm{se}}(\widehat{s}).$$

No delta transform is needed (the map $s \mapsto -s$ is exact and linear).

Regularity, certification, and BRST/Nielsen safety. The log–transform requires $D_x(L_n) > 0$, guaranteed on certified plateaus where measurements lie strictly above the floor (cf. the kernel/spectral floors and mask eligibility). Because D_x is built from band–descended, BRST–closed quantities and the taggers commute with BRST/G (Proposition 7.573), the regression statistics are gauge–parameter independent (Lemma 7.552 and Proposition 7.556). Standard linear–model regularity (bounded design, $\sum_n w_n(X_n - \bar{X}_w)^2 > 0$, finite fourth moments of η_n) yields consistency and asymptotic normality of the WLS slope, justifying the CIs above.

Conclusion. In log–lin (gapped) and log–log (critical non–SSB) coordinates, WLS provides slope estimators whose transforms yield $\widehat{\xi}(x)$ and $\widehat{\gamma}(x)$, with confidence intervals obtained from the slope–CI by the delta–method (exponential) or direct sign–flip (power–law). This establishes the proposition. □

Definition 7.593 (Model selection and mask aggregation)**.** For each $x \in \mathfrak{P}$, compute WLS residual sums $RSS_E(x)$ and $RSS_P(x)$ and the small–sample AIC_c:

$$\mathrm{AIC}_c^{(M)}(x) = N\log\frac{RSS_M(x)}{N} + 2k + \frac{2k(k+1)}{N-k-1}, \quad M \in \{E,P\},$$

with $k = 2$ (intercept and slope). Let $\Delta(x) := \mathrm{AIC}_c^{(P)}(x) - \mathrm{AIC}_c^{(E)}(x)$. Choose the envelope per x by:

$$\text{If } \Delta(x) \ge \Delta_\star \;\Rightarrow\; \text{Exp at } x \quad ; \quad \text{if } \Delta(x) \le -\Delta_\star \;\Rightarrow\; \text{Pow at } x \quad ; \quad \text{else: ambiguous.}$$

We recommend $\Delta_\star \in [4,6]$ (strong evidence). Define the *plateau envelopes*

$$\xi_{\max} := \sup_{x\in\mathfrak{P}_E} \overline{\xi}(x), \qquad \gamma := \inf_{x\in\mathfrak{P}_P} \underline{\gamma}(x),$$

where $\mathfrak{P}_E = \{x : \text{Exp chosen}\}$, $\mathfrak{P}_P = \{x : \text{Pow chosen}\}$, and $\overline{\xi}(x)$ (resp. $\underline{\gamma}(x)$) are the upper (resp. lower) ends of the chosen $(1-\beta)$ CIs.

Proposition 7.594 (Guardrail acceptance with CIs)**.** *If $\mathfrak{P}_E \cup \mathfrak{P}_P$ covers $\mathfrak{P}$ and the aggregated $\xi_{\max} < \infty$ and $\gamma > 0$, then the guardrail of Definition 7.582 holds uniformly on $\mathfrak{P}$ with the envelope*

$$D_x(L) \;\le\; \begin{cases} C\, e^{-L/\xi_{\max}}, & x \in \mathfrak{P}_E, \\ C\, L^{-\gamma}, & x \in \mathfrak{P}_P, \end{cases}$$

up to the plateau oscillation $\eta_{\mathfrak{P}}$. Gauge-parameter independence follows from Proposition 7.556.

Proof. Step 1: Pointwise envelopes. For $x \in \mathfrak{P}_E$ (gapped), Lemma 7.584 provides constants $C_E(x) < \infty$ and $\xi(x) < \infty$ such that

$$D_x(L) \;\le\; C_E(x)\, e^{-L/\xi(x)}. \tag{7.697}$$

For $x \in \mathfrak{P}_P$ (critical, non-SSB), Lemma 7.585 provides $C_P(x) < \infty$ and $\gamma(x) > 0$ with

$$D_x(L) \;\le\; C_P(x)\, L^{-\gamma(x)}. \tag{7.698}$$

Here $D_x(L) := 1 - |\Lambda_{\text{state}}(x; V)|$ on a certified mask for volume $V \sim L^d$.

Step 2: Aggregating decay rates. By hypothesis there exist *aggregated* exponents

$$\xi_{\max} := \sup_{x\in\mathfrak{P}_E} \xi(x) \;<\; \infty, \qquad \gamma := \inf_{x\in\mathfrak{P}_P} \gamma(x) \;>\; 0.$$

Then for any $x \in \mathfrak{P}_E$, $e^{-L/\xi(x)} \le e^{-L/\xi_{\max}}$, hence (7.697) implies $D_x(L) \le C_E(x)\, e^{-L/\xi_{\max}}$. For any $x \in \mathfrak{P}_P$, $L^{-\gamma(x)} \le L^{-\gamma}$, so (7.698) gives $D_x(L) \le C_P(x)\, L^{-\gamma}$.

Step 3: Uniform prefactor. Set

$$C \;:=\; \max\Big\{ \sup_{x\in\mathfrak{P}_E} C_E(x),\; \sup_{x\in\mathfrak{P}_P} C_P(x) \Big\} \;<\; \infty,$$

where finiteness follows from certified plateau regularity/compactness (Definition 6.300) and continuity of the band-preparation channel used in Lemmas 7.584 and 7.585. Then, for all $x \in \mathfrak{P}$,

$$D_x(L) \;\le\; \begin{cases} C\, e^{-L/\xi_{\max}}, & x \in \mathfrak{P}_E, \\ C\, L^{-\gamma}, & x \in \mathfrak{P}_P. \end{cases}$$

Step 4: Incorporating plateau oscillations. By the oscillation bound in Definition 6.300 and the uniformization argument (Lemma 7.588), passing to $\sup_{x\in\mathfrak{P}} D_x(L)$ inflates the envelope by at most $\eta_{\mathfrak{P}}$ on any certified window. This yields the stated envelope "up to $\eta_{\mathfrak{P}}$".

Step 5: How CIs supply the aggregates (optional). From the WLS fits in Proposition 7.592, let the slope CIs be $s_E(x) \in [\widehat{s}_E^-(x), \widehat{s}_E^+(x)] \subset (-\infty, 0)$ in the exponential case and $s_P(x) \in [\widehat{s}_P^-(x), \widehat{s}_P^+(x)] \subset (-\infty, 0)$ in the power-law case. With $\xi(x) = -1/s_E(x)$ and $\gamma(x) = -s_P(x)$, conservative CI–based aggregates are

$$\widehat{\xi}_{\max} := \sup_{x \in \mathfrak{P}_E} \Big(- \frac{1}{\widehat{s}_E^+(x)} \Big), \qquad \widehat{\gamma} := \inf_{x \in \mathfrak{P}_P} \Big(- \widehat{s}_P^+(x) \Big),$$

which satisfy $\xi(x) \le \widehat{\xi}_{\max}$ and $\gamma(x) \ge \widehat{\gamma}$ simultaneously on $\mathfrak{P}$ with the desired (simultaneous) confidence level (e.g. via Bonferroni). Plugging these into Steps 2–4 gives a CI–validated uniform guardrail.

Step 6: Gauge-parameter independence. All constructions are in the physical sector and the taggers commute with BRST/G (Proposition 7.556), hence the envelope is gauge-parameter independent.

Combining the steps establishes the proposition. □

Definition 7.595 (Fallback protocol for ambiguous fits)**.** If $\Delta(x) \in (-\Delta_\star, \Delta_\star)$ (*ambiguous*) or both slope CIs include 0, proceed:

1. **Tighten the mask:** shrink to a submask $\mathfrak{P}' \subset \mathfrak{P}$ with reduced oscillation $\eta_{\mathfrak{P}'} < \eta_{\mathfrak{P}}$ (cf. Definition 6.300) and/or increase the minimum volume $L_{\min}$ to improve separation of models; refit.
2. **Volume extension:** if feasible, add one or two larger L points to increase dynamic range; refit.
3. **Flag drift toward QII:** if for some subsequence $L_m \to \infty$ we observe:

$$\liminf_{m \to \infty} D_x(L_m) \ge \delta_0 > 0$$

with δ_0 exceeding the plateau tolerance (and stable under (1)–(2)), then $|\Lambda_{\text{state}}(x; V)|$ fails to approach 1; flag drift toward QII at x (orthogonalization of vacua), per Theorem 7.589.

Remark 7.596 (Operational thresholds)**.** Set $\Delta_\star = 6$ (strong AIC_c evidence), confidence level $1 - \beta = 0.95$, and require at least $N \ge 5$ volumes with ratio $r \in [1.4, 2]$. For the drift flag, take $\delta_0 = c_s\, \eta_{\mathfrak{P}}$ with $c_s \in [5, 10]$ (cf. Remark 7.600); report per–x decisions and the coverage of $\mathfrak{P}$ by $\mathfrak{P}_E \cup \mathfrak{P}_P$.

Definition 7.597 (Reporting for the state–visibility envelope)**.** For each $x \in \mathfrak{P}$: (i) chosen model (Exp/Pow/ambiguous), (ii) $(\widehat{\xi}(x), \text{CI})$ or $(\widehat{\gamma}(x), \text{CI})$, (iii) AIC_c difference $\Delta(x)$, (iv) residual plot and lack–of–fit test, (v) guardrail decision (pass/fail), and (vi) drift flag if triggered. Aggregate to $(\xi_{\max}, \gamma)$ with CIs as in Definition 7.593, and certify the guardrail via Proposition 7.594.

7.9.7 Law–visibility Slope Test and Tomographic Calibration

Context. On a certified plateau $\mathfrak{P}$ (Definition 6.300), QIV demands a *scale–independent* law–deficit: $1 - |\Lambda_{\text{law}}^{(x)}|$ stays bounded away from 0 with no IR improvement (Lemmas 7.578

and 7.579, Proposition 7.616, and Corollary 7.617). We now (i) make the *numerical slope test* explicit and (ii) give a BRST/Nielsen–safe *calibration protocol* for $\kappa_{\mathrm{spec}}(x)$ and $c_0(x)$ (entering the T–odd tomographic lower bound, Proposition 7.609, and the low–frequency tracking, Lemma 7.608).

Definition 7.598 (Log–slope estimator on the mask)**.** Fix $x = (\lambda_{\mathrm{UV}}, \ell) \in \mathfrak{P}$ and measure $y(\ell) := 1 - |\Lambda_{\mathrm{law}}^{(\lambda_{\mathrm{UV}},\ell)}|$ on a log–spaced window $\ell_n = \ell_0\, r^n$, $n = 0, \dots, N$ with $r > 1$. Define midpoint log–derivative estimates

$$S_n(x) \;:=\; \frac{\log y(\ell_{n+1}) - \log y(\ell_n)}{\log \ell_{n+1} - \log \ell_n} \;=\; \frac{\log\big(y(\ell_{n+1})/y(\ell_n)\big)}{\log r}, \qquad n = 0, \dots, N-1.$$

Let $\widehat{S}(x)$ be their inverse–variance weighted mean, with weights set by the readout uncertainties; define the mask–uniform statistic $S_{\max} := \sup_{x\in\mathfrak{P}} |\widehat{S}(x)|$.

Proposition 7.599 (QIV acceptance vs. QIII rejection (slope test))**.** *Choose a tolerance $\sigma_{\mathrm{tol}} > 0$ satisfying $\sigma_{\mathrm{tol}} \gg \eta_{\mathfrak{P}}$ (instrument floor) yet $\sigma_{\mathrm{tol}} \ll 1$ (no spurious power–law). Then:*

*(i) (*QIV accept*) If $S_{\max} \le \sigma_{\mathrm{tol}}$ and the constant model $y(\ell) \equiv y_\star$ lies within the plateau envelope (oscillation bound of Definition 6.300), the law channel passes the "no IR improvement" criterion uniformly on $\mathfrak{P}$.*

*(ii) (*QIII reject*) Fit the power–law model $y(\ell) = A\,\ell^{\sigma}$ by weighted least squares. If the 95% CI for σ excludes 0 and the likelihood–ratio (or F–test) favors the power–law over the constant by more than the plateau tolerance budget, reject QIV in favor of QIII on that mask.*

Gauge–parameter independence is guaranteed by Proposition 7.556; BRST safety of the readouts by Lemma 7.552.

Proof. Notation and statistic. Take a geometric IR grid $\ell_n = \ell_0 r^{\,n}$ with $r > 1$, $n = 0, \dots, N-1$, and measurements $y_n := y(\ell_n)$ for the (dimensionless) T–odd law–channel readout on a certified mask. Define the log–log secant slopes

$$S_n(x) \;:=\; \frac{\log y_{n+1} - \log y_n}{\log \ell_{n+1} - \log \ell_n} = \frac{\log y_{n+1} - \log y_n}{\log r}\,, \qquad n = 0, \dots, N-2,$$

and their maximum magnitude $S_{\max} := \max_n |S_n(x)|$. (Any WLS slope $\widehat{S}(x)$ fitted to $(\log \ell_n, \log y_n)$ lies between the min/max secants, so $|\widehat{S}(x)| \le S_{\max}$.)

(1) QIV accept. Assume the *constant* model $y(\ell) \equiv y_\star$ holds up to the plateau oscillation budget:

$$|y(\ell) - y_\star| \;\le\; \eta_{\mathfrak{P}} \qquad \text{for all } \ell \text{ on the certified window.} \tag{7.699}$$

Let $y_n = y_\star + \delta_n$ with $|\delta_n| \le \eta_{\mathfrak{P}}$. By the mean–value theorem,

$$\log y_{n+1} - \log y_n = \frac{\delta_{n+1} - \delta_n}{\xi_n}\,, \qquad \xi_n \in \big[y_\star - \eta_{\mathfrak{P}},\, y_\star + \eta_{\mathfrak{P}}\big].$$

Hence

$$|S_n(x)| \;=\; \frac{|\delta_{n+1}-\delta_n|}{\xi_n\,\log r} \;\le\; \frac{2\eta_{\mathfrak{P}}}{(y_\star-\eta_{\mathfrak{P}})\,\log r}.$$

On certified masks the *channel floors* (e.g. $s_{\min},\kappa_{\min}$ in Section 7.9.16) ensure $y_\star \ge c_{\text{floor}}\,\eta_{\mathfrak{P}}$ with $c_{\text{floor}}>1$; hence

$$S_{\max} \;\le\; \frac{2}{(c_{\text{floor}}-1)\,\log r}\;\eta_{\mathfrak{P}}. \tag{7.700}$$

If, in addition, $S_{\max}\le\sigma_{\text{tol}}$ and the constant model satisfies (7.699), then the law channel exhibits *no IR improvement* beyond plateau oscillations; by Definition 6.300 this certifies QIV on the window. Since the bounds and the mask are uniform on $\mathfrak{P}$, the acceptance is uniform on $\mathfrak{P}$.

(2) QIII reject. Suppose $y(\ell)=A\,\ell^{\sigma}(1+\varepsilon(\ell))$ with $|\varepsilon(\ell)|\ll 1$ and $\sigma\neq 0$. Then $\log y_n = \log A+\sigma\log\ell_n+\eta_n$ with $\eta_n=\log(1+\varepsilon(\ell_n))=\mathcal{O}(\varepsilon)$. Weighted least squares of $\log y_n$ on $\log\ell_n$ yields a slope $\widehat{\sigma}(x)$ with asymptotic normal CI. If the 95% CI excludes 0, we have statistically significant $\sigma\neq 0$.

To guard against overfitting plateau oscillations, compare the *power–law* (1–slope) model to the *constant* (0–slope) model via an F–test / likelihood–ratio:

$$F \;=\; \frac{\big(\mathrm{RSS}_0-\mathrm{RSS}_1\big)/1}{\mathrm{RSS}_1/(N-2)}.$$

Under the null (constant up to (7.699)) and well–specified WLS, F has approximately an $F_{1,N-2}$ law; more importantly, the *maximal* reduction in RSS achievable by fitting a spurious slope is $O(\eta_{\mathfrak{P}}^2)$. Thus, if the observed RSS reduction exceeds the *plateau tolerance budget* (a multiple of $\eta_{\mathfrak{P}}^2$ fixed by certification), the power–law fit is genuinely preferred and we reject QIV in favor of QIII on that mask. Both the CI decision and the F–test are invariant under the BRST/G structure by Lemma 7.552 and Proposition 7.556.

Uniformity on $\mathfrak{P}$. Apply Lemma 7.579 to the map $x\mapsto S_{\max}(x)$ and to the residual series to extend the decision uniformly over $x\in\mathfrak{P}$, with at most an $\eta_{\mathfrak{P}}$ slack, which is already absorbed into the tolerance budget.

This proves both statements. □

Remark 7.600 (Practical choices)**.** *Grid.* With a geometric IR grid $\ell_n=\ell_0 r^{\,n}$, take $r\in[1.4,2]$ and $N\ge 5$. Then the log–span is $\log(\ell_{N-1}/\ell_0)=(N-1)\log r\gtrsim 4\log 1.4\approx 1.35$, which stabilizes slope estimates and tightens the bound (7.700).

Tolerance. Set $\sigma_{\text{tol}}=c_s\,\eta_{\mathfrak{P}}$ with $c_s\in[5,10]$. Together with (7.700) and the channel floor $c_{\text{floor}}>1$, this makes false positives from plateau oscillations unlikely; e.g. for $r=1.6$ and $c_{\text{floor}}\ge 3$, the bound gives $S_{\max}\lesssim 1.6\,\eta_{\mathfrak{P}}$.

Reporting. Report $\big(\widehat{S}(x),\,\mathrm{CI}_{95\%}\big)$ per band point x (WLS slope on $(\log\ell_n,\log y_n)$) and the aggregate $S_{\max}$ over $x\in\mathfrak{P}$. Use the CI *and* the model–comparison test as in item (2).

These settings are BRST/Nielsen stable on $\mathcal{H}_{\text{phys}}$ (Lemma 7.552 and Proposition 7.556) and compatible with certified–plateau masking.

Definition 7.601 (Calibration targets)**.** At $x \in \mathfrak{P}$, the tomographic constants are:

$$\kappa_{\mathrm{spec}}(x) := \inf_{|\omega| \le \omega_0(x)} \mathsf{K}_{\mathrm{spec}}(x;\omega),$$

where $c_0(x)$ is the proportionality constant in the relation (Lemma 7.608):

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] = c_0(x)\,|\mathcal{R}_a^{(x)}| + \mathcal{O}(\omega_0^2).$$

Here $\mathsf{K}_{\mathrm{spec}}$ is the positive tomography kernel (Definition 7.607), $\omega_0(x)$ is the bandwidth chosen by (7.736).

Proposition 7.602 (Kernel floor from taggers (BRST/Nielsen safe))**.** *Let $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ be computed from the UV/IR taggers (Definition 7.551) via the spectral representation of the law branch (Definition 7.607). Since $\mathsf{K}_{\mathrm{spec}}(x;\omega) \ge 0$ and is continuous in ω on compact sets,*

$$\kappa_{\mathrm{spec}}(x) \;=\; \min_{m\in\{-M,\dots,M\}} \mathsf{K}_{\mathrm{spec}}(x;\omega_m) \;-\; \delta_{\mathrm{disc}}(x),$$

with a uniform grid $\omega_m \in [-\omega_0(x),\omega_0(x)]$ and a discretization slack $\delta_{\mathrm{disc}}(x) = \mathcal{O}(\omega_0(x)/M)$ chosen so that $\kappa_{\mathrm{spec}}(x) > 0$ remains valid as a lower confidence bound. This construction commutes with BRST/G actions and is gauge–parameter independent on $\mathcal{H}_{\mathrm{phys}}$ (Proposition 7.556 and Lemma 7.552).

Proof. (A) Positivity and continuity from the taggers. By Definition 7.551, the IR tagger is a C^∞ c–number kernel $\kappa_x(t,\mathbf{r}) = \chi_\ell(t)\,\phi_\ell(\mathbf{r})$ with $\chi_\ell, \phi_\ell \in C_c^\infty$ real and even. Hence

$$\widehat{\kappa}_x(\omega,\mathbf{k}) = \widehat{\chi}_\ell(\omega)\,\widehat{\phi}_\ell(\mathbf{k})$$

is C^∞ in $(\omega,\mathbf{k})$ and real–even in ω (Paley–Wiener). The tomography kernel of Definition 7.607 reads

$$\mathsf{K}_{\mathrm{spec}}(x;\omega) = \int_{\mathbb{R}^{d-1}} W_x(\mathbf{k})\,\big|\widehat{\kappa}_x(\omega,\mathbf{k})\big|^2\,d\mathbf{k} = \big|\widehat{\chi}_\ell(\omega)\big|^2\,C_x, \qquad C_x := \int W_x(\mathbf{k})\,|\widehat{\phi}_\ell(\mathbf{k})|^2\,d\mathbf{k} \ge 0, \tag{7.701}$$

with $W_x(\mathbf{k}) \ge 0$ the channel weight. On certified plateaus W_x has positive mass on some compact set, while $\widehat{\phi}_\ell \not\equiv 0$, hence $C_x > 0$. Therefore $\mathsf{K}_{\mathrm{spec}} \ge 0$ and is continuous (indeed C^∞) in ω on any compact interval. In particular, by Lemma 7.575 there exists $\omega_0(x) > 0$ such that $\inf_{|\omega|\le\omega_0(x)} \mathsf{K}_{\mathrm{spec}}(x;\omega) > 0$.

(B) A Lipschitz bound on $[-\omega_0,\omega_0]$. Differentiating (7.701) gives

$$\partial_\omega \mathsf{K}_{\mathrm{spec}}(x;\omega) = 2\,\mathrm{Re}\Big(\widehat{\chi}_\ell'(\omega)\,\overline{\widehat{\chi}_\ell(\omega)}\Big)\,C_x,$$

hence on the compact interval $[-\omega_0,\omega_0]$,

$$\big|\partial_\omega \mathsf{K}_{\mathrm{spec}}(x;\omega)\big| \;\le\; L_x \;:=\; 2\,C_x \sup_{|\omega|\le\omega_0}\big|\widehat{\chi}_\ell'(\omega)\big| \sup_{|\omega|\le\omega_0}\big|\widehat{\chi}_\ell(\omega)\big| \;<\; \infty. \tag{7.702}$$

Thus $\mathsf{K}_{\mathrm{spec}}(x;\cdot)$ is Lipschitz on $[-\omega_0,\omega_0]$ with constant L_x.

(C) Discretization slack on a uniform grid. Let the uniform grid have spacing $\Delta\omega := 2\omega_0/M$ and nodes $\omega_m = -\omega_0 + m\Delta\omega$, $m = -M, \dots, M$. For any $\omega \in [-\omega_0, \omega_0]$ choose the nearest gridpoint $\omega_{m(\omega)}$ so that $|\omega - \omega_{m(\omega)}| \le \Delta\omega/2$. By the mean–value inequality and (7.702),

$$\mathsf{K}_{\mathrm{spec}}(x;\omega) \;\ge\; \mathsf{K}_{\mathrm{spec}}(x;\omega_{m(\omega)}) - L_x\,|\omega - \omega_{m(\omega)}| \;\ge\; \min_m \mathsf{K}_{\mathrm{spec}}(x;\omega_m) - \frac{L_x}{2}\,\Delta\omega.$$

Taking the infimum over $\omega \in [-\omega_0, \omega_0]$,

$$\inf_{|\omega|\le\omega_0} \mathsf{K}_{\mathrm{spec}}(x;\omega) \;\ge\; \min_m \mathsf{K}_{\mathrm{spec}}(x;\omega_m) - \delta_{\mathrm{disc}}(x), \qquad \delta_{\mathrm{disc}}(x) := \frac{L_x}{2}\,\Delta\omega = \mathcal{O}\!\left(\frac{\omega_0}{M}\right).$$

Defining

$$\kappa_{\mathrm{spec}}(x) \;:=\; \min_m \mathsf{K}_{\mathrm{spec}}(x;\omega_m) - \delta_{\mathrm{disc}}(x),$$

we obtain a *rigorous lower bound* $\kappa_{\mathrm{spec}}(x) \le \inf_{|\omega|\le\omega_0} \mathsf{K}_{\mathrm{spec}}(x;\omega)$. By choosing M large enough (or, equivalently, $\Delta\omega$ small enough) and using the positive floor guaranteed by Lemma 7.575, one can ensure $\kappa_{\mathrm{spec}}(x) > 0$. This realizes the statement with $\delta_{\mathrm{disc}}(x) = \mathcal{O}(\omega_0/M)$ and certifies $\kappa_{\mathrm{spec}}(x)$ as a *lower confidence bound* against discretization error.

(D) BRST/G commutation and gauge independence. The taggers $K_{\mathrm{IR}}^{(\ell)}$ and $P_x(\lambda_{\mathrm{UV}})$ act by c–number convolution/multiplication and commute with BRST and G actions (Proposition 7.573). The kernel $\mathsf{K}_{\mathrm{spec}}$ is a positive quadratic functional of $\widehat{\kappa}_x$ (cf. (7.701)), hence it inherits this commutation and is built from BRST-closed, gauge–invariant data on $\mathcal{H}_{\mathrm{phys}}$. Therefore $\kappa_{\mathrm{spec}}(x)$ constructed above is gauge–parameter independent (Lemma 7.552 and Proposition 7.556).

Combining (A)–(D) proves the proposition. □

Definition 7.603 (Probe normalization $c_0(x)$ via Ward matching)**.** At fixed x, select a small spurion amplitude window $\epsilon \in (0, \epsilon_{\max}]$ within the linear regime. For each setting, measure the Ward source magnitude $|\mathcal{R}_a^{(x)}(\epsilon)|$ and the tomographic functional $\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}](\epsilon)$ (same $\omega_0(x)$ as in Definition 7.636). Fit the constrained line through the origin:

$$\widehat{c}_0(x) \;:=\; \arg\min_{c\ge 0} \sum_n w_n \left(\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}](\epsilon_n) - c\,|\mathcal{R}_a^{(x)}(\epsilon_n)|\right)^2,$$

with weights w_n from measurement uncertainties. Reject points with relative $|\epsilon|$ beyond the GMOR linear window (per Definition 7.634); report $\widehat{c}_0(x)$ and its CI.

Lemma 7.604 (Uniform control with the bandwidth schedule)**.** *With the schedule $\omega_0(x)$ of Definition 7.636, the model error in the regression of Definition 7.603 is $\mathcal{O}(\theta^2)$ uniformly on $\mathfrak{P}$ (Lemma 7.637); the estimate $\widehat{c}_0(x)$ is thus plateau–consistent and Nielsen–independent.*

Proof. Step 1: Low–frequency expansion and evenness. By the spectral construction of the law branch (Definition 7.607) and the tagger regularity (Definition 7.551), the descended T–odd readout admits, for $|\omega| \le \omega_0(x)$,

$$Y_x(\omega) \;:=\; 1 - |\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)}(\omega)| \;=\; c_0(x)\,\mathsf{K}_{\mathrm{spec}}(x;\omega)\,|\mathcal{R}_a^{(x)}| \;+\; R_x(\omega), \tag{7.703}$$

where $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ is C^∞ and even in ω (cf. Lemma 7.575), and the remainder R_x is even and satisfies $R_x(\omega) = \mathcal{O}(\omega^2)$ as $\omega \to 0$. The evenness and smoothness follow from the real–even IR time window and the T–odd projection being linear in the spectrum; the ω^2 order is the first nontrivial even correction in the Taylor series at $\omega = 0$.

Step 2: Bandwidth schedule and uniform bound. By Definition 7.636, the bandwidth is scheduled as $\omega_0(x) \le c_*\,\theta$ with c_* independent of $x \in \mathfrak{P}$. Hence

$$\sup_{|\omega|\le\omega_0(x)} |R_x(\omega)| \;\le\; C_1(x)\,\omega_0(x)^2 \;\le\; C_1(x)\,c_*^2\,\theta^2.$$

On certified plateaus (Definition 6.300) the derivatives of $\mathsf{K}_{\mathrm{spec}}$ and the channel weights are uniformly bounded, so $C_1(x)$ is bounded on $\mathfrak{P}$; write $\sup_{x\in\mathfrak{P}} C_1(x) =: C_1 < \infty$. Therefore

$$\sup_{x\in\mathfrak{P}}\ \sup_{|\omega|\le\omega_0(x)} |R_x(\omega)| \;\le\; C_1\,\theta^2. \tag{7.704}$$

Step 3: WLS normal equation and bias of $\widehat{c}_0(x)$. The regression of Definition 7.603 fits $Y_x(\omega_m)$ (on a grid $|\omega_m| \le \omega_0(x)$) to the one–parameter model $c\,\mathsf{K}_{\mathrm{spec}}(x;\omega_m)\,|\mathcal{R}_a^{(x)}|$ with weights w_m. Let $K_m := \mathsf{K}_{\mathrm{spec}}(x;\omega_m)\,|\mathcal{R}_a^{(x)}|$ and $\varepsilon_m := R_x(\omega_m)$. The WLS estimator solves the normal equation

$$\widehat{c}_0(x) \;=\; c_0(x) \;+\; \frac{\sum_m w_m K_m\,\varepsilon_m}{\sum_m w_m K_m^2}.$$

On the scheduled window, Lemma 7.575 and Proposition 7.602 give $K_m \ge \kappa_{\mathrm{spec}}(x)\,|\mathcal{R}_a^{(x)}|$, hence

$$\left|\widehat{c}_0(x) - c_0(x)\right| \;\le\; \frac{\sum_m w_m K_m\,|\varepsilon_m|}{\sum_m w_m K_m^2} \;\le\; \frac{\max_m |\varepsilon_m|}{\kappa_{\mathrm{spec}}(x)\,|\mathcal{R}_a^{(x)}|}\;\cdot\;\frac{\sum_m w_m K_m}{\sum_m w_m K_m^2} \;\le\; \frac{\max_m |\varepsilon_m|}{\kappa_{\mathrm{spec}}(x)\,|\mathcal{R}_a^{(x)}|}.$$

Using (7.704) and the plateau floor $\inf_{x\in\mathfrak{P}} \kappa_{\mathrm{spec}}(x) > 0$ (cf. Lemma 7.575 and Proposition 7.602) and $|\mathcal{R}_a^{(x)}|$ bounded away from 0 on the certified mask, we obtain

$$\sup_{x\in\mathfrak{P}} \left|\widehat{c}_0(x) - c_0(x)\right| \;\le\; C_2\,\theta^2,$$

for some $C_2 < \infty$ independent of x. This is precisely the $\mathcal{O}(\theta^2)$ model–error control of Lemma 7.637.

Step 4: Plateau consistency and Nielsen/BRST independence. The bound is uniform on $\mathfrak{P}$; hence $\widehat{c}_0(x) \to c_0(x)$ as $\theta \to 0$ uniformly, i.e. plateau–consistency. Since the UV/IR taggers commute with BRST and G actions (Proposition 7.573), and all regressors are c–number functionals of band–descended observables on $\mathcal{H}_{\mathrm{phys}}$, the estimate is gauge–parameter independent (Lemma 7.552 and Proposition 7.556).

This proves the lemma. □

Corollary 7.605 (Certified tomographic lower bound)**.** *For all $x \in \mathfrak{P}$,*

$$1 - |\Lambda_{\mathrm{law}}^{(x)}| \;\ge\; \underbrace{\kappa_{\mathrm{spec}}(x)\,\widehat{c}_0(x)}_{=:K_{\mathrm{low}}(x)}\;|\mathcal{R}_a^{(x)}| \;-\; C\,\theta^2 \;-\; O(\eta_{\mathfrak{P}}),$$

with C gauge–independent. Hence the measured T–odd signal tracks the Ward source with a calibrated *constant $K_{\mathrm{low}}(x)$, uniform on the mask (Proposition 7.609 and Lemma 7.608).*

Proof. Step 1: Pointwise lower bound for the spectral window. From (7.703) (used in Lemma 7.604) and Lemma 7.575, for $|\omega| \le \omega_0(x)$, we have

$$Y_x(\omega) \ge c_0(x)\,\kappa_{\mathrm{spec}}(x)\,|\mathcal{R}_a^{(x)}| - |R_x(\omega)|.$$

Taking the infimum over $\{|\omega| \le \omega_0(x)\}$ and using the uniform bound $\sup_{|\omega|\le\omega_0(x)}|R_x(\omega)| \le C_1\theta^2$ gives

$$\inf_{|\omega|\le\omega_0(x)} Y_x(\omega) \;\ge\; c_0(x)\,\kappa_{\mathrm{spec}}(x)\,|\mathcal{R}_a^{(x)}| - C_1\,\theta^2. \tag{7.705}$$

Step 2: Replace $c_0(x)$ by $\widehat{c}_0(x)$. By Lemma 7.604, $|\widehat{c}_0(x) - c_0(x)| \le C_2\theta^2$ uniformly on $\mathfrak{P}$. Hence $c_0(x) \ge \widehat{c}_0(x) - C_2\theta^2$, and plugging into eq. (7.705) yields

$$\inf_{|\omega|\le\omega_0(x)} Y_x(\omega) \;\ge\; \kappa_{\mathrm{spec}}(x)\,\widehat{c}_0(x)\,|\mathcal{R}_a^{(x)}| \;-\; \Big(C_1 + C_2\,\kappa_{\mathrm{spec}}(x)\,|\mathcal{R}_a^{(x)}|\Big)\,\theta^2.$$

Absorb the bracket into a gauge–independent constant C (uniform on $\mathfrak{P}$ by plateau regularity and the tagger floors).

Step 3: From window infimum to the reported statistic. By the construction of the tomographic readout (Definition 7.607) and the certified–plateau masking, the reported $1 - |\Lambda_{\mathrm{law}}^{(x)}|$ differs from the window infimum by at most the oscillation budget $\mathcal{O}(\eta_{\mathfrak{P}})$ (plateau envelope). Therefore

$$1 - |\Lambda_{\mathrm{law}}^{(x)}| \;\ge\; \kappa_{\mathrm{spec}}(x)\,\widehat{c}_0(x)\,|\mathcal{R}_a^{(x)}| \;-\; C\,\theta^2 \;-\; \mathcal{O}(\eta_{\mathfrak{P}}).$$

This is the stated lower bound with the calibrated constant $K_{\mathrm{low}}(x) := \kappa_{\mathrm{spec}}(x)\,\widehat{c}_0(x)$.

Step 4: Uniformity and Nielsen–independence. Uniformity on $\mathfrak{P}$ follows from the uniform bounds in Lemmas 7.575 and 7.604 and Proposition 7.602 and plateau compactness. BRST/Nielsen–safety is inherited from the commutation of the taggers with BRST/G and the use of band–descended observables (Propositions 7.556 and 7.573 and Lemma 7.552). This aligns with the tracking statements of Proposition 7.609 and Lemma 7.608. □

Definition 7.606 (Reporting for the law–visibility curve)**.** On $\mathfrak{P}$ (or $\mathfrak{M}_{\mathrm{mask}}$):

1. Report the log–slope statistics $\widehat{S}(x)$ with CIs and $S_{\max}$; include the constant vs. power–law model selection (AIC/BIC or F–test) and decision (QIV accept / QIII reject) per Proposition 7.599.
2. Provide $\kappa_{\mathrm{spec}}(x)$ (grid definition, M, and δ_{disc}), $\widehat{c}_0(x)$ with CI, and the product $K_{\mathrm{low}}(x)$ used in the tomographic bound.
3. State the bandwidth $\omega_0(x)$ and the global θ; confirm the $\mathcal{O}(\theta^2)$ control.
4. Confirm gauge–flatness (Nielsen slopes ≈ 0) for all reported quantities (Proposition 7.556).

Only quote inside $\mathfrak{M}_{\mathrm{mask}}$; if the slope test fails on a subwindow, refine the mask.

7.9.8 T-odd Tomography & Cones (No Law-signalling; Anomaly Filters)

Definition 7.607 (T-odd spectral density and tomography kernel)**.** At a certified band point $x = (\lambda_{\mathrm{UV}}, \ell) \in \mathfrak{P}$ (Definition 6.300), define the *T-odd spectral density* for a broken generator a on $\mathcal{H}_{\mathrm{phys}}$ by the retarded two-point function of the adjoint-covariant divergence:

$$\mathsf{S}_a(x;\omega) \;:=\; \frac{1}{\pi}\,\mathrm{Im}\int d^d t\, e^{i\omega t}\,\theta(t)\,\Big\langle\,\Big[\,\nabla^{(\mathrm{ad})}_{\mu}\bar{J}^{(x)\mu}_{a,\mathrm{imp}}(t),\,\mathcal{W}^{(x)}(0)\Big]\,\Big\rangle_{\mathbf{\Psi}},$$

where $\mathcal{W}^{(x)}$ is any admissible local probe density that generates the holosymmetric law visibility (Definition 6.275) at x. The *tomography kernel* is the positive function $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ (dependent only on the UV/IR taggers, Definition 7.551) appearing in the spectral representation

$$-\,\mathrm{Re}\;\Lambda^{(\mathrm{spec};x)}_{\mathrm{law}} \;=\; \int_{\mathbb{R}} d\omega\,\mathsf{K}_{\mathrm{spec}}(x;\omega)\,\mathsf{S}_a(x;\omega), \tag{7.706}$$

as established in the proof of Lemma 7.578. Define the *tomography functional* $\mathcal{T}^{(x)}_a[\varphi] := \int d\omega\,\varphi(\omega)\,\mathsf{S}_a(x;\omega)$ for test functions $\varphi \in C^\infty_c(\mathbb{R})$.

Lemma 7.608 (Ward-source tracking at low frequency)**.** *Let $\chi_\tau(\omega)$ be a normalized, even mollifier supported in $[-\omega_0(\tau),\omega_0(\tau)]$ with $\omega_0(\tau)\downarrow 0$ as $\tau\to\infty$. Then, on $\mathcal{H}_{\mathrm{phys}}$,*

$$\lim_{\tau\to\infty}\;\mathcal{T}^{(x)}_a[\chi_\tau] \;=\; c_0(x)\,\Big|\mathcal{R}^{(x)}_a\Big|, \qquad \mathcal{R}^{(x)}_a := \sum_k \epsilon_k\Big\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a}\Big\rangle_{\mathbf{\Psi}},$$

with $c_0(x) > 0$ a normalization fixed by the choice of probe $\mathcal{W}^{(x)}$ and the taggers. The limit is gauge–parameter independent (Proposition 7.556) and BRST–safe (Lemma 7.552).

Proof. Step 1: Tomographic functional and low–frequency model. Denote the spectral (T–odd) law–channel readout by

$$Y_x(\omega) \;:=\; 1 - \big|\Lambda^{(\mathrm{spec};x)}_{\mathrm{law}}(\omega)\big|\,,$$

and the IR/UV tagger kernel by $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ (Definitions 7.551 and 7.607). Near $\omega = 0$, the band–descended Ward identity (Fourier transform of eq. (7.665)) together with the PCAC/LSZ matching gives the even Taylor expansion

$$Y_x(\omega) \;=\; c_0(x)\,\mathsf{K}_{\mathrm{spec}}(x;\omega)\,|\mathcal{R}^{(x)}_a| \;+\; R_x(\omega), \qquad R_x(\omega) = \mathcal{O}(\omega^2), \tag{7.707}$$

where the constant $c_0(x) > 0$ depends only on the fixed probe $\mathcal{W}^{(x)}$ and the taggers. Evenness of the expansion follows from time–reversal on the T–odd channel combined with the even tagger window; the ω^2 remainder is the first nontrivial even correction.

We define the *tomographic functional* that extracts the zero–frequency coefficient as

$$\mathcal{T}^{(x)}_a[\chi] \;:=\; \int_{-\infty}^{\infty} d\omega\;\chi(\omega)\,\frac{Y_x(\omega)}{\mathsf{K}_{\mathrm{spec}}(x;\omega)}\,. \tag{7.708}$$

This is the continuum counterpart of the one–parameter regression in Definition 7.603: fitting $Y_x(\omega)$ against $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ on a small window is a Riemann–sum discretization of (7.708) with χ proportional to the sampling weights.

Step 2: Kernel floor and regularity on shrinking windows. By Lemma 7.575 and Proposition 7.602 there exists $\omega_0 > 0$ such that

$$\mathsf{K}_{\mathrm{spec}}(x;\omega) \;\geq\; \kappa_{\mathrm{spec}}(x) \;>\; 0 \quad \text{for all } |\omega| \leq \omega_0,$$

and $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ is C^∞ in ω. Hence $1/\mathsf{K}_{\mathrm{spec}}(x;\omega)$ is bounded and smooth on $[-\omega_0,\omega_0]$. Because χ_τ has support in $[-\omega_0(\tau),\omega_0(\tau)]$ with $\omega_0(\tau) \downarrow 0$, for all large τ the support lies inside $[-\omega_0,\omega_0]$.

Step 3: Mollifier limit. Insert (7.707) into (7.708):

$$\mathcal{T}_a^{(x)}[\chi_\tau] \;=\; c_0(x)\,|\mathcal{R}_a^{(x)}|\,\underbrace{\int \chi_\tau(\omega)\,d\omega}_{=1} \;+\; \int \chi_\tau(\omega)\,\frac{R_x(\omega)}{\mathsf{K}_{\mathrm{spec}}(x;\omega)}\,d\omega.$$

The first term gives $c_0(x)|\mathcal{R}_a^{(x)}|$ by normalization of χ_τ. For the second term, use the expansion $R_x(\omega) = \mathcal{O}(\omega^2)$ and the kernel floor to bound

$$\left|\int \chi_\tau(\omega)\,\frac{R_x(\omega)}{\mathsf{K}_{\mathrm{spec}}(x;\omega)}\,d\omega\right| \;\leq\; \frac{1}{\kappa_{\mathrm{spec}}(x)}\int \chi_\tau(\omega)\,C_x\,\omega^2\,d\omega \;\leq\; \frac{C_x}{\kappa_{\mathrm{spec}}(x)}\sup_{|\omega|\leq\omega_0(\tau)}\omega^2 \;\xrightarrow[\tau\to\infty]{}\; 0,$$

for some $C_x < \infty$ (uniform on certified plateaus). Thus

$$\lim_{\tau\to\infty}\;\mathcal{T}_a^{(x)}[\chi_\tau] \;=\; c_0(x)\,|\mathcal{R}_a^{(x)}|.$$

The limit is an instance of dominated (indeed uniform) convergence, using the bounded denominator and compact support.

Step 4: Positivity and BRST/Nielsen safety. Positivity $c_0(x) > 0$ follows from the positivity of the spectral measure in the retarded law–channel (Källén–Lehmann) and the nonnegativity of $\mathsf{K}_{\mathrm{spec}}$ (Lemma 7.575). Gauge–parameter independence and BRST safety hold because the UV/IR taggers commute with BRST and G (Proposition 7.573), and expectations are taken on $\mathcal{H}_{\mathrm{phys}}$ (Proposition 7.556 and Lemma 7.552); BRST–exact and Noether–improvement pieces do not contribute.

Combining the steps proves the claim. □

Proposition 7.609 (Tomographic lower bound for the law-deficit)**.** *On any $x \in \mathfrak{P}$,*

$$1 - \left|\Lambda_{\mathrm{law}}^{(x)}\right| \;\geq\; \kappa_{\mathrm{spec}}(x)\;\mathcal{T}_a^{(x)}[\chi_\tau] \;-\; O(\eta_{\mathfrak{P}}) \;-\; o_\tau(1),$$

where $\kappa_{\mathrm{spec}}(x) > 0$ is the kernel floor on $[-\omega_0,\omega_0]$ (cf. Lemma 7.575 and Proposition 7.602), $\eta_{\mathfrak{P}}$ is the plateau tolerance (Definition 6.300), and $o_\tau(1) \to 0$ as $\tau \to \infty$.

Proof. Step 1: Spectral lower bound on the law channel. By the channel-resolved signature (Corollary 7.677(i)),

$$1 - \left|\Lambda_{\mathrm{law}}^{(x)}\right| \;\geq\; -\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;-\; O(\eta_{\mathfrak{P}}).$$

By the spectral/tomographic representation (Definition 7.607), there exists a nonnegative spectral density $S_a^{(x)}(\omega) \geq 0$ (the T–odd weight) such that

$$-\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;=\; \int_{\mathbb{R}} d\omega\;\mathsf{K}_{\mathrm{spec}}(x;\omega)\,S_a^{(x)}(\omega),$$

with $\mathsf{K}_{\mathrm{spec}}(x;\omega) \geq 0$ continuous in ω and, on $|\omega| \leq \omega_0$, bounded below by the positive floor $\kappa_{\mathrm{spec}}(x)$ (Lemma 7.575 and Proposition 7.602). Restricting to the low–frequency window,

$$1 - \left|\Lambda_{\mathrm{law}}^{(x)}\right| \;\geq\; \int_{|\omega|\leq\omega_0} \mathsf{K}_{\mathrm{spec}}(x;\omega)\, S_a^{(x)}(\omega)\, d\omega \;-\; O(\eta_{\mathfrak{P}}). \tag{7.709}$$

Step 2: Relate the spectral weight to the measured $Y_x(\omega)$. Write

$$Y_x(\omega) \;:=\; 1 - \left|\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)}(\omega)\right|.$$

Near $\omega = 0$, smoothness of the taggers and the Ward projection imply the even expansion

$$Y_x(\omega) \;=\; \mathsf{K}_{\mathrm{spec}}(x;\omega)\, S_a^{(x)}(\omega) \;+\; R_x(\omega), \qquad R_x(\omega) = \mathcal{O}(\omega^2) \quad (\omega \to 0), \tag{7.710}$$

uniformly on certified plateaus (bounded derivatives of the taggers and channel weights).

Step 3: Insert a normalized mollifier and use positivity. Let χ_τ be even, supported in $[-\omega_0(\tau), \omega_0(\tau)]$, and normalized: $\int \chi_\tau = 1$, with $\omega_0(\tau) \downarrow 0$. Multiply (7.710) by $\chi_\tau(\omega)$ and integrate over $\mathbb{R}$ (effectively over the support):

$$\int \chi_\tau(\omega)\, Y_x(\omega)\, d\omega = \int \chi_\tau(\omega)\, \mathsf{K}_{\mathrm{spec}}(x;\omega)\, S_a^{(x)}(\omega)\, d\omega \;+\; \int \chi_\tau(\omega)\, R_x(\omega)\, d\omega.$$

Since $\mathsf{K}_{\mathrm{spec}}(x;\omega) \geq \kappa_{\mathrm{spec}}(x)$ on the support of χ_τ,

$$\int \chi_\tau\, \mathsf{K}_{\mathrm{spec}}\, S_a^{(x)} \;\geq\; \kappa_{\mathrm{spec}}(x) \int \chi_\tau\, S_a^{(x)}.$$

By the definition of the tomographic functional (eq. (7.708) in the proof of Lemma 7.608),

$$\mathcal{T}_a^{(x)}[\chi_\tau] \;=\; \int \chi_\tau(\omega)\, \frac{Y_x(\omega)}{\mathsf{K}_{\mathrm{spec}}(x;\omega)}\, d\omega,$$

and, using again $\mathsf{K}_{\mathrm{spec}} \geq \kappa_{\mathrm{spec}}$ on the support,

$$\int \chi_\tau(\omega)\, Y_x(\omega)\, d\omega = \int \chi_\tau\, \mathsf{K}_{\mathrm{spec}} \cdot \frac{Y_x}{\mathsf{K}_{\mathrm{spec}}} \;\geq\; \kappa_{\mathrm{spec}}(x)\, \mathcal{T}_a^{(x)}[\chi_\tau].$$

Combining with the remainder gives

$$\int_{|\omega|\leq\omega_0(\tau)} Y_x(\omega)\, \chi_\tau(\omega)\, d\omega \;\geq\; \kappa_{\mathrm{spec}}(x)\, \mathcal{T}_a^{(x)}[\chi_\tau] \;-\; \left|\int \chi_\tau(\omega)\, R_x(\omega)\, d\omega\right|. \tag{7.711}$$

Step 4: Link the windowed spectral mass to the mollified average. Because $S_a^{(x)} \geq 0$ and $\mathsf{K}_{\mathrm{spec}} \geq 0$, from (7.709),

$$1 - \left|\Lambda_{\mathrm{law}}^{(x)}\right| \;\geq\; \int_{|\omega|\leq\omega_0(\tau)} \mathsf{K}_{\mathrm{spec}}\, S_a^{(x)}\, d\omega \;-\; O(\eta_{\mathfrak{P}}) \;\geq\; \int \chi_\tau\, \mathsf{K}_{\mathrm{spec}}\, S_a^{(x)}\, d\omega \;-\; O(\eta_{\mathfrak{P}}).$$

Using (7.710),

$$\int \chi_\tau\, \mathsf{K}_{\mathrm{spec}}\, S_a^{(x)} = \int \chi_\tau\, Y_x \;-\; \int \chi_\tau\, R_x.$$

Plug this and (7.711) into the previous inequality to obtain

$$1 - \left|\Lambda^{(x)}_{\mathrm{law}}\right| \;\geq\; \kappa_{\mathrm{spec}}(x)\,\mathcal{T}^{(x)}_{a}[\chi_\tau] \;-\; O(\eta_{\mathfrak{P}}) \;-\left|\int \chi_\tau R_x\right|.$$

Step 5: Control of the remainder $o_\tau(1)$. By (7.710), $|R_x(\omega)| \leq C_x\,\omega^2$ for $|\omega| \leq \omega_0$, with C_x bounded uniformly on $\mathfrak{P}$ (plateau regularity). Hence

$$\left|\int \chi_\tau(\omega)\,R_x(\omega)\,d\omega\right| \;\leq\; C_x \sup_{|\omega|\leq\omega_0(\tau)} \omega^2 \;=:\; o_\tau(1) \;\xrightarrow[\tau\to\infty]{}\; 0.$$

Collecting terms yields the claimed bound. □

Corollary 7.610 (Quantitative tracking of the Ward-source residual)**.** *Combining Lemma 7.608 and Proposition 7.609, for large τ and within plateau tolerances,*

$$1 - \left|\Lambda^{(x)}_{\mathrm{law}}\right| \;\gtrsim\; \kappa_{\mathrm{spec}}(x)\,c_0(x)\left|\mathcal{R}^{(x)}_{a}\right|.$$

Thus the measured T–odd holosymmetric signal tracks the Ward–source residual linearly at low frequency.

Proof. From Proposition 7.609,

$$1 - \left|\Lambda^{(x)}_{\mathrm{law}}\right| \;\geq\; \kappa_{\mathrm{spec}}(x)\;\mathcal{T}^{(x)}_{a}[\chi_\tau] \;-\; O(\eta_{\mathfrak{P}}) \;-\; o_\tau(1).$$

By Lemma 7.608, $\mathcal{T}^{(x)}_{a}[\chi_\tau] \to c_0(x)\,|\mathcal{R}^{(x)}_{a}|$ as $\tau \to \infty$, with $c_0(x) > 0$. Therefore, taking τ large and using the plateau envelope to absorb $O(\eta_{\mathfrak{P}})$,

$$1 - \left|\Lambda^{(x)}_{\mathrm{law}}\right| \;\geq\; \kappa_{\mathrm{spec}}(x)\,c_0(x)\,|\mathcal{R}^{(x)}_{a}| \;-\; \underbrace{O(\eta_{\mathfrak{P}}) - o_\tau(1)}_{\text{small}},$$

which is precisely the stated quantitative tracking; the symbol $\gtrsim$ indicates dominance up to these controlled small terms. □

Definition 7.611 (Cone preservation (no law-signalling))**.** Let $\mathsf{C}^{\pm}$ be the forward/backward light-cones (or causal cones with dynamic exponent z). The UV/IR taggers are *cone-preserving* if their time-domain kernels have support contained in $\mathsf{C}^{+} \cup \mathsf{C}^{-}$ and commute with the BRST/G actions (Definition 7.551). We say the law-channel readout is *non-signalling* if, for spacelike-separated regions A, B,

$$\left\langle [\,\bar{J}^{(x)\mu}_{a,\mathrm{imp}}(A),\; \mathcal{W}^{(x)}(B)\,] \right\rangle_{\Psi} = 0,$$

for all $x \in \mathfrak{P}$ (microcausality after band descent).

Proposition 7.612 (Cone preservation under band descent)**.** *If the microscopic theory is microcausal and the taggers are cone-preserving, then the band–retarded correlators vanish outside $\mathsf{C}^{\pm}$, and the law channel is non–signalling in the sense of Definition 7.611.*

Proof. Setting. Let $A(y), B(z)$ be (smeared) local operators and let

$$R_{AB}(y,z) \;:=\; \theta(y^0-z^0)\,\big\langle [\,A(y),B(z)\,]\big\rangle_{\mathbf{\Psi}}$$

be their microscopic retarded bi–distribution. *Microcausality* means

$$\operatorname{supp} R_{AB} \;\subset\; \{(y,z):\, y-z\in \mathsf{C}^+\}\,, \qquad \operatorname{supp}\langle [A(y),B(z)]\rangle_{\mathbf{\Psi}} \;\subset\; \{(y,z):\, y-z\in \mathsf{C}^+\cup\mathsf{C}^-\}. \tag{7.712}$$

Taggers and cone preservation. By hypothesis (cone–preserving taggers), there exist C_c^∞ kernels κ_x (IR) and π_x (the inverse Fourier transform of the UV projector P_x), real and even, such that

$$\operatorname{supp}\kappa_x \;\subset\; \mathsf{C}^+\cup\mathsf{C}^-, \qquad \operatorname{supp}\pi_x \;\subset\; \mathsf{C}^+\cup\mathsf{C}^-. \tag{7.713}$$

Band descent acts on operator–valued distributions by spacetime convolution:

$$A^{(x)} := \kappa_x * (\pi_x * A), \qquad B^{(x)} := \kappa_x * (\pi_x * B),$$

and on bi–distributions by the corresponding left–right convolutions.[19]

(I) Support of the band–retarded correlator. Consider the band–retarded bi–distribution

$$R^{(x)}_{AB}(y,z) \;:=\; \theta(y^0-z^0)\,\big\langle [\,A^{(x)}(y),B^{(x)}(z)\,]\big\rangle_{\mathbf{\Psi}}.$$

Using bilinearity of the commutator and Fubini for distributions,

$$R^{(x)}_{AB}(y,z)=\iint dy_1\,dz_1\;\kappa_x(y-y_1)\,\kappa_x(z-z_1)\;\theta(y^0-z^0)\;\big\langle [\,(\pi_x*A)(y_1),(\pi_x*B)(z_1)\,]\big\rangle_{\mathbf{\Psi}}.$$

Writing $(\pi_x * A)(y_1)=\int dy_2\,\pi_x(y_1-y_2)A(y_2)$ and similarly for B, we obtain

$$R^{(x)}_{AB}(y,z)=\iiiint dy_1dz_1dy_2dz_2\;\kappa_x(y-y_1)\,\kappa_x(z-z_1)\,\pi_x(y_1-y_2)\,\pi_x(z_1-z_2)\;R_{AB}(y_2,z_2)\,.$$

Hence, by successive applications of the support rule for convolutions $\operatorname{supp}(f*g)\subset \operatorname{supp}f+\operatorname{supp}g$ and by (7.712)–(7.713),

$$\operatorname{supp} R^{(x)}_{AB}\subset\Big\{(y,z):\;\exists(y_2,z_2)\text{ s.t. }\; y-y_2\in\operatorname{supp}\kappa_x+\operatorname{supp}\pi_x,\;\; z-z_2\in\operatorname{supp}\kappa_x+\operatorname{supp}\pi_x,\\ y_2-z_2\in\mathsf{C}^+\Big\}.$$

Therefore

$$y-z \;=\; (y_2-z_2)\;+\;(y-y_2)-(z-z_2)\;\in\;\mathsf{C}^+\;+\;(\mathsf{C}^\pm-\mathsf{C}^\pm)\;\subset\;\mathsf{C}^+,$$

because C^+ is a closed convex cone and $\mathsf{C}^\pm\pm\mathsf{C}^\pm\subset\mathsf{C}^\pm$ while $\mathsf{C}^+-\mathsf{C}^+\subset\mathsf{C}^+$.[20] Thus

$$\operatorname{supp} R^{(x)}_{AB} \;\subset\; \{(y,z):\, y-z\in\mathsf{C}^+\}. \tag{7.714}$$

[19] All convolutions are well–defined because the taggers are C_c^∞, hence the usual theory of convolution of distributions applies.

[20] Equivalently, in Fourier space one uses that the multipliers are supported in the dual cone and preserve retardedness.

The same argument without the Heaviside factor gives $\operatorname{supp}\langle[A^{(x)}(y),B^{(x)}(z)]\rangle_{\mathbf{\Psi}} \subset \{(y,z) : y-z \in \mathsf{C}^+ \cup \mathsf{C}^-\}$. Hence *band–retarded correlators vanish outside* C^+.

(II) Non–signalling of the law channel. Let A, B be spacelike–separated regions and let f_A, g_B be test functions supported in A, B, respectively. Define the band–smeared operators

$$\mathcal{J}_A^{(x)} := A^{(x)}(f_A), \qquad \mathcal{W}_B^{(x)} := B^{(x)}(g_B).$$

Their commutator expectation equals the distributional pairing of the microscopic commutator with the *effective* test functions after descent, i.e.

$$\Big\langle [\,\mathcal{J}_A^{(x)}, \mathcal{W}_B^{(x)}\,] \Big\rangle_{\mathbf{\Psi}} = \Big\langle [\,A, B\,],\ (K_x^\dagger f_A) \otimes (K_x^\dagger g_B) \Big\rangle, \quad K_x := \kappa_x * \pi_x,$$

so that $K_x^\dagger$ acts by convolution with $\tilde\kappa_x * \tilde\pi_x$, and

$$\operatorname{supp}(K_x^\dagger f_A) \ \subset\ A + \operatorname{supp}\kappa_x + \operatorname{supp}\pi_x =: A^\sharp, \qquad \operatorname{supp}(K_x^\dagger g_B) \ \subset\ B + \operatorname{supp}\kappa_x + \operatorname{supp}\pi_x =: B^\sharp.$$

By (7.713), $A^\sharp$ and $B^\sharp$ are *thickenings within the cones*. If A, B are spacelike–separated and the tagger apertures (time cutoffs and cone thickness) are chosen within the certified–plateau margins, then $A^\sharp$ and $B^\sharp$ remain spacelike–separated. Because the microscopic commutator distribution vanishes on spacelike pairs (7.712), the pairing is zero:

$$\Big\langle [\,\mathcal{J}_A^{(x)}, \mathcal{W}_B^{(x)}\,] \Big\rangle_{\mathbf{\Psi}} = 0.$$

This is precisely the *non–signalling* property in the sense of Definition 7.611 for the law channel.

(III) BRST/G structure and gauge independence. The taggers act by c–number spacetime convolution (and Fourier multiplication), with no action on field indices, hence they commute with BRST and G transformations (cf. Proposition 7.573). Passing to the physical sector $\mathcal{H}_{\text{phys}}$ removes BRST–exact/improvement terms (Lemma 7.552); therefore no gauge artefact can generate support outside $\mathsf{C}^\pm$ or spoil non–signalling.

Combining (I)–(III) proves the proposition. □

Definition 7.613 (Anomaly filter)**.** The *anomaly filter* is passed on $\mathfrak{P}$ if the following equivalent conditions hold:

1. (BRST nilpotency) $\zeta^2 = 0$ and $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ (Stage-I gate).
2. (Adjoint covariance) The band Ward identity is adjoint-covariant (Proposition 7.568).
3. (Spectral matching) For all test functions φ supported near $\omega = 0$, $\mathcal{T}_a^{(x)}[\varphi] = C_\varphi(x)\,\mathcal{R}_a^{(x)}$ with $C_\varphi(x)$ independent of gauge parameters and free of non-covariant contact terms.

Failure of any condition signals an anomaly (e.g., a Wess–Zumino obstruction).

Theorem 7.614 (T-odd tomography & cones: completion criterion for Point 4)**.** *Assume the Stage-I gate (BRST anomaly–free), cone–preserving taggers, and a certified plateau* $\mathfrak{P}$*. Then:*

1. *(*Tracking*) The T–odd holosymmetric signal* $-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)}$ *tracks the Ward–source residual via* (7.706)*; the quantitative lower bound of Corollary 7.610 holds uniformly on* $\mathfrak{P}$*.*
2. *(*No law–signalling*) Cone preservation implies non–signalling in the law channel (Proposition 7.612).*
3. *(*Anomaly filter*) The conditions in Definition 7.613 are satisfied; any observed deviation beyond plateau tolerances indicates either plateau failure or a (BRST/ward) anomaly.*

All statements are gauge–parameter independent on $\mathcal{H}_{\mathrm{phys}}$ *(Proposition 7.556) and stable under BRST/Noether improvements (Lemma 7.552).*

Proof. Preliminaries. Stage–I (*anomaly–free*) means the Wess–Zumino consistency holds for the band–descended Ward structure, with improvement/BRST–exact freedoms organized as in Lemma 7.563 and their spurion–sector versions unique on $\mathcal{H}_{\mathrm{phys}}$ by Corollary 7.564. Cone–preserving taggers commute with BRST/G and act by c–number spacetime convolution (cf. Proposition 7.573). Certified plateaus (Definition 6.300) give the oscillation budget $\eta_{\mathfrak{P}}$ and uniform floors for the spectral kernel (Lemma 7.575 and Proposition 7.602).

(1) Tracking. By the spectral/tomographic representation of the T–odd law channel (Definition 7.607) and the low–frequency Ward matching (Lemma 7.608), with a normalized, even mollifier χ_τ supported in $[-\omega_0(\tau),\omega_0(\tau)]$,

$$\mathcal{T}_a^{(x)}[\chi_\tau] \xrightarrow[\tau\to\infty]{} c_0(x)\,|\mathcal{R}_a^{(x)}|, \qquad c_0(x)>0.$$

The tomographic *lower bound* (Proposition 7.609) gives, uniformly on $\mathfrak{P}$,

$$1-|\Lambda_{\mathrm{law}}^{(x)}| \;\geq\; \kappa_{\mathrm{spec}}(x)\;\mathcal{T}_a^{(x)}[\chi_\tau] \;-\; O(\eta_{\mathfrak{P}}) \;-\; o_\tau(1).$$

Letting $\tau\to\infty$ yields the quantitative tracking bound of Corollary 7.610:

$$1-|\Lambda_{\mathrm{law}}^{(x)}| \;\gtrsim\; \kappa_{\mathrm{spec}}(x)\,c_0(x)\,|\mathcal{R}_a^{(x)}| \quad (\text{up to } O(\eta_{\mathfrak{P}})).$$

This proves Item (1).

(2) No law–signalling. By microcausality of the microscopic theory and cone–preserving taggers, band–retarded correlators have support inside $\mathsf{C}^{\pm}$ and band–smeared commutators vanish at spacelike separations (Proposition 7.612). Hence the law channel is non–signalling in the sense of Definition 7.611. This proves Item (2).

(3) Anomaly filter. Define the *tomographic residual*

$$\Delta_\tau(x) \;:=\; \Big(1-|\Lambda_{\mathrm{law}}^{(x)}|\Big) \;-\; \kappa_{\mathrm{spec}}(x)\,\mathcal{T}_a^{(x)}[\chi_\tau].$$

From Proposition 7.609 we have, uniformly on $\mathfrak{P}$,

$$\Delta_\tau(x) \;\geq\; -\,O(\eta_{\mathfrak{P}}) \;-\; o_\tau(1). \tag{7.715}$$

On the other hand, Stage–I anomaly–freeness plus Lemma 7.608 control the *model side*: $\mathcal{T}_a^{(x)}[\chi_\tau] \to c_0(x)|\mathcal{R}_a^{(x)}|$ with BRST/Noether–improvement pieces dropping out on $\mathcal{H}_{\mathrm{phys}}$

(Lemma 7.552, Proposition 7.556, and Corollary 7.564). Therefore any observed *systematic* violation

$$\limsup_{\tau\to\infty}\ \sup_{x\in\mathfrak{P}}\ \Delta_\tau(x)\ >\ c_\star\,\eta_{\mathfrak{P}}\qquad\text{for some } c_\star>0$$

cannot be accommodated by the $O(\eta_{\mathfrak{P}})$ oscillation budget in (7.715). The only remaining possibilities are: (i) failure of plateau certification (e.g. loss of kernel floor, non–monotone refinement, or masking issues), or (ii) breakdown of the Ward matching—i.e. a BRST/ward anomaly as formulated in Definition 7.613. Hence the anomaly–filter conditions are satisfied: deviations beyond the plateau tolerance trigger a (plateau–or–anomaly) alert. This proves Item (3).

Gauge/BRST robustness. Every step uses band–descended, BRST–closed quantities; taggers commute with BRST/G (Proposition 7.573), and physical expectations are taken on $\mathcal{H}_{\text{phys}}$ (Proposition 7.556 and Lemma 7.552). Thus all conclusions are gauge–parameter independent and immune to BRST/Noether improvements.

The theorem follows. □

7.9.9 Law–channel Diagnosis: Saturation vs. QIII

Definition 7.615 (Admissible preparations on a certified band point)**.** Fix $x=(\lambda_{\text{UV}},\ell)\in\mathfrak{P}$ (Definition 6.300). Let $\mathcal{C}_x$ denote the set of band-prepared, BRST-closed, gauge-parameter–independent density operators $\rho_0^{(x)}$ constructed by the protocol of Definitions 6.275 and 7.551 (same UV/IR taggers, same boundary preparation class).

Proposition 7.616 (Law-channel saturation via Duhamel/BCH (QIV))**.** *Let $x\in\mathfrak{P}$ and write the tagged branch unitaries as $U_A^{(x)},U_B^{(x)}$ with $U_B^{(x)\dagger}U_A^{(x)}=\exp\{i\,\varepsilon_{\text{IR}}(x)\,G_x+\mathcal{O}(\varepsilon_{\text{IR}}^2)\}$ in the interaction picture, where G_x is a self-adjoint, band-local generator proportional to the explicit breaking source (Duhamel representation), and $\varepsilon_{\text{IR}}(x)$ is the band IR-norm of the spurion deformation (non-running in QIV). Then for all $\rho_0^{(x)}\in\mathcal{C}_x$,*

$$1-\left|\Lambda_{\text{law}}^{(x)}\right|=1-\left|\operatorname{Tr}\!\left(U_B^{(x)\dagger}U_A^{(x)}\,\rho_0^{(x)}\right)\right|\ \geq\ \tfrac{1}{2}\,\varepsilon_{\text{IR}}(x)^2\,\operatorname{Var}_{\rho_0^{(x)}}(G_x)\ +\ o\!\left(\varepsilon_{\text{IR}}(x)^2\right).$$

Moreover, on a certified plateau there exists $c_x>0$ (gauge-parameter independent) such that $\operatorname{Var}_{\rho_0^{(x)}}(G_x)\geq c_x$ for all $\rho_0^{(x)}\in\mathcal{C}_x$, and hence

$$\sup_{\rho_0^{(x)}\in\mathcal{C}_x}\left|\Lambda_{\text{law}}^{(x)}\right|\ \leq\ 1-\tfrac{1}{2}\,c_x\,\varepsilon_{\text{IR}}(x)^2\ +\ o\!\left(\varepsilon_{\text{IR}}(x)^2\right).$$

Uniformly on $\mathfrak{P}$, c_x can be replaced by a strictly positive $c_\star$ (plateau uniformization, Lemma 7.579).

Proof sketch. (i) Duhamel/BCH reduction. Set $U_B^{(x)\dagger}U_A^{(x)}=\mathcal{T}\exp\!\left(i\int_0^1 ds\,\Delta H_x(s)\right)$ with ΔH_x the band-IR explicit-breaking Hamiltonian density (spurion-sourced). Duhamel's formula yields

$$U_B^{(x)\dagger}U_A^{(x)}=\exp\!\Big(i\,\varepsilon_{\text{IR}}(x)\,G_x-\tfrac{1}{2}\varepsilon_{\text{IR}}(x)^2\,C_x+\mathcal{O}(\varepsilon_{\text{IR}}^3)\Big),$$

where G_x is self-adjoint and C_x collects the time-ordered commutators (BCH/Dyson series); both are band-local and BRST/Nielsen safe by Definition 7.551, Lemma 7.552, and Proposition 7.556.

(ii) Quantum characteristic function bound. For any density matrix ρ and small ϵ, expand

$$\mathrm{Tr}\Big(e^{i\epsilon G_x}\rho\Big) = 1 + i\epsilon\,\langle G_x\rangle_\rho - \tfrac{1}{2}\epsilon^2\langle G_x^2\rangle_\rho + \mathcal{O}(\epsilon^3).$$

Taking modulus and using $|1 + iz - \frac{1}{2}a + o(1)| \le 1 - \frac{1}{2}(a - z^2) + o(1)$ gives

$$\begin{aligned} 1 - \Big|\,\mathrm{Tr}(e^{i\epsilon G_x}\rho)\Big| &\ge \tfrac{1}{2}\,\epsilon^2\Big(\langle G_x^2\rangle_\rho - \langle G_x\rangle_\rho^{\,2}\Big) + o(\epsilon^2) \\ &= \tfrac{1}{2}\,\epsilon^2\ \mathrm{Var}_\rho(G_x) + o(\epsilon^2). \end{aligned}$$

The additional $\mathcal{O}(\varepsilon_{\mathrm{IR}}^2)$ term from C_x only strengthens the deficit (it is T-even and does not cancel the variance term). Plug in $\epsilon = \varepsilon_{\mathrm{IR}}(x)$ and $\rho = \rho_0^{(x)}$.

(iii) Plateau lower bound for the variance. The non-vanishing Ward source on $\mathfrak{P}$ (Theorem 7.570) together with the T-odd tomography representation (Definition 7.607, Lemma 7.578 and Proposition 7.609) implies a strictly positive low-frequency spectral weight tied to G_x. This gives a uniform positive lower bound

$$\Big\langle G_x^2\Big\rangle_{\rho_0^{(x)}} - \Big\langle G_x\Big\rangle_{\rho_0^{(x)}}^{2} \ \ge\ c_x > 0$$

over the certified class $\mathcal{C}_x$ independent of gauge parameters (Proposition 7.556). Plateau uniformization (Lemma 7.579) yields $c_x \ge c_\star > 0$ for all $x \in \mathfrak{P}$ after tightening tolerances if needed. □

Corollary 7.617 (QIV vs. QIII saturation test)**.** *Under QIV (relevant/marginal spurions),* $\varepsilon_{\mathrm{IR}}(x)$ *does* not *run to* 0 *with* ℓ *on* $\mathfrak{P}$*; hence*

$$\Big|\Lambda_{\mathrm{law}}^{(x)}\Big| \ \le\ 1 - \delta_\star + o(1), \qquad \delta_\star := \tfrac{1}{2}\,c_\star\,\varepsilon_{\mathrm{IR},\star}^2 \in (0,1),$$

uniformly in $x \in \mathfrak{P}$*. By contrast, in QIII the effective spurion norm scales as* $\varepsilon_{\mathrm{IR}}(x) \sim \ell^{\Delta-(d+z)}$ *(emergent symmetry), so the measured law-deficit* improves *as* $1 - |\Lambda_{\mathrm{law}}(x)| = A\,\ell^{\,\Delta-(d+z)} + o(\ell^{\,\Delta-(d+z)})$ *(Theorem 7.580 and the QIII scaling overlay), cleanly disentangling QIV from QIII.*

Proof. Step 1: Quadratic lower bound from the BCH/Duhamel expansion. On a certified plateau, the branch-link has the expansion

$$U_B^{(x)\dagger}U_A^{(x)} = \exp\Big(i\,\varepsilon_{\mathrm{IR}}(x)\,G_x - \tfrac{1}{2}\varepsilon_{\mathrm{IR}}(x)^2 C_x + \cdots\Big)$$

(cf. the BCH form used in Definition 7.674).

Let $\langle\cdot\rangle_{\mathbf{\Psi}}$ denote the physical expectation on $\mathcal{H}_{\mathrm{phys}}$. For small ε one has the standard characteristic–function inequality (second–order cumulant expansion)

$$\Big|\Big\langle e^{\,i\varepsilon G_x}\Big\rangle_{\mathbf{\Psi}}\Big| \ \le\ 1 - \tfrac{1}{2}\,\varepsilon^2\ \mathrm{Var}_{\mathbf{\Psi}}(G_x) + O(\varepsilon^3).$$

hence for the (law–channel) overlap magnitude,

$$1 - |\Lambda^{(x)}_{\mathrm{law}}| \;\geq\; \tfrac{1}{2}\,\varepsilon_{\mathrm{IR}}(x)^2\,\mathrm{Var}_{\Psi}(G_x) \;-\; \mathcal{O}\big(\varepsilon_{\mathrm{IR}}(x)^3\big) \;-\; \mathcal{O}(\eta_{\mathfrak{P}}). \tag{7.716}$$

The $O(\eta_{\mathfrak{P}})$ term reflects the plateau envelope between channels (Definition 6.300, Corollary 7.677). By cone–preserving taggers and kernel positivity (Lemma 7.575 and Proposition 7.602), the band–descended variance has a plateau–uniform strictly positive lower bound:

$$\mathrm{Var}_{\Psi}(G_x) \;\geq\; c_\star > 0 \qquad (x \in \mathfrak{P}).$$

because G_x inherits a positive spectral weight on the certified window (nontrivial T–odd floor; cf. the tracking statements in Corollary 7.677(i), Corollary 7.610).

Step 2: QIV saturation. QIV means the IR spurion does *not* decay with the IR scale on $\mathfrak{P}$ ("no IR improvement"): by Theorem 7.580 (and the slope test Proposition 7.599), there exists

$$\varepsilon_{\mathrm{IR},\star} \;:=\; \inf_{\ell \text{ on the certified window}}\; \inf_{x\in\mathfrak{P}}\; \varepsilon_{\mathrm{IR}}(x;\ell) \;>\; 0.$$

Plugging $\varepsilon_{\mathrm{IR}}(x) \geq \varepsilon_{\mathrm{IR},\star}$ and $\mathrm{Var}(G_x) \geq c_\star$ into (7.716), and absorbing $O(\varepsilon^3_{\mathrm{IR}})$ into $o(1)$ along the window (fixed $\varepsilon_{\mathrm{IR},\star}$, $\ell \to \infty$), we obtain

$$1 - |\Lambda^{(x)}_{\mathrm{law}}| \;\geq\; \tfrac{1}{2}\,c_\star\,\varepsilon^2_{\mathrm{IR},\star} \;-\; o(1) \;-\; O(\eta_{\mathfrak{P}}).$$

Equivalently,

$$|\Lambda^{(x)}_{\mathrm{law}}| \;\leq\; 1 - \delta_\star + o(1), \qquad \delta_\star := \tfrac{1}{2}\,c_\star\,\varepsilon^2_{\mathrm{IR},\star} \in (0,1),$$

uniformly for $x \in \mathfrak{P}$ (plateau compactness). This is the claimed QIV saturation bound.

Step 3: QIII power–law improvement. In QIII (emergent symmetry), the spurion is *irrelevant* at the IR fixed point with scaling dimension $\Delta > d + z$. Under anisotropic RG with dynamic exponent z, the effective IR spurion scales as

$$\varepsilon_{\mathrm{IR}}(\ell) \;\sim\; \ell^{\,\Delta-(d+z)} \qquad (\ell \to \infty),$$

i.e. it runs to 0 with a negative exponent $y = d + z - \Delta < 0$. By the tomographic tracking bound (Proposition 7.609 and Lemma 7.608),

$$1 - |\Lambda^{(x)}_{\mathrm{law}}| \;\geq\; \kappa_{\mathrm{spec}}(x)\,c_0(x)\,|\mathcal{R}^{(x)}_a| \;-\; o(1) \;-\; O(\eta_{\mathfrak{P}}).$$

The Ward residual is linear in the spurion source (eq. (7.665) implicitly used in Lemma 7.608): $|\mathcal{R}^{(x)}_a| \asymp \varepsilon_{\mathrm{IR}}(\ell)$ along the certified window (the proportionality is uniform on $\mathfrak{P}$ by the spectral floors and probe normalization). Consequently,

$$1 - |\Lambda^{(x)}_{\mathrm{law}}| \;=\; A(x)\,\ell^{\,\Delta-(d+z)} \;+\; o\big(\ell^{\,\Delta-(d+z)}\big), \quad A(x) := \kappa_{\mathrm{spec}}(x)\,c_0(x)\,\big\|\text{PCAC factor at } x\big\|,$$

uniformly up to the plateau tolerance. Taking $A := \sup_{x\in\mathfrak{P}} A(x)$ yields the displayed QIII scaling law.

Step 4: Clean separation. In QIV, the uniform *positive* constant $\delta_\star$ forces a nonvanishing law–deficit as $\ell \to \infty$; in QIII, the power–law with exponent $\Delta - (d+z) < 0$ guarantees

improvement (decay to 0). Thus the behaviors are disjoint on certified windows, providing a robust operational separation of QIV vs. QIII as stated.

Gauge/BRST robustness. All inputs—kernel floors, tomographic functionals, Ward residuals—are built from band–descended, BRST–closed observables; taggers commute with BRST/G (Proposition 7.573), and expectations are taken on $\mathcal{H}_{\text{phys}}$ (Lemma 7.552 and Proposition 7.556). Hence the conclusions are gauge–parameter independent and Nielsen–stable.

This completes the proof. □

7.9.10 Near–degeneracies and GMOR Fits in the Mass Ledger

Context. On $\mathcal{H}_{\text{phys}}$ the band Hessian $\mathbb{H}^{(x)}(\epsilon)$ is a self–adjoint, type–(A) analytic family in the spurions $\epsilon = (\epsilon_k)$ (Proposition 7.642); pseudo–NG eigenvalues and their Riesz projectors vary real–analytically, and residues/poles are Nielsen–independent (Proposition 7.644). We now (i) formalize *analytic eigenvector labeling* in the presence of near–crossings and (ii) give a one–line *fit specification* for $m_{\pi_b}^2$ vs. ϵ_j with vanishing intercept within plateau tolerance.

Definition 7.618 (Near–degeneracy window and isolated cluster)**.** Fix a line in spurion space $\epsilon(t) = \epsilon^{(0)} + t\,\hat{\mathbf{e}}_j$ with $t \in I \subset \mathbb{R}$ small, and a band point $x \in \mathfrak{P}$. Let $\{\lambda_\beta^{(x)}(t)\}$ be pseudo–NG eigenvalues of $\mathbb{H}^{(x)}(\epsilon(t))$ with Riesz projectors $\mathsf{P}_\beta^{(x)}(t)$. We say that a finite index set $\mathcal{B}$ forms an *isolated cluster* on I with *gap* $\delta_{\text{gap}} > 0$ if

$$\operatorname{dist}\Big(\ \sigma\Big(\mathbb{H}^{(x)}(\epsilon(t))\Big) \restriction \operatorname{Ran}\textstyle\sum_{\beta\in\mathcal{B}} \mathsf{P}_\beta^{(x)}(t)\ ,\ \sigma\Big(\mathbb{H}^{(x)}(\epsilon(t))\Big)\setminus \operatorname{Ran}\textstyle\sum_{\beta\in\mathcal{B}} \mathsf{P}_\beta^{(x)}(t)\ \Big)\ \geq\ \delta_{\text{gap}} \quad \forall\, t \in I.$$

Equivalently, the spectral subspace $\mathcal{E}_{\mathcal{B}}^{(x)}(t) = \operatorname{Ran}\mathsf{P}_{\mathcal{B}}^{(x)}(t)$ with $\mathsf{P}_{\mathcal{B}}^{(x)}(t) = \frac{1}{2\pi i}\oint_\gamma (z - \mathbb{H}^{(x)}(\epsilon(t)))^{-1}\,dz$ is well–defined for a fixed contour γ enclosing that cluster.

Lemma 7.619 (Analytic subspace tracking (Riesz projectors))**.** *Under Definition 7.618, $t \mapsto \mathsf{P}_{\mathcal{B}}^{(x)}(t)$ is real–analytic on I and so is any spectral invariant (e.g. the eigenvalue sum $\sum_{\beta\in\mathcal{B}} \lambda_\beta^{(x)}(t)$). Gauge independence holds on $\mathcal{H}_{\text{phys}}$ by Proposition 7.644.*

Proof. Setup and gap. Let $\mathsf{H}^{(x)}(t)$ denote the (band) Hermitian operator/matrix depending on $t \in I \subset \mathbb{R}$. By Proposition 7.642 the family $\{\mathsf{H}^{(x)}(t)\}_{t\in I}$ is a type–(A) real–analytic family. By Definition 7.618 there exists a *fixed* positively oriented contour $\Gamma \subset \mathbb{C}$ such that, for all $t \in I$,

$$\Gamma \subset \rho\Big(\mathsf{H}^{(x)}(t)\Big) \qquad \text{and} \qquad \operatorname{dist}\Big(\Gamma,\ \sigma\Big(\mathsf{H}^{(x)}(t)\Big)\Big)\ \geq\ \delta > 0,$$

and Γ encloses exactly the eigenvalue cluster $\mathcal{B}$ (with constant total multiplicity $m := \dim \operatorname{Ran}\mathsf{P}_{\mathcal{B}}^{(x)}(t)$).

Analyticity of the Riesz projector. Write the resolvent $R(t,z) := (z - \mathsf{H}^{(x)}(t))^{-1}$. For type–(A) families, the map $(t,z) \mapsto R(t,z)$ is holomorphic in $z \in \rho(\mathsf{H}^{(x)}(t))$ and real–analytic in t, jointly locally bounded on $I \times \{\text{neigh. of } \Gamma\}$ (standard Kato theory; cf. Proposition 7.642). Define the Riesz projector by the holomorphic functional calculus

$$\mathsf{P}_{\mathcal{B}}^{(x)}(t)\ :=\ \frac{1}{2\pi i}\oint_\Gamma R(t,z)\,dz.$$

Because $R(t,\cdot)$ is holomorphic on and inside Γ and depends real–analytically on t with uniform bounds on Γ, the contour integral preserves real–analyticity: $t \mapsto \mathsf{P}^{(x)}_{\mathcal{B}}(t)$ is real–analytic on I. In particular, $\mathsf{P}^{(x)}_{\mathcal{B}}(t)$ is a projector of constant rank m and depends continuously (indeed, real–analytically) on t. Differentiating under the integral gives the familiar formula (valid for all $t \in I$):

$$\partial_t \mathsf{P}^{(x)}_{\mathcal{B}}(t) \;=\; \frac{1}{2\pi i}\oint_{\Gamma} R(t,z)\,\Big(\partial_t \mathsf{H}^{(x)}(t)\Big)\,R(t,z)\,dz,$$

which exhibits real–analyticity of all derivatives.

Analyticity of spectral invariants. Let f be holomorphic on a neighbourhood of the spectrum inside Γ. Then

$$f\Big(\mathsf{H}^{(x)}(t)\Big)\,\mathsf{P}^{(x)}_{\mathcal{B}}(t) \;=\; \frac{1}{2\pi i}\oint_{\Gamma} f(z)\,R(t,z)\,dz,$$

is real–analytic in t (same argument). Since the trace is a continuous linear functional, $t \mapsto \mathrm{Tr}\Big(f(\mathsf{H}^{(x)}(t))\,\mathsf{P}^{(x)}_{\mathcal{B}}(t)\Big)$ is real–analytic. Choosing $f(z) = z$ yields

$$\sum_{\beta\in\mathcal{B}} \lambda^{(x)}_{\beta}(t) \;=\; \mathrm{Tr}\Big(\mathsf{H}^{(x)}(t)\,\mathsf{P}^{(x)}_{\mathcal{B}}(t)\Big)\,,$$

hence the eigenvalue sum is real–analytic on I. More generally, any spectral invariant that can be written as a trace of a holomorphic functional of $\mathsf{H}^{(x)}(t)$ restricted by $\mathsf{P}^{(x)}_{\mathcal{B}}(t)$ (e.g. power sums $\sum_{\beta\in\mathcal{B}} \lambda_\beta^p$, elementary symmetric polynomials via det on the range, etc.) is real–analytic by the same calculus.

Gauge/Nielsen independence on $\mathcal{H}_{\mathrm{phys}}$. Gauge–parameter variations act as Nielsen reparametrizations that either (i) implement similarity/adjoint actions commuting with the projection onto $\mathcal{H}_{\mathrm{phys}}$, or (ii) add BRST–exact/improvement pieces that are null on $\mathcal{H}_{\mathrm{phys}}$. By Proposition 7.644, spectral quantities built via the holomorphic functional calculus (Riesz projectors, eigenvalue sums on the physical sector) are gauge–parameter independent. Therefore the statements above hold on $\mathcal{H}_{\mathrm{phys}}$.

This completes the proof. □

Proposition 7.620 (Kato parallel transport and analytic labeling)**.** *Let $\mathcal{E}^{(x)}_{\mathcal{B}}(t)$ be as above with $\dim \mathcal{E}^{(x)}_{\mathcal{B}}(t) = r$. Choose an orthonormal frame $\{|\psi^{(x)}_\ell(t)\rangle\}_{\ell=1}^{r}$ in $\mathcal{E}^{(x)}_{\mathcal{B}}(t)$ by* Kato parallel transport*:*

$$\frac{d}{dt}\,|\psi^{(x)}_\ell(t)\rangle = \Big[\partial_t \mathsf{P}^{(x)}_{\mathcal{B}}(t),\,\mathsf{P}^{(x)}_{\mathcal{B}}(t)\Big]\,|\psi^{(x)}_\ell(t)\rangle\,, \qquad |\psi^{(x)}_\ell(t_0)\rangle = |\psi^{(x)}_\ell(t_0)\rangle_0\,, \tag{7.717}$$

for some initial orthonormal eigenbasis at $t_0 \in I$. Then $t \mapsto |\psi^{(x)}_\ell(t)\rangle$ is real–analytic, and the principal angles *between $\{|\psi^{(x)}_\ell(t)\rangle\}$ and a fixed reference basis give analytic, gauge–independent* mixing angles*. If the cluster is actually simple ($r = 1$) at t, this choice coincides with the unique normalized eigenvector up to a constant phase.*

Proof. Step 0: Analytic projectors and identities. By Lemma 7.619, the Riesz projector $\mathsf{P}(t) := \mathsf{P}^{(x)}_{\mathcal{B}}(t)$ is real–analytic on I and self–adjoint. Differentiating $\mathsf{P}(t)^2 = \mathsf{P}(t)$ gives

$$\mathsf{P}\,\dot{\mathsf{P}}\,\mathsf{P} = 0, \qquad (\mathbf{1}-\mathsf{P})\,\dot{\mathsf{P}}\,(\mathbf{1}-\mathsf{P}) = 0, \qquad [\dot{\mathsf{P}},\mathsf{P}]^\dagger = -[\dot{\mathsf{P}},\mathsf{P}]. \tag{7.718}$$

Hence the *Kato generator* $K(t) := [\dot{\mathsf{P}}(t), \mathsf{P}(t)]$ is bounded, real–analytic in t, and skew–adjoint.

Step 1: Existence/uniqueness, unitarity, and invariance of the subspace. Consider the matrix ODE on the ambient Hilbert space,

$$\dot{U}(t) = K(t)\,U(t), \qquad U(t_0) = \mathbf{1}.$$

Since K is continuous (indeed analytic), the Picard–Dyson series converges on compact intervals; hence there is a unique strongly–continuous (indeed analytic) solution $U(t)$. Skew–adjointness of K implies $\frac{d}{dt}\big(U^\dagger U\big) = U^\dagger(K^\dagger + K)U = 0$, so $U(t)$ is unitary for all t.

Define the transported frame by $|\psi_\ell(t)\rangle := U(t)\,|\psi_\ell(t_0)\rangle_0$; orthonormality follows from unitarity. To see that $|\psi_\ell(t)\rangle \in \operatorname{Ran}\mathsf{P}(t)$, set $\eta_\ell(t) := (\mathbf{1} - \mathsf{P}(t))\,|\psi_\ell(t)\rangle$ and differentiate, using (7.718) and $\dot{\psi}_\ell = K\psi_\ell$:

$$\dot{\eta}_\ell = -(\dot{\mathsf{P}})\psi_\ell + (\mathbf{1}-\mathsf{P})K\psi_\ell = -(\dot{\mathsf{P}})\psi_\ell + (\mathbf{1}-\mathsf{P})\dot{\mathsf{P}}\,\mathsf{P}\psi_\ell - (\mathbf{1}-\mathsf{P})\mathsf{P}\,\dot{\mathsf{P}}\psi_\ell = -(\mathbf{1}-\mathsf{P})\,\dot{\mathsf{P}}\,(\mathbf{1}-\mathsf{P})\psi_\ell = 0,$$

where we used $(\mathbf{1} - \mathsf{P})\mathsf{P} = 0$ and (7.718). Since $\eta_\ell(t_0) = 0$, we have $\eta_\ell(t) \equiv 0$; thus $\mathsf{P}(t)\,|\psi_\ell(t)\rangle = |\psi_\ell(t)\rangle$ for all t.

Step 2: Real–analytic dependence. Because $K(t)$ is real–analytic in t (products/commutators of analytic maps), the unique solution $U(t)$ depends real–analytically on t (standard ODE theory with analytic coefficients on finite–dimensional ranges; equivalently, use the convergent time–ordered exponential with analytic integrand). Consequently $t \mapsto |\psi_\ell(t)\rangle = U(t)\,|\psi_\ell(t_0)\rangle_0$ is real–analytic on I.

Step 3: Analytic, gauge–independent mixing angles (principal angles). Fix a reference orthonormal basis $\{|\phi_j\rangle\}_{j=1}^r$ of $\mathcal{E}_{\mathcal{B}}^{(x)}(t_0)$ and let P_0 be the orthogonal projector onto their span. The *principal angles* $\{\vartheta_j(t)\}_{j=1}^r$ between $\mathcal{E}_{\mathcal{B}}^{(x)}(t)$ and $\mathcal{E}_{\mathcal{B}}^{(x)}(t_0)$ are defined by

$$\cos^2\vartheta_j(t) \;=\; \lambda_j\Big(C(t)\Big), \qquad C(t) := P_0\,\mathsf{P}(t)\,P_0 \;\text{ on }\; \operatorname{Ran} P_0,$$

where $\lambda_j(\cdot)$ are the eigenvalues (counting multiplicity). Since $\mathsf{P}(t)$ is analytic and P_0 is constant, the compressed operator $C(t)$ is a finite–dimensional Hermitian analytic family. By Kato's analytic perturbation theory, its eigenprojections/eigenvalues admit real–analytic branches (after choosing an analytic labeling via Riesz projectors around clusters). Therefore $\cos^2\vartheta_j(t)$ are real–analytic, and so are $\vartheta_j(t) = \arccos\sqrt{\lambda_j\Big(C(t)\Big)}$ (the square–root and arccos are analytic on $(0,1]$, which contains the spectrum for isolated subspaces).

Gauge independence. Replacing the transported frame $\{|\psi_\ell(t)\rangle\}$ by any t–dependent unitary rotation inside $\mathcal{E}_{\mathcal{B}}^{(x)}(t)$ leaves $\mathsf{P}(t)$ (hence $C(t)$) invariant; thus the principal angles are independent of the choice of frame. Variations of gauge parameters act by Nielsen–safe transformations that leave spectral projectors on $\mathcal{H}_{\text{phys}}$ invariant (Proposition 7.644); hence the mixing angles are gauge–parameter independent on $\mathcal{H}_{\text{phys}}$.

Step 4: Simple cluster ($r = 1$). If $r = 1$, then $\mathsf{P}(t) = |\psi(t)\rangle\langle\psi(t)|$ is rank one. The Kato ODE (7.717) reduces to the *parallel–transport* condition $\langle\psi(t)\rangle\,\dot{\psi}(t) = 0$ (since K maps $\operatorname{Ran}\mathsf{P}$ to its orthogonal complement by (7.718)). Thus $|\psi(t)\rangle$ is the unique normalized eigenvector in $\operatorname{Ran}\mathsf{P}(t)$ up to a *constant* phase: if $|\varphi(t)\rangle = e^{i\theta(t)}\,|\psi(t)\rangle$ also solves (7.717), then taking inner products with $|\psi(t)\rangle$ shows $\dot{\theta}(t) = 0$.

Combining Steps 1–4 proves the proposition. □

Definition 7.621 (Operational tolerance for near–crossings)**.** On the mask $\mathfrak{M}_{\mathrm{mask}}$ (Proposition 7.663), we enforce the rule:

1. If along $\epsilon(t)$ two pseudo–NG levels approach with minimal separation $\min_{t\in I}|\lambda_\beta^{(x)}(t)-\lambda_{\beta'}^{(x)}(t)|\geq\delta_{\mathrm{gap}}$, we *label* them individually by Kato transport (Proposition 7.620) and report separate masses/mixings.
2. If the separation drops below δ_{gap}, we *merge* them into a single cluster $\mathcal{B}$, report the eigenvalue *mean* and *spread* $\bar\lambda_{\mathcal{B}}=\frac{1}{r}\sum_{\beta\in\mathcal{B}}\lambda_\beta,\quad \Delta_{\mathcal{B}}=\max_{\beta\in\mathcal{B}}|\lambda_\beta-\bar\lambda_{\mathcal{B}}|$, and quote mixing angles inside $\mathcal{B}$ (frame–independent principal angles). We do *not* over–interpret slopes of individual levels through an avoided crossing.

The constant δ_{gap} is chosen $\mathcal{O}(\eta_{\mathfrak{P}})$–larger than the spectral grid resolution, ensuring mask stability under refinement (Lemma 7.662).

Remark 7.622 (Consistency with GMOR)**.** Within any cluster, the linear GMOR relation of Theorem 7.630 applies at the *subspace* level: $F^{(x)}M^2_{\pi,\mathcal{B}}=\sum_k\epsilon_k C^{(x)}_{k,\mathcal{B}}+\mathcal{O}(\epsilon^2)$ with matrices restricted/prolonged to $\mathcal{E}^{(x)}_{\mathcal{B}}(t)$. Individual level slopes are well–defined away from mergers; at mergers, report the linear map on the subspace.

Definition 7.623 (One–line GMOR fit specification (single spurion))**.** Fix $x\in\mathfrak{P}$ and a broken mode label b (or a Kato–labeled branch within a cluster obeying Definition 7.621). Vary a single spurion ϵ_j along $\epsilon=\epsilon^{(0)}+\epsilon_j\hat{\mathbf{e}}_j$ with all other $\epsilon_{k\neq j}$ fixed at their working values. On the admissible interval where Theorem 7.630 holds, fit

$$m^2_{\pi_b}(x;\epsilon_j)\;=\;\alpha^{(x)}_{bj}\,\epsilon_j\quad(+\text{ report }\;\hat\beta\text{ but enforce }|\hat\beta|\leq\eta_{\mathfrak{P}}\text{ for intercept}),$$

by *constrained weighted least squares*:

$$\min_{\alpha,\beta}\;\sum_n w_n\Big(m^2_{\pi_b}(x;\epsilon^{(n)}_j)-\alpha\,\epsilon^{(n)}_j-\beta\Big)^2\quad\text{s.t.}\quad|\beta|\leq\eta_{\mathfrak{P}},$$

with weights w_n from the spectral–fit uncertainties and $\eta_{\mathfrak{P}}$ the plateau tolerance. Report the slope $\hat\alpha^{(x)}_{bj}$ and its CI; verify *linearity* by an F–test against a quadratic extension. By Corollary 7.631, $\hat\alpha^{(x)}_{bj}$ should match $\frac{1}{f^2_{\pi_b}(x)}\big\langle\mathcal{S}^{(\lambda_{\mathrm{UV}})}_{j,b}\big\rangle_{\mathbf{\Psi}}$ within tolerance and is gauge–independent (Proposition 7.644).

7.9.11 Ward–mass Link (GMOR–type Control of Pseudo–NG)

In QIV, explicit spurions select a unique vacuum and render the would–be NG excitations gapped (pseudo–NG). Here we relate those gaps to the *band* Ward source via a GMOR–type identity, and show *linear* scaling in the spurions on certified plateaus.

Definition 7.624 (Non–conservation operator on the band)**.** At a band point $x=(\lambda_{\mathrm{UV}},\ell)$, define the divergence (non–conservation) operator

$$\Delta^{(x)}_a\;:=\;\nabla^{(\mathrm{ad})}_\mu\,\bar J^{(x)\mu}_{a,\mathrm{imp}},\qquad \bar J^{(x)\mu}_{a,\mathrm{imp}}:=K^{(\ell)}_{\mathrm{IR}}P_x\,J^\mu_{a,\mathrm{imp}}\,P_xK^{(\ell)}_{\mathrm{IR}}.$$

On $\mathcal{H}_{\mathrm{phys}}$, the scale–tagged Ward identity (eq. (7.665)) gives $\Delta^{(x)}_a=\mathcal{R}^{(x)}_a:=\sum_k\epsilon_k\,\langle\mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a}\rangle_{\mathbf{\Psi}}$ as an operator statement modulo BRST/exact and improvement terms that vanish in physical matrix elements (Lemma 7.552 and Proposition 7.569).

Definition 7.625 (Broken basis, pseudo–NG states and decay constants)**.** Work in the *broken basis* on the band where the mass/mixing ledger (physical Hessian) of Section 7.9 is block–diagonal between (i) light pseudo–NG modes $\{\pi_\beta^{(x)}\}$, $\beta = 1, \dots, N_{\rm br}$, and (ii) heavier modes h. Let $|\pi_\beta^{(x)}(p)\rangle$ be the one–particle pseudo–NG state (relativistic or Lifshitz with $z < \infty$ as appropriate). Define the (band) decay–constant matrix $F^{(x)}$ by the current–pole residue

$$\left\langle \Omega^{(x)} \right| \bar{J}^{(x)\mu}_{a,\rm imp}(0) \left| \pi^{(x)}_\beta(p) \right\rangle = i\, F^{(x)}_{a\beta}\, p^\mu \;+\; \mathcal{O}(p^2), \tag{7.719}$$

and let $m^2_\beta(x)$ denote the pseudo–NG squared masses read from the physical Hessian/mass operator. All objects are evaluated on $\mathcal{H}_{\rm phys}$ and are gauge–parameter independent by Proposition 7.556.

Lemma 7.626 (Band–PCAC on one–particle states)**.** *For each broken index a and pseudo–NG label β,*

$$\left\langle \Omega^{(x)} \right| \Delta^{(x)}_a(0) \left| \pi^{(x)}_\beta(p) \right\rangle = F^{(x)}_{a\beta}\, m^2_\beta(x) \;+\; \mathcal{O}(p^2).$$

Proof. Step 1: Decay constant at band level. By the band–decay definition (eq. (7.719)), the improved band current couples to one–particle pseudo–NG states as

$$\left\langle \Omega^{(x)} \right| \bar{J}^{(x)\mu}_{a,\rm imp}(0) \left| \pi^{(x)}_\beta(p) \right\rangle = i\, F^{(x)}_{a\beta}\, p^\mu \;+\; \mathcal{O}(p^3), \tag{7.720}$$

where the remainder encodes higher–derivative (irrelevant) couplings suppressed at small p. Here $\bar{J}^{(x)\mu}_{a,\rm imp}$ is the cone–preserving, BRST–improved band current (Definition 7.551 and Proposition 7.573), and $|\pi^{(x)}_\beta(p)\rangle$ is normalized in the usual one–particle way.

Step 2: Taking the divergence (PCAC step). Let $\nabla^{(\rm ad)}_\mu$ denote the ad–covariant divergence entering the band Ward identity. Since the UV/IR taggers act by c–number spacetime convolution, they commute with both $\nabla^{(\rm ad)}_\mu$ and the BRST charge ζ ($[\nabla^{(\rm ad)}_\mu, K^{(\ell)}_{\rm IR}] = [\zeta, K^{(\ell)}_{\rm IR}] = 0$ and likewise for P_x; Definition 7.551 and Proposition 7.573). Hence differentiation can be pulled through the descent.

Fourier transforming (7.720) and evaluating at $x = 0$ gives

$$\left\langle \Omega^{(x)} \right| \nabla^{(\rm ad)}_\mu \bar{J}^{(x)\mu}_{a,\rm imp}(0) \left| \pi^{(x)}_\beta(p) \right\rangle = ip_\mu \left\langle \Omega^{(x)} \right| \bar{J}^{(x)\mu}_{a,\rm imp}(0) \left| \pi^{(x)}_\beta(p) \right\rangle = F^{(x)}_{a\beta}\, p^2 \;+\; \mathcal{O}(p^2),$$

where the last estimate uses (7.720): contracting p_μ with the $\mathcal{O}(p^3)$ remainder yields $\mathcal{O}(p^4)$, which we absorb in $\mathcal{O}(p^2)$ once we go on shell.

Step 3: Band–PCAC operator and on–shell reduction. By definition, the band–level PCAC operator is the gauge–invariant, scheme–independent combination

$$\Delta^{(x)}_a \;:=\; \nabla^{(\rm ad)}_\mu \bar{J}^{(x)\mu}_{a,\rm imp} \;+\; \zeta(B^{(x)}_a),$$

with $B^{(x)}_a$ the induced spurion–sector scalar from Corollary 7.564. On the physical Hilbert space $\mathcal{H}_{\rm phys}$, BRST–exact insertions vanish between physical states, so $\left\langle \Omega^{(x)} \right| \zeta(B^{(x)}_a) \left| \pi^{(x)}_\beta(p) \right\rangle = 0$ (Lemma 7.552). Thus

$$\left\langle \Omega^{(x)} \right| \Delta^{(x)}_a(0) \left| \pi^{(x)}_\beta(p) \right\rangle = \left\langle \Omega^{(x)} \right| \nabla^{(\rm ad)}_\mu \bar{J}^{(x)\mu}_{a,\rm imp}(0) \left| \pi^{(x)}_\beta(p) \right\rangle = F^{(x)}_{a\beta}\, p^2 \;+\; \mathcal{O}(p^2).$$

Placing the state on shell, $p^2 = m_\beta^2(x)$, gives

$$\left\langle \Omega^{(x)} \right| \Delta_a^{(x)}(0) \left| \pi_\beta^{(x)}(p) \right\rangle = F_{a\beta}^{(x)}\, m_\beta^2(x) \;+\; \mathcal{O}(p^2).$$

Step 4: Gauge/Nielsen independence. Because all band constructions commute with BRST and internal G actions (Proposition 7.573), and physical matrix elements are taken on $\mathcal{H}_{\mathrm{phys}}$, the result is gauge–parameter independent (Proposition 7.556).

This establishes the lemma. □

Proposition 7.627 (GMOR–type matrix identity on the band)**.** *Let $C_k^{(x)}$ be the* source–overlap *matrices with entries $\left[C_k^{(x)}\right]_{a\beta} := \left\langle \Omega^{(x)} \right| \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \left| \pi_\beta^{(x)} \right\rangle$. Then, to first order in the spurions,*

$$F^{(x)}\, M_\pi^2(x) \;=\; \sum_k \epsilon_k\, C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2), \tag{7.721}$$

where $F^{(x)} = [F_{a\beta}^{(x)}]$, $M_\pi^2(x) = \mathrm{diag}\left(m_\beta^2(x)\right)$ in the pseudo–NG basis, and the $\mathcal{O}(\epsilon^2)$ term collects higher–order spurion effects (operator/state mixing, wave–function renormalization).

Proof. Step 1: Band Ward identity to $\mathcal{O}(\epsilon)$. On the band and on $\mathcal{H}_{\mathrm{phys}}$, the tagged Ward identity takes the form

$$\Delta_a^{(x)} \;:=\; \nabla_\mu^{(\mathrm{ad})}\, \bar{J}_{a,\mathrm{imp}}^{(x)\mu} \;+\; \zeta(B_a^{(x)}) \;=\; \sum_k \epsilon_k\, \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \;+\; \mathcal{O}(\epsilon^2), \tag{7.722}$$

where $\bar{J}_{a,\mathrm{imp}}^{(x)\mu}$ is the BRST–improved band current and $B_a^{(x)}$ the induced scalar from Corollary 7.564. The $\mathcal{O}(\epsilon^2)$ remainder accounts for operator mixing and higher–order deformations under explicit breaking. The UV/IR taggers commute with $\nabla_\mu^{(\mathrm{ad})}$ and with BRST/G (cone–preserving, c–number action), cf. Definition 7.551 and Proposition 7.573.

Step 2: Sandwich the Ward identity between one–particle states. Insert (7.722) between the band vacuum and a normalized one–pion state:

$$\left\langle \Omega^{(x)} \right| \Delta_a^{(x)}(0) \left| \pi_\beta^{(x)}(p) \right\rangle \;=\; \sum_k \epsilon_k \left\langle \Omega^{(x)} \right| \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})}(0) \left| \pi_\beta^{(x)}(p) \right\rangle \;+\; \mathcal{O}(\epsilon^2). \tag{7.723}$$

By BRST–exactness on $\mathcal{H}_{\mathrm{phys}}$, $\langle \Omega^{(x)} | \zeta(\cdot) | \pi_\beta^{(x)} \rangle = 0$ (Lemma 7.552), so the improvement term in $\Delta_a^{(x)}$ does not contribute.

Step 3: PCAC reduction on the left-hand side. By the band–PCAC lemma Lemma 7.626,

$$\left\langle \Omega^{(x)} \right| \Delta_a^{(x)}(0) \left| \pi_\beta^{(x)}(p) \right\rangle = F_{a\beta}^{(x)}\, m_\beta^2(x) \;+\; \mathcal{O}(p^2).$$

Evaluating on shell ($p^2 = m_\beta^2(x)$) collapses the $\mathcal{O}(p^2)$ remainder to higher–order derivative corrections, which are absorbed into the stated $\mathcal{O}(\epsilon^2)$ once the expansion in explicit breakings is organized at fixed $x \in \mathfrak{P}$ (the pole dominance of the one–particle contribution is ensured by the cone–preserving taggers and the certified window).

Step 4: Identify the source–overlap matrix on the right-hand side. Define $[C_k^{(x)}]_{a\beta} := \langle \Omega^{(x)} | \, \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \, | \pi_\beta^{(x)} \rangle$ as in the statement. Then (7.723) reads, componentwise in (a, β),

$$F_{a\beta}^{(x)} \, m_\beta^2(x) \;=\; \sum_k \epsilon_k \left[C_k^{(x)} \right]_{a\beta} \;+\; \mathcal{O}(\epsilon^2).$$

Collecting the entries over a and β yields the matrix identity

$$F^{(x)} \, M_\pi^2(x) \;=\; \sum_k \epsilon_k \, C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2),$$

after choosing the pseudo–NG basis that diagonalizes the one–particle mass matrix, $M_\pi^2(x) = \mathrm{diag}(m_\beta^2(x))$ (existence and analytic labeling along x follow from Lemma 7.619 and Proposition 7.620).

Step 5: Remarks on higher orders and gauge/BRST safety. Corrections of order ϵ^2 arise from: (i) second–order operator mixing in the Ward operator, (ii) spurion–induced state deformations beyond the one–pole approximation, and (iii) wave–function/mass renormalization beyond linear order. All such contributions are uniformly controlled on certified plateaus and are gathered in $\mathcal{O}(\epsilon^2)$. Since the taggers commute with BRST/G and matrix elements are taken on $\mathcal{H}_{\mathrm{phys}}$, the identity is gauge–parameter independent (Nielsen–stable) by Proposition 7.556.

The proposition follows. □

Corollary 7.628 (Diagonal (single–mode) GMOR relation; linear spurion scaling)**.** *In a basis where $F^{(x)}$ is diagonal at $\epsilon = 0$ (or after projecting onto a single pseudo–NG mode b), we have*

$$\boxed{ f_{\pi_b}^2(x) \, m_{\pi_b}^2(x) \;=\; \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\boldsymbol{\Psi}} \;+\; \mathcal{O}(\epsilon^2) } \tag{7.724}$$

with $f_{\pi_b}(x) := F_{bb}^{(x)} + O(\epsilon)$. Consequently, on any certified plateau $\mathfrak{P}$, $m_{\pi_b}^2(x) = \alpha_b^{(x)} \cdot \epsilon + \mathcal{O}(\epsilon^2)$ (linear in spurions), uniformly in $x \in \mathfrak{P}$.

Proof. Step 1: Extract the b–mode from the matrix GMOR. From Proposition 7.627,

$$F^{(x)} \, M_\pi^2(x) \;=\; \sum_k \epsilon_k \, C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2), \qquad [C_k^{(x)}]_{a\beta} = \left\langle \Omega^{(x)} \right| \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \left| \pi_\beta^{(x)} \right\rangle.$$

Project onto the broken direction b (or choose a basis where $F^{(x)}$ is diagonal at $\epsilon = 0$):

$$F_{bb}^{(x)} \, m_{\pi_b}^2(x) \;=\; \sum_k \epsilon_k \left[C_k^{(x)} \right]_{bb} \;+\; \mathcal{O}(\epsilon^2). \tag{7.725}$$

Define $f_{\pi_b}(x) := F_{bb}^{(x)} + O(\epsilon)$; analyticity of spectral data (Lemma 7.619 and Proposition 7.620) implies $f_{\pi_b}(x)$ depends smoothly on ϵ on $\mathfrak{P}$.

Step 2: LSZ/PCAC reduction of the vacuum–pion matrix element. For the b–channel, the soft–pion (PCAC) reduction on the band gives, at small momentum and to leading order,

$$\left\langle \Omega^{(x)} \right| \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})}(0) \left| \pi_b^{(x)}(p) \right\rangle \;=\; f_{\pi_b}(x) \left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\boldsymbol{\Psi}} \;+\; \mathcal{O}(p^2) \;+\; \mathcal{O}(\epsilon). \tag{7.726}$$

Indeed, the usual LSZ/PCAC commutator reduction (soft–theorem) yields $\langle\Omega|\mathcal{S}_{k,b}|\pi_b\rangle = \frac{i}{f_{\pi_b}}\langle\Omega|[Q_b,\mathcal{S}_{k,b}]|\Omega\rangle + O(m^2_{\pi_b})$; in the band construction the broken–channel commutator reproduces (up to fixed conventions absorbed in $\mathcal{S}_{k,b}$) the order–parameter insertion, i.e. the vacuum expectation $\langle\mathcal{S}_{k,b}\rangle_{\mathbf{\Psi}}$, with BRST–/improvement pieces dropping out on $\mathcal{H}_{\rm phys}$ (Lemma 7.552 and Proposition 7.556) and cone–preserving taggers ensuring single–pole dominance (Propositions 7.573 and 7.612). Evaluated on shell ($p^2 = m^2_{\pi_b}(x)$), the $\mathcal{O}(p^2)$ term is subleading and can be absorbed into $\mathcal{O}(\epsilon^2)$ once (7.725) is used.

Thus, to the accuracy of (7.725),

$$\left[C_k^{(x)}\right]_{bb} \;=\; \left\langle \Omega^{(x)}\right|\mathcal{S}_{k,b}^{(\lambda_{\rm UV})}\left|\pi_b^{(x)}\right\rangle \;=\; f_{\pi_b}(x)\left\langle \mathcal{S}_{k,b}^{(\lambda_{\rm UV})}\right\rangle_{\mathbf{\Psi}} \;+\; \mathcal{O}(\epsilon).$$

Step 3: Conclude the scalar GMOR and linear scaling. Insert the last expression into (7.725):

$$f_{\pi_b}(x)\, m^2_{\pi_b}(x) \;=\; \sum_k \epsilon_k\, f_{\pi_b}(x)\left\langle \mathcal{S}_{k,b}^{(\lambda_{\rm UV})}\right\rangle_{\mathbf{\Psi}} \;+\; \mathcal{O}(\epsilon^2).$$

Cancel $f_{\pi_b}(x)$ (nonzero on certified $\mathfrak{P}$), obtaining the boxed relation (7.724). Since $f_{\pi_b}(x) = F^{(x)}_{bb} + O(\epsilon)$ and $\langle\mathcal{S}^{(\lambda_{\rm UV})}_{k,b}\rangle_{\mathbf{\Psi}}$ are ϵ–smooth and uniformly bounded on $\mathfrak{P}$, the right–hand side is *linear* in ϵ up to $\mathcal{O}(\epsilon^2)$. Therefore

$$m^2_{\pi_b}(x) \;=\; \sum_k \alpha^{(x)}_{b,k}\,\epsilon_k \;+\; \mathcal{O}(\epsilon^2), \qquad \alpha^{(x)}_{b,k} \;:=\; \left.\frac{\left\langle \mathcal{S}_{k,b}^{(\lambda_{\rm UV})}\right\rangle_{\mathbf{\Psi}}}{f^2_{\pi_b}(x)}\right|_{\epsilon=0},$$

with the coefficients continuous in x; plateau compactness and the mask floors imply uniformity on $\mathfrak{P}$.

Gauge/BRST robustness. All ingredients are constructed on $\mathcal{H}_{\rm phys}$; taggers commute with BRST/G (Proposition 7.573), and Nielsen–independence of spectral/PCAC data holds (Proposition 7.556). Thus (7.724) and the linear scaling are gauge–parameter independent and BRST–safe.

The corollary follows. □

Proposition 7.629 (Band–Hessian ↔ Ward–source consistency)**.** *Let $\mathbb{H}^{(\lambda_{\rm UV},\ell)}$ be the band Hessian (mass/mixing ledger) of Section 7.9, projected to the pseudo–NG subspace to give $M^2_\pi(x)$. Then (7.721) is equivalent to matching the* linear *spurion block of $\mathbb{H}^{(\lambda_{\rm UV},\ell)}$ against the right–hand side of eq. (7.665):*

$$F^{(x)}\left(M^2_{\pi,0}(x) + \sum_k \epsilon_k\,\delta M^2_{\pi,k}(x)\right) = \sum_k \epsilon_k\, C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2),$$

with $M^2_{\pi,0}(x) = 0$ in the exact–symmetry limit, so $M^2_\pi(x) = \sum_k \epsilon_k\,\delta M^2_{\pi,k}(x) + \mathcal{O}(\epsilon^2)$. Hence $\delta M^2_{\pi,k}(x)$ extracted from the ledger must equal $F^{(x)-1}C_k^{(x)}$ to leading order.

Proof. Step 1: Ledger decomposition and projection to the pseudo–NG subspace. Fix $x \in \mathfrak{P}$. Write the (band) Hessian on the relevant sector as an analytic perturbation in the spurions:

$$\mathbb{H}(\epsilon) \;:=\; \mathbb{H}_0 \;+\; \sum_k \epsilon_k\,\delta\mathbb{H}_k \;+\; \mathcal{O}(\epsilon^2),$$

where $\mathbb{H}_0$ has an r–dimensional *Goldstone* kernel (exact symmetry), and $\delta\mathbb{H}_k$ are the linear spurion insertions (all objects are those of Section 7.9). Let $\mathsf{P}(\epsilon)$ be the Riesz projector onto the pseudo–NG cluster (near 0) and $\mathcal{E}(\epsilon) = \operatorname{Ran}\mathsf{P}(\epsilon)$ the corresponding subspace. By Lemma 7.619 and Proposition 7.620, both $\mathsf{P}(\epsilon)$ and analytic frames of $\mathcal{E}(\epsilon)$ are real–analytic in ϵ.

Define the compressed (projected) mass/mixing matrix

$$M_\pi^2(\epsilon) \;:=\; \Big(\mathsf{P}(\epsilon)\,\mathbb{H}(\epsilon)\,\mathsf{P}(\epsilon)\Big)\Big|_{\mathcal{E}(\epsilon)}.$$

At $\epsilon = 0$, $M_{\pi,0}^2 := M_\pi^2(0) = 0$ because $\mathbb{H}_0$ vanishes on the Goldstone subspace.

Step 2: First–order variation in Kato gauge. Differentiate $M_\pi^2(\epsilon)$ at $\epsilon = 0$ along the k–th spurion. Using $\frac{d}{d\epsilon_k}\big(\mathsf{P}\,\mathbb{H}\,\mathsf{P}\big) = (\partial_k\mathsf{P})\,\mathbb{H}\,\mathsf{P} + \mathsf{P}\,(\partial_k\mathbb{H})\,\mathsf{P} + \mathsf{P}\,\mathbb{H}\,(\partial_k\mathsf{P})$, and the identities for projectors (Kato calculus) $\mathsf{P}_0\,\dot{\mathsf{P}}_0\,\mathsf{P}_0 = 0$ with $\mathsf{P}_0 := \mathsf{P}(0)$, plus $\mathbb{H}_0\,\mathsf{P}_0 = 0 = \mathsf{P}_0\,\mathbb{H}_0$ on the Goldstone space, we obtain

$$\delta M_{\pi,k}^2 \;:=\; \partial_{\epsilon_k} M_\pi^2(\epsilon)\Big|_{\epsilon=0} \;=\; \mathsf{P}_0\,\delta\mathbb{H}_k\,\mathsf{P}_0 \quad \text{on} \quad \mathcal{E}(0). \tag{7.727}$$

In an analytically transported orthonormal basis $\{|\pi_\beta^{(x)}\rangle\}_{\beta=1}^r$ of $\mathcal{E}(0)$ (Kato parallel transport, Proposition 7.620), (7.727) reads componentwise

$$\Big[\delta M_{\pi,k}^2(x)\Big]_{\beta\beta'} \;=\; \Big\langle \pi_\beta^{(x)}\Big|\,\delta\mathbb{H}_k\,\Big|\pi_{\beta'}^{(x)}\Big\rangle.$$

Therefore, to linear order,

$$M_\pi^2(x) \;=\; \sum_k \epsilon_k\,\delta M_{\pi,k}^2(x) \;+\; \mathcal{O}(\epsilon^2), \qquad M_{\pi,0}^2(x) = 0. \tag{7.728}$$

Step 3: Ward identity matrix elements (GMOR) and identification. On the other hand, by the band Ward identity and PCAC reduction, Proposition 7.627 and Lemma 7.626 give the GMOR–type matrix relation

$$F^{(x)}\,M_\pi^2(x) \;=\; \sum_k \epsilon_k\,C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2), \tag{7.729}$$

with $F^{(x)} = [F_{a\beta}^{(x)}]$ and $[C_k^{(x)}]_{a\beta} = \langle\Omega^{(x)}|\,\mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})}\,|\pi_\beta^{(x)}\rangle$.

Insert the linear decomposition (7.728) into (7.729):

$$F^{(x)}\sum_k \epsilon_k\,\delta M_{\pi,k}^2(x) \;=\; \sum_k \epsilon_k\,C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2).$$

By linear independence of the $\{\epsilon_k\}$, the $\mathcal{O}(\epsilon)$ coefficients must match *for each* k:

$$F^{(x)}\,\delta M_{\pi,k}^2(x) \;=\; C_k^{(x)} \qquad\Longleftrightarrow\qquad \delta M_{\pi,k}^2(x) \;=\; F^{(x)-1}\,C_k^{(x)}. \tag{7.730}$$

Thus the *linear spurion block* of the ledger, when projected to the pseudo–NG subspace, equals $F^{(x)-1}C_k^{(x)}$.

Step 4: Equivalence in both directions. ($\Rightarrow$) If the ledger's linear block satisfies (7.730), then summing over k gives $M_\pi^2(x) = \sum_k \epsilon_k F^{(x)-1} C_k^{(x)} + \mathcal{O}(\epsilon^2)$ and hence (7.729). ($\Leftarrow$) Conversely, if (7.729) holds for all small spurions, differentiation with respect to ϵ_k at $\epsilon = 0$ forces (7.730), hence (7.727) identifies the ledger's linear block with $F^{(x)-1} C_k^{(x)}$.

Step 5: Gauge/BRST robustness and plateau uniformity. All constructions are on $\mathcal{H}_{\text{phys}}$; the UV/IR taggers commute with BRST/G and preserve cones (Propositions 7.573 and 7.612), while spectral data and Riesz projectors are gauge–parameter independent (Proposition 7.644). The analytic subspace tracking guarantees smooth x–dependence (Lemma 7.619 and Proposition 7.620); certified–plateau bounds ensure the identifications are uniform on $\mathfrak{P}$.

Combining Steps 1–5 proves the proposition. □

Theorem 7.630 (Ward–mass link on certified plateaus (GMOR control))**.** *Assume QIV hypotheses, Stage–I BRST gate, and a certified plateau $\mathfrak{P}$. Then the pseudo–NG masses satisfy, uniformly on $\mathfrak{P}$,*

$$M_\pi^2(x) \;=\; \sum_k \epsilon_k \, F^{(x)-1} C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2),$$

and, in the single–mode projection b, the scalar GMOR relation (7.724). In particular, $m_{\pi_b}^2(x)$ scales linearly *with the spurions $\{\epsilon_k\}$ up to $\mathcal{O}(\epsilon^2)$, with coefficients that are BRST/Nielsen safe and vary at most by the plateau tolerance $\eta_{\mathfrak{P}}$.*

Proof. Step 1: Matrix GMOR and ledger linearization. On the band and on $\mathcal{H}_{\text{phys}}$, the Ward/PCAC analysis yields the matrix GMOR relation

$$F^{(x)} \, M_\pi^2(x) \;=\; \sum_k \epsilon_k \, C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2), \tag{7.731}$$

(Proposition 7.627). Independently, projecting the band Hessian (mass/mixing ledger) to the pseudo–NG subspace and expanding to first order in spurions gives

$$M_\pi^2(x) \;=\; \sum_k \epsilon_k \, \delta M_{\pi,k}^2(x) + \mathcal{O}(\epsilon^2), \qquad \delta M_{\pi,k}^2(x) \;=\; F^{(x)-1} C_k^{(x)} \quad \text{(componentwise)}, \tag{7.732}$$

(Proposition 7.629).

Step 2: Invertibility and uniform conditioning of $F^{(x)}$. The matrix $F^{(x)} = [F_{a\beta}^{(x)}]$ collects current–to–pseudo–NG residues (band decay constants). On a certified plateau, the IR taggers have a strictly positive kernel floor and the T–odd channel carries a nonzero spectral weight (Lemma 7.575, Proposition 7.602, and Corollary 7.677); thus each broken current couples to the corresponding pseudo–NG sector with strictly positive residue. Consequently

$$\sigma_{\min}\!\left(F^{(x)}\right) \;\geq\; f_\star \;>\; 0, \qquad \|F^{(x)}\| \;\leq\; f^\star \;<\; \infty \qquad (x \in \mathfrak{P}),$$

for plateau–uniform constants $f_\star, f^\star$ (compactness of $\mathfrak{P}$ and analyticity of spectral data; see Lemma 7.619 and Proposition 7.620). Hence $F^{(x)}$ is invertible with $\|F^{(x)-1}\| \leq f_\star^{-1}$ uniformly on $\mathfrak{P}$.

Step 3: Ward–mass link and uniform $\mathcal{O}(\epsilon^2)$ control. Left–multiplying (7.731) by $F^{(x)-1}$ and using Step 2,

$$M_\pi^2(x) \;=\; \sum_k \epsilon_k\, F^{(x)-1} C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2),$$

with the $\mathcal{O}(\epsilon^2)$ remainder bounded uniformly on $\mathfrak{P}$ (all ingredients are uniformly bounded and analytic, and $\|F^{(x)-1}\|$ is uniformly controlled). This proves the first claim.

Step 4: Single–mode projection and scalar GMOR. Projecting onto a single mode b (or working in a basis in which $F^{(x)}$ is diagonal at $\epsilon = 0$) reduces the matrix identity to

$$f_{\pi_b}(x)\, m_{\pi_b}^2(x) \;=\; \sum_k \epsilon_k \left\langle \Omega^{(x)} \middle| \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \middle| \pi_b^{(x)} \right\rangle \;+\; \mathcal{O}(\epsilon^2).$$

Using the standard LSZ/PCAC reduction on the band to replace the one–pion matrix element by the order–parameter expectation in the b–channel (up to $\mathcal{O}(\epsilon)$; see Corollary 7.628), we obtain the scalar GMOR formula

$$f_{\pi_b}^2(x)\, m_{\pi_b}^2(x) \;=\; \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} \;+\; \mathcal{O}(\epsilon^2),$$

with $f_{\pi_b}(x) = F_{bb}^{(x)} + O(\epsilon)$.

Step 5: Linear scaling and plateau uniformization. From the displayed relations,

$$m_{\pi_b}^2(x) \;=\; \sum_k \alpha_{b,k}^{(x)}\, \epsilon_k \;+\; \mathcal{O}(\epsilon^2), \qquad \alpha_{b,k}^{(x)} \;:=\; \left. \frac{\left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}}}{f_{\pi_b}^2(x)} \right|_{\epsilon=0}.$$

The coefficients $\alpha_{b,k}^{(x)}$ are continuous (real–analytic) functions of x on $\mathfrak{P}$ by Lemma 7.619 and Proposition 7.620; the certified–plateau oscillation bound then implies that their variation across $\mathfrak{P}$ is at most $O(\eta_{\mathfrak{P}})$ (Lemma 7.579). Thus the linear scaling holds uniformly on $\mathfrak{P}$ with coefficients stable to within the plateau tolerance.

Step 6: BRST/Nielsen safety. All quantities are constructed from band–descended, cone–preserving taggers that commute with BRST and the G–action (Proposition 7.573); physical matrix elements are taken on $\mathcal{H}_{\mathrm{phys}}$, and spectral objects are gauge–parameter independent (Proposition 7.556 and Lemma 7.552). Hence the coefficients and statements above are BRST/Nielsen safe.

Combining the steps proves the theorem. □

Corollary 7.631 (Operational GMOR fit on the band)**.** *Fix a broken direction b and vary a single spurion ϵ_j on a certified plateau. Then*

$$m_{\pi_b}^2(x) \;=\; \alpha_{bj}^{(x)}\, \epsilon_j \;+\; o(\epsilon_j), \qquad \alpha_{bj}^{(x)} = \frac{1}{f_{\pi_b}^2(x)} \left\langle \mathcal{S}_{j,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}}.$$

A log–log or linear fit in ϵ_j on the plateau recovers slope 1 (within tolerance), and the intercept vanishes within the statistical/systematic budget; deviations indicate either plateau failure or higher–order spurion effects.

Proof. Step 1: Linearization from the matrix Ward–mass link. By Theorem 7.630,

$$M_\pi^2(x) \;=\; \sum_k \epsilon_k\, F^{(x)-1} C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2).$$

Project onto the single pseudo–NG mode b:

$$m_{\pi_b}^2(x) \;=\; \sum_k \epsilon_k \left[e_b^\top F^{(x)-1} C_k^{(x)} e_b\right] \;+\; \mathcal{O}(\epsilon^2),$$

with e_b the unit vector in the b–channel. Holding all spurions fixed except ϵ_j gives

$$m_{\pi_b}^2(x) \;=\; \underbrace{e_b^\top F^{(x)-1} C_j^{(x)} e_b}_{\alpha_{bj}^{(x)}}\, \epsilon_j \;+\; \mathcal{O}(\epsilon_j^2). \tag{7.733}$$

Step 2: Identify $\alpha_{bj}^{(x)}$ via the scalar GMOR. From the diagonal (single–mode) GMOR relation Corollary 7.628,

$$f_{\pi_b}^2(x)\, m_{\pi_b}^2(x) \;=\; \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} \;+\; \mathcal{O}(\epsilon^2).$$

Varying only ϵ_j and comparing with (7.733) yields

$$f_{\pi_b}^2(x)\, \alpha_{bj}^{(x)} \;=\; \left\langle \mathcal{S}_{j,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}}, \qquad \text{i.e.} \quad \alpha_{bj}^{(x)} \;=\; \frac{1}{f_{\pi_b}^2(x)} \left\langle \mathcal{S}_{j,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}}.$$

Analyticity of spectral/projector data on certified plateaus (Lemma 7.619 and Proposition 7.620) implies that $f_{\pi_b}(x)$ and the vacuum expectation on the right are smooth in x; hence the identification is uniform on $\mathfrak{P}$.

Step 3: Little–o control and plateau uniformity. Since the remainder in (7.733) is $\mathcal{O}(\epsilon_j^2)$ and coefficients vary at most by the plateau oscillation $\eta_{\mathfrak{P}}$ (Lemma 7.579), we can write

$$m_{\pi_b}^2(x) \;=\; \alpha_{bj}^{(x)}\, \epsilon_j \;+\; o(\epsilon_j) \qquad (\epsilon_j \to 0),$$

uniformly in $x \in \mathfrak{P}$.

Step 4: Consequences for operational fits. Linear fit: Regress $m_{\pi_b}^2(x)$ against ϵ_j on the plateau. From the exact–symmetry limit, $m_{\pi_b}^2(x)\big|_{\epsilon=0} = 0$, so the true intercept is 0; the fitted intercept is therefore bounded by the systematic/statistical budget ($O(\eta_{\mathfrak{P}})$ plus sampling noise), while the fitted slope converges to $\alpha_{bj}^{(x)}$ up to $o(1)$ as the maximal ϵ_j in the window shrinks.

Log–log fit: For $\epsilon_j > 0$,

$$\log m_{\pi_b}^2(x) \;=\; \log \alpha_{bj}^{(x)} \;+\; \log \epsilon_j \;+\; \log\bigl(1 + o(1)\bigr),$$

so the log–log slope tends to 1 with an $o(1)$ deviation controlled by the window size in ϵ_j; the vertical offset estimates $\log \alpha_{bj}^{(x)}$ (plateau–uniformly up to $O(\eta_{\mathfrak{P}})$).

Step 5: Robustness (BRST/Nielsen). All objects are band–descended and computed on $\mathcal{H}_{\mathrm{phys}}$; the taggers commute with BRST/G, and spectral data are gauge–parameter independent (Propositions 7.556 and 7.573 and Lemma 7.552). Hence the coefficients $\alpha_{bj}^{(x)}$ are BRST/Nielsen safe.

Therefore the stated expansion and operational fitting statements hold; significant deviations indicate either (i) plateau failure (violating the certification/oscillation bounds) or (ii) visible higher–order spurion effects beyond the linear window. □

7.9.12 Multi–spurion GMOR Fits and PCAC/LSZ Bandwidth on the Plateau

Context. On $\mathfrak{P}$ the matrix GMOR identity holds (linear in the spurions) *on the physical sector*:

$$F^{(x)}\, M_\pi^2(x;\epsilon) \;=\; \sum_k \epsilon_k\, C_k^{(x)} \;+\; \mathcal{O}(\epsilon^2), \qquad x \in \mathfrak{P}, \tag{7.734}$$

with $F^{(x)}$ the (positive definite) decay–constant matrix, M_π^2 the pNG mass matrix, and $C_k^{(x)}$ the Ward–source matrices defined in Propositions 7.627 and 7.629 and Corollary 7.628. Gauge–parameter independence holds by Proposition 7.644, and type–(A) analyticity by Proposition 7.642.

Definition 7.632 (Multi–spurion linear model and design)**.** Fix $x \in \mathfrak{P}$ and perform N runs with spurion vectors $\epsilon^{(n)} = (\epsilon_1^{(n)}, \dots, \epsilon_K^{(n)})$, $n = 1, \dots, N$, all within the linear regime. For each run, measure $Y^{(n)} := F^{(x)} M_\pi^2(x;\epsilon^{(n)})$ and (optionally) symmetrize it if M_π^2 is symmetric in the chosen basis.

Let $\operatorname{svec}(\cdot)$ denote half–vectorization of symmetric matrices and $p := B(B{+}1)/2$ the length (with B the number of broken directions). Define

$$\mathbf{y}^{(n)} := \operatorname{svec} Y^{(n)} \in \mathbb{R}^p, \qquad \mathbf{c}_k := \operatorname{svec} C_k^{(x)} \in \mathbb{R}^p.$$

Stack $\mathbf{y}^{(n)}$ into $\mathbf{y} \in \mathbb{R}^{Np}$ and form the block design matrix

$$\mathbf{X} \;:=\; \begin{bmatrix} \epsilon_1^{(1)}\mathbb{I}_p & \cdots & \epsilon_K^{(1)}\mathbb{I}_p \\ \vdots & \ddots & \vdots \\ \epsilon_1^{(N)}\mathbb{I}_p & \cdots & \epsilon_K^{(N)}\mathbb{I}_p \end{bmatrix} \in \mathbb{R}^{Np \times Kp}, \qquad \mathbf{c} \;:=\; \begin{bmatrix} \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_K \end{bmatrix} \in \mathbb{R}^{Kp}.$$

Then (7.734) becomes the linear model

$$\mathbf{y} \;=\; \mathbf{X}\,\mathbf{c} \;+\; \mathbf{r}, \qquad \|\mathbf{r}\| = \mathcal{O}(\|\epsilon\|^2). \tag{7.735}$$

Proposition 7.633 (Constrained weighted least squares; intercept–free)**.** *Let* $\mathbf{W} = \operatorname{diag}(w_1\mathbb{I}_p, \dots, w_N\mathbb{I}_p)$ *be a positive weight matrix (inverse variances of* $\operatorname{svec} Y^{(n)}$*). The GMOR estimate of the source tensors is*

$$\widehat{\mathbf{c}} \;:=\; \arg\min_{\mathbf{c}} \; \big\|\mathbf{W}^{1/2}\big(\mathbf{y} - \mathbf{X}\mathbf{c}\big)\big\|_2^2,$$

with no intercept (the $\epsilon = 0$ *datum is* $\mathbf{y}^{(0)} = \mathbf{0}$ *on* $\mathcal{H}_{\mathrm{phys}}$*, within* $\eta_{\mathfrak{P}}$*). If* $\mathbf{X}$ *has full column rank, then*

$$\widehat{\mathbf{c}} = (\mathbf{X}^\top \mathbf{W}\, \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W}\, \mathbf{y},$$

and the normal–equation residual is

$$\mathbf{r}_{\mathrm{WLS}} \;:=\; \mathbf{y} - \mathbf{X}\widehat{\mathbf{c}}, \qquad \mathcal{R}_{\mathrm{GMOR}}(x) \;:=\; \frac{\big\|\mathbf{W}^{1/2}\mathbf{r}_{\mathrm{WLS}}\big\|_2}{\sqrt{Np}\,\eta_{\mathfrak{P}}}.$$

Proof. Step 1: Linear GMOR model and stacking. From the matrix GMOR relation (Proposition 7.627 and Theorem 7.630), for each experiment $n = 1, \dots, N$ with spurion vector $\epsilon^{(n)} = (\epsilon_1^{(n)}, \dots, \epsilon_K^{(n)})$ we have, up to $\mathcal{O}(\epsilon^2)$,

$$Y^{(n)} \;:=\; F^{(x)} M_\pi^2(x; \epsilon^{(n)}) \;=\; \sum_{k=1}^{K} \epsilon_k^{(n)}\, C_k^{(x)} \;+\; \mathrm{noise}_{(n)},$$

in the p–dimensional readout (e.g. p is the length of svec). Vectorize with $\mathbf{y}^{(n)} := \operatorname{svec} Y^{(n)} \in \mathbb{R}^p$ and $\mathbf{c}_k := \operatorname{svec} C_k^{(x)} \in \mathbb{R}^p$. Then

$$\mathbf{y}^{(n)} \;=\; \begin{pmatrix} \epsilon_1^{(n)}\mathbb{I}_p & \cdots & \epsilon_K^{(n)}\mathbb{I}_p \end{pmatrix} \begin{bmatrix} \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_K \end{bmatrix} + \boldsymbol{\eta}^{(n)} \;=:\; \mathbf{X}^{(n)}\mathbf{c} + \boldsymbol{\eta}^{(n)}.$$

Stacking over n gives $\mathbf{y} := \left(\mathbf{y}^{(1)}; \dots; \mathbf{y}^{(N)}\right) \in \mathbb{R}^{Np}$, $\mathbf{X} := \operatorname{blkrow}(\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N)}) \in \mathbb{R}^{Np \times Kp}$, and $\mathbf{c} := (\mathbf{c}_1; \dots; \mathbf{c}_K) \in \mathbb{R}^{Kp}$:

$$\mathbf{y} \;=\; \mathbf{X}\,\mathbf{c} \;+\; \boldsymbol{\eta}.$$

Step 2: Intercept–free constraint from physics. At $\epsilon = 0$ the exact–symmetry limit yields $M_\pi^2 = 0$ on $\mathcal{H}_{\text{phys}}$; hence $Y^{(0)} = 0$ and $\mathbf{y}^{(0)} = \mathbf{0}$ within the plateau tolerance $\eta_{\text{Ψ}}$ (Definition 6.300 and Corollary 7.628). Therefore no intercept term is allowed: adding an intercept column $\mathbf{1} \otimes \mathbb{I}_p$ would impose a coefficient constrained to 0 by physics. Equivalently, the constrained problem (intercept fixed to 0) reduces to the unconstrained WLS in $\mathbf{c}$ as stated.

Step 3: WLS normal equations and closed form. Define the weighted loss $L(\mathbf{c}) := \left\| \mathbf{W}^{1/2}(\mathbf{y} - \mathbf{X}\mathbf{c}) \right\|_2^2$, with $\mathbf{W} = \operatorname{diag}(w_1\mathbb{I}_p, \dots, w_N\mathbb{I}_p) \succ 0$ (inverse variances per experiment). The gradient is

$$\nabla L(\mathbf{c}) \;=\; -2\,\mathbf{X}^\top \mathbf{W}\,(\mathbf{y} - \mathbf{X}\mathbf{c}).$$

Setting $\nabla L(\widehat{\mathbf{c}}) = 0$ gives the *normal equations*

$$\mathbf{X}^\top \mathbf{W}\,\mathbf{X}\,\widehat{\mathbf{c}} \;=\; \mathbf{X}^\top \mathbf{W}\,\mathbf{y}.$$

If $\mathbf{X}$ has full column rank, $\mathbf{X}^\top\mathbf{W}\,\mathbf{X}$ is invertible and $\widehat{\mathbf{c}} = (\mathbf{X}^\top\mathbf{W}\,\mathbf{X})^{-1}\mathbf{X}^\top\mathbf{W}\,\mathbf{y}$. Equivalently, *whitening* with $\widetilde{\mathbf{X}} := \mathbf{W}^{1/2}\mathbf{X}$, $\widetilde{\mathbf{y}} := \mathbf{W}^{1/2}\mathbf{y}$ reduces the problem to ordinary least squares, whose solution is unique under $\operatorname{rank}(\widetilde{\mathbf{X}}) = \operatorname{rank}(\mathbf{X}) = Kp$.

Step 4: Residual orthogonality and expression. The WLS residual is $\mathbf{r}_{\text{WLS}} := \mathbf{y} - \mathbf{X}\widehat{\mathbf{c}}$. By the normal equations,

$$\mathbf{X}^\top \mathbf{W}\,\mathbf{r}_{\text{WLS}} \;=\; \mathbf{0},$$

i.e. $\mathbf{r}_{\text{WLS}}$ is $\mathbf{W}$–orthogonal to the column space of $\mathbf{X}$. In whitened coordinates, $\widetilde{\mathbf{r}} = \widetilde{\mathbf{y}} - \widetilde{\mathbf{X}}\widehat{\mathbf{c}}$ satisfies $\widetilde{\mathbf{X}}^\top\widetilde{\mathbf{r}} = 0$ and $\|\mathbf{W}^{1/2}\mathbf{r}_{\text{WLS}}\|_2 = \|\widetilde{\mathbf{r}}\|_2$.

Step 5: Plateau–normalized misfit. Define the dimensionless misfit

$$\mathcal{R}_{\text{GMOR}}(x) \;:=\; \frac{\|\mathbf{W}^{1/2}\mathbf{r}_{\text{WLS}}\|_2}{\sqrt{Np}\,\eta_{\text{Ψ}}}.$$

If each component residual in experiment n satisfies the plateau envelope in its natural (weighted) units, $\|\mathbf{W}_n^{1/2}\mathbf{r}^{(n)}\|_2 \le \sqrt{p}\,\eta_{\mathfrak{P}}$ with $\mathbf{W}_n = w_n\mathbb{I}_p$, then

$$\|\mathbf{W}^{1/2}\mathbf{r}_{\mathrm{WLS}}\|_2^2 = \sum_{n=1}^{N} \|\mathbf{W}_n^{1/2}\mathbf{r}^{(n)}\|_2^2 \;\le\; Np\,\eta_{\mathfrak{P}}^2,$$

so $\mathcal{R}_{\mathrm{GMOR}}(x) \le 1$. Thus the normalization compares the weighted misfit directly to the certified plateau tolerance budget.

Step 6: Rank–deficient remark (completeness). If $\mathbf{X}$ is not full column rank, the minimizer exists but is not unique; the minimum–norm solution is $\widehat{\mathbf{c}} = \mathbf{X}_{\mathbf{W}}^{\dagger}\,\mathbf{y}$ with the $\mathbf{W}$–weighted Moore–Penrose pseudoinverse $\mathbf{X}_{\mathbf{W}}^{\dagger} := (\mathbf{X}^{\top}\mathbf{W}\,\mathbf{X})^{\dagger}\mathbf{X}^{\top}\mathbf{W}$. In practice, identifiability requires sufficiently rich spurion variations so that $\mathrm{rank}(\mathbf{X}) = Kp$.

All claims follow. □

Definition 7.634 (Acceptance and conditioning)**.** We *accept* the multi–spurion GMOR fit at $x \in \mathfrak{P}$ if

$$\mathcal{R}_{\mathrm{GMOR}}(x) \;\le\; 1 \quad \text{and} \quad \kappa\Big(\mathbf{X}^{\top}\mathbf{W}\,\mathbf{X}\Big) \;\le\; \kappa_{\max},$$

for a fixed conditioning threshold $\kappa_{\max}$ (documented with the mask). Otherwise we (i) shrink the ϵ–window or (ii) redesign the spurion directions to improve rank/conditioning. Gauge–parameter flatness of $\widehat{\mathbf{c}}$ follows from Proposition 7.644.

Remark 7.635 (Single–spurion slice equals the one–line fit)**.** For a single active spurion component ϵ_j and a Kato–labeled branch b, (7.735) reduces to the constrained one–line fit of Definition 7.623, with slope $\alpha_{bj}^{(x)}$ and intercept bounded by $\eta_{\mathfrak{P}}$.

Definition 7.636 (PCAC/LSZ test function and bandwidth schedule)**.** Let $\phi \in C_c^{\infty}([-1,1])$ be an even, nonnegative bump with $\int_{-1}^{1}\phi(u)\,du = 1$ (e.g. $\phi(u) = c\exp\!\Big(-\frac{1}{1-u^2}\Big)\mathbf{1}_{|u|<1}$). For a bandwidth $\omega_0 > 0$, define the *mollifier*

$$\chi_{\omega_0}(\omega) \;:=\; \frac{1}{\omega_0}\,\phi\!\left(\frac{\omega}{\omega_0}\right), \qquad \operatorname{supp}\chi_{\omega_0} \subset [-\omega_0,\omega_0], \quad \int \chi_{\omega_0} = 1.$$

At a band point $x \in \mathfrak{P}$ set the bandwidth by

$$\omega_0(x) \;:=\; \theta\;\min\Big\{\;\tfrac{1}{2}\,m_{\min}(x)\;,\;\Omega_{\mathrm{IR}}(x)\;\Big\}, \qquad 0<\theta<1, \tag{7.736}$$

where $m_{\min}(x)$ is the smallest pseudo–NG mass at x (from the mass ledger) and $\Omega_{\mathrm{IR}}(x)$ is the instrument IR cutoff implied by the taggers (Definition 7.551); take θ uniform across $\mathfrak{P}$ (e.g. $\theta = 0.3$). Define the tomographic functional

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] \;:=\; \int_{\mathbb{R}} \chi_{\omega_0(x)}(\omega)\,\mathsf{S}_a(x;\omega)\,d\omega,$$

with S_a the T–odd spectral density of Definition 7.607.

Lemma 7.637 (Zero–frequency extraction with uniform error control)**.** *With the schedule* (7.736)*, for all* $x \in \mathfrak{P}$*,*

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] \;=\; c_0(x)\,\big|\mathcal{R}_a^{(x)}\big| \;+\; \mathcal{O}\!\left(\frac{\omega_0(x)^2}{m_{\min}(x)^2}\right),$$

where $c_0(x) > 0$ *is the probe normalization of Lemma 7.608. The error term is* $O(\theta^2)$ *uniformly on* $\mathfrak{P}$ *(since* $\omega_0 \le \frac{1}{2}\theta\, m_{\min}$*); the statement is BRST/Nielsen safe by Lemma 7.552 and Proposition 7.556.*

Proof. Step 1: Tomographic functional as a mollified evaluation at $\omega = 0$*.* By definition of the tomographic functional (see Definition 7.607 and the construction used in Lemma 7.608 and Proposition 7.609), there exists an even, normalized compactly supported mollifier χ_{ω_0} with

$$\chi_{\omega_0}(\omega) \;=\; \frac{1}{\omega_0}\,\chi\!\left(\frac{\omega}{\omega_0}\right), \qquad \int_{\mathbb{R}} \chi(\omega)\,d\omega = 1, \quad \chi(\omega) = \chi(-\omega),$$

such that

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0}] \;=\; \int_{\mathbb{R}} \chi_{\omega_0}(\omega)\, f_x(\omega)\,d\omega, \qquad f_x(\omega) \;:=\; \frac{Y_x(\omega)}{\mathsf{K}_{\mathrm{spec}}(x;\omega)}. \tag{7.737}$$

Here $Y_x(\omega)$ is the measured T–odd holosymmetric readout (cf. Proposition 7.609), and $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ is the nonnegative spectral kernel with a positive floor near $\omega = 0$ (Lemma 7.575 and Proposition 7.602). On the certified window, f_x is even in ω and C^2 in a neighbourhood of 0.

Step 2: Identification of $f_x(0)$ *and even Taylor expansion.* By the low–frequency Ward matching (Lemma 7.608),

$$f_x(0) \;=\; c_0(x)\,|\mathcal{R}_a^{(x)}|, \qquad c_0(x) > 0.$$

Since f_x is even, its Taylor expansion at 0 reads

$$f_x(\omega) \;=\; f_x(0) \;+\; \frac{1}{2} f_x''(\xi_{x,\omega})\,\omega^2,$$

for some $\xi_{x,\omega}$ between 0 and ω.

Step 3: Bounding f_x'' *by the mass gap (two equivalent routes).* Assume the would–be NG sector is gapped with minimal band mass $m_{\min}(x) > 0$ (the gap parameter that also enters (7.736)). Then f_x is real–analytic on $|\omega| < m_{\min}(x)$ (retarded correlators are analytic away from the cut, and the denominator $\mathsf{K}_{\mathrm{spec}}$ is positive and smooth near 0). Two standard bounds give

$$\sup_{|\omega|\le\omega_0} |f_x''(\omega)| \;\le\; \frac{C_*(x)}{m_{\min}(x)^2}, \qquad 0 < \omega_0 < m_{\min}(x), \tag{7.738}$$

with $C_*(x)$ locally bounded on the plateau:

(a) *Cauchy estimate (analytic disk).* For any $r < m_{\min}(x)$, by analyticity of f_x on $|z| \le r$, $|f_x''(0)| \le \frac{2}{r^2}\sup_{|z|=r}|f_x(z)|$, and similarly for $|f_x''(\omega)|$ by translating the centre. Taking $r = m_{\min}(x)$ up to a fixed factor and using plateau–uniform bounds on $|f_x|$ (from tagger normalization and Definition 6.300) gives (7.738).

(b) *Spectral (Källén–Lehmann) estimate.* Writing the retarded correlator through its spectral density supported on $|\Omega| \geq m_{\min}(x)$ and expanding around $\omega = 0$, evenness cancels the linear term and yields $f_x''(0) = 2\int d\Omega\, \rho_x(\Omega)\, \Omega^{-3}\, g_x(\Omega)$, with g_x bounded by tagger/probe constants; hence $|f_x''(0)| \leq C \int \rho_x(\Omega)/\Omega^3 \leq C'/m_{\min}(x)^2$.

Either route gives (7.738). By certified–plateau regularity and compactness, $C_*(x)$ is uniformly bounded on $\mathfrak{P}$: $\sup_{x\in\mathfrak{P}} C_*(x) =: C_* < \infty$.

Step 4: Mollifier's second moment and the averaged error. Let $\mu_2(\chi) := \int \omega^2 \chi(\omega)\, d\omega < \infty$. For the scaled mollifier, $\int \omega^2 \chi_{\omega_0}(\omega)\, d\omega = \mu_2(\chi)\, \omega_0^2$. Insert the Taylor remainder into (7.737) and use evenness ($\int \omega\, \chi_{\omega_0} = 0$):

$$\left|\mathcal{T}_a^{(x)}[\chi_{\omega_0}] - f_x(0)\right| \;\leq\; \frac{1}{2} \sup_{|\omega|\leq\omega_0} |f_x''(\omega)| \int \omega^2 \chi_{\omega_0}(\omega)\, d\omega \;\leq\; \frac{1}{2}\, \frac{C_*}{m_{\min}(x)^2}\, \mu_2(\chi)\, \omega_0^2.$$

Thus

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0}] \;=\; f_x(0) \;+\; \mathcal{O}\!\left(\frac{\omega_0^2}{m_{\min}(x)^2}\right) \;=\; c_0(x)\, |\mathcal{R}_a^{(x)}| \;+\; \mathcal{O}\!\left(\frac{\omega_0^2}{m_{\min}(x)^2}\right).$$

Step 5: Uniform $O(\theta^2)$ bound under the bandwidth schedule. By the schedule (7.736), $\omega_0(x) \leq \frac{1}{2}\theta\, m_{\min}(x)$ with fixed $0 < \theta \ll 1$ on $\mathfrak{P}$; hence

$$\frac{\omega_0(x)^2}{m_{\min}(x)^2} \;\leq\; \frac{\theta^2}{4} \;=\; O(\theta^2),$$

uniformly in $x \in \mathfrak{P}$. Absorbing the fixed constants $\frac{1}{2} C_* \mu_2(\chi)$ into the big–O proves the claimed uniform error control.

Step 6: BRST/Nielsen safety. All objects entering $\mathcal{T}_a^{(x)}$ are built from band–descended operators via taggers that commute with BRST/G; expectations are taken on $\mathcal{H}_{\text{phys}}$. Gauge–parameter variations are Nielsen–trivial for these spectral/tomographic quantities (Lemma 7.552 and Proposition 7.556). Therefore both the leading term and the error control are BRST/Nielsen safe.

The lemma follows. □

Proposition 7.638 (Plateau–consistent PCAC/LSZ schedule)**.** *Choose a single $\theta \in (0,1)$ (e.g. 0.3) and set $\omega_0(x)$ by (7.736). Then*

$$\left|\, \mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] - c_0(x)\, |\mathcal{R}_a^{(x)}| \,\right| \;\leq\; C\, \theta^2 \;+\; \mathcal{O}(\eta_{\mathfrak{P}}), \quad \forall\, x \in \mathfrak{P},$$

for a constant C independent of gauge parameters. Consequently, the T–odd tomographic lower bound of Proposition 7.609 tracks the measured law–deficit uniformly on $\mathfrak{P}$ (Corollary 7.610).

Proof. Step 1: Zero–frequency extraction with uniform error. By Lemma 7.637, for all $x \in \mathfrak{P}$,

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] \;=\; c_0(x)\, |\mathcal{R}_a^{(x)}| \;+\; \mathcal{O}\!\left(\frac{\omega_0(x)^2}{m_{\min}(x)^2}\right),$$

with $c_0(x) > 0$ and $m_{\min}(x)$ the minimal band mass in the would–be NG sector.

Step 2: Bandwidth schedule $\Rightarrow O(\theta^2)$ control (uniform on $\mathfrak{P}$). The schedule (7.736) imposes $\omega_0(x) \le \frac{1}{2}\theta\, m_{\min}(x)$ on $\mathfrak{P}$. Hence

$$\frac{\omega_0(x)^2}{m_{\min}(x)^2} \;\le\; \tfrac{1}{4}\,\theta^2,$$

so the remainder in Step 1 is bounded by $C\,\theta^2$ with a constant C independent of x (plateau compactness and the uniform bounds used in Lemma 7.637). This yields

$$\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] \;=\; c_0(x)\,|\mathcal{R}_a^{(x)}| \;+\; \mathcal{O}(\theta^2), \qquad x \in \mathfrak{P}. \tag{7.739}$$

Step 3: Plateau envelope between channels. Certified plateaus control cross–channel oscillations at level $\eta_{\mathfrak{P}}$ (Definition 6.300 and the uniformization principle Lemma 7.579). Thus any residual bias from replacing the idealized zero–frequency readout by the finite–band functional on the certified mask contributes at most $\mathcal{O}(\eta_{\mathfrak{P}})$. Combining with (7.739) gives the displayed inequality.

Step 4: Consequence for the tomographic lower bound. By Proposition 7.609, for any band–limited even mollifier supported in $[-\omega_0(x), \omega_0(x)]$,

$$1 - |\Lambda_{\text{law}}^{(x)}| \;\ge\; \kappa_{\text{spec}}(x)\,\mathcal{T}_a^{(x)}[\chi_{\omega_0(x)}] \;-\; \mathcal{O}(\eta_{\mathfrak{P}}),$$

with $\kappa_{\text{spec}}(x) > 0$ on the certified window (Lemma 7.575 and Proposition 7.602). Using Step 2,

$$1 - |\Lambda_{\text{law}}^{(x)}| \;\ge\; \kappa_{\text{spec}}(x)\,c_0(x)\,|\mathcal{R}_a^{(x)}| \;-\; \kappa_{\text{spec}}(x)\,C\,\theta^2 \;-\; \mathcal{O}(\eta_{\mathfrak{P}}),$$

which is precisely the uniform tracking asserted in Corollary 7.610 (up to the controlled $O(\theta^2)$ and plateau envelope).

Step 5: BRST/Nielsen safety. The taggers commute with BRST/G and act by c–number spacetime convolutions; expectations are taken on $\mathcal{H}_{\text{phys}}$; therefore $c_0(x)$, $\kappa_{\text{spec}}(x)$, and the bounds above are gauge–parameter independent (Lemma 7.552 and Proposition 7.556).

The proposition follows. □

Definition 7.639 (GMOR reporting on the mask)**.** On $\mathfrak{P}$ (or $\mathfrak{M}_{\text{mask}}$ when enforced), report:

- **(i)** $\widehat{C}_k^{(x)} = \text{svec}^{-1}(\hat{\mathbf{c}}_k)$ with CIs, together with $\mathcal{R}_{\text{GMOR}}(x)$ of Proposition 7.633.
- **(ii)** The conditioning $\kappa(\mathbf{X}^\top \mathbf{W} \mathbf{X})$ and (if used) ridge parameter for regularization.
- **(iii)** The PCAC/LSZ bandwidth $\omega_0(x)$, the chosen θ, and the uniform error proxy $C\theta^2$.
- **(iv)** A gauge–flatness audit: numerical Nielsen slopes ≈ 0 for the fitted coefficients and the tomographic functional (cf. Proposition 7.644).

Only values inside $\mathfrak{M}_{\text{mask}}$ (Theorem 7.664) should be quoted.

7.9.13 Gauge/BRST Safety & Spectral Shifts

We show that the *band-tagged quadratic kernel* on the physical sector is a self-adjoint analytic (type-A) family in the explicit couplings $\{\epsilon_k\}$, so that isolated poles and residues (equivalently, eigenvalues/eigenprojections of the band Hessian/inverse propagator) vary *analytically* with $\{\epsilon_k\}$ and are *gauge-parameter independent* (Nielsen stability). This underwrites reliable tracking of pseudo–NG masses and mixing angles as we dial the spurions.

Definition 7.640 (Band-tagged kernels on the physical sector)**.** At a band point $x = (\lambda_{\mathrm{UV}}, \ell)$ define the band-tagged quadratic kernel (inverse propagator / second variation) by

$$\mathbb{K}^{(x)}(\epsilon) \;:=\; \Big(\mathbb{K}_0 \;+\; \sum_k \epsilon_k\, \mathbb{V}_k\Big)^{(x)}_{\mathrm{phys}} \;:=\; \mathsf{P}_{\mathrm{phys}}\, K_{\mathrm{IR}}^{(\ell)} P_x \left(\mathbb{K}_0 + \sum_k \epsilon_k \mathbb{V}_k\right) P_x K_{\mathrm{IR}}^{(\ell)}\, \mathsf{P}_{\mathrm{phys}},$$

where $\mathsf{P}_{\mathrm{phys}}$ is the projector onto $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, and $P_x, K_{\mathrm{IR}}^{(\ell)}$ are the UV/IR taggers of Definition 7.551. The *band Hessian* (mass/mixing ledger) is the restriction of $\mathbb{K}^{(x)}(\epsilon)$ to the equal-time quadratic form (or to the one-particle sector), which we denote $\mathbb{H}^{(x)}(\epsilon)$ (cf. Section 7.9).

Lemma 7.641 (Self-adjointness and domain independence)**.** *Assume $\mathbb{K}_0$ is self-adjoint on a dense domain $\mathcal{D} \subset \mathcal{H}_{\mathrm{phys}}$, and each perturbation $\mathbb{V}_k$ is symmetric and $\mathbb{K}_0$-bounded with relative bound < 1 (local polynomial interactions after gauge-fixing/BRST completion). Then, for all ϵ in a neighborhood of 0, $\mathbb{K}^{(x)}(\epsilon)$ is self-adjoint on the* same *domain $\mathcal{D}$; likewise for $\mathbb{H}^{(x)}(\epsilon)$.*

Proof. Step 1: Kato–Rellich setup and smallness of the total perturbation. By $\mathbb{K}_0$-boundedness of each $\mathbb{V}_k$, there exist constants $a_k \in [0, 1)$ and $b_k \geq 0$ such that, for all $\psi \in \mathcal{D}$,

$$\|\mathbb{V}_k \psi\| \;\leq\; a_k\, \|\mathbb{K}_0 \psi\| + b_k\, \|\psi\|. \tag{7.740}$$

Let $\epsilon = (\epsilon_k)$ and set $\mathbb{V}(\epsilon) := \sum_k \epsilon_k \mathbb{V}_k$. Then for all $\psi \in \mathcal{D}$,

$$\|\mathbb{V}(\epsilon)\psi\| \;\leq\; \sum_k |\epsilon_k|\, \|\mathbb{V}_k \psi\| \;\leq\; \Big(\sum_k |\epsilon_k| a_k\Big)\, \|\mathbb{K}_0 \psi\| \;+\; \Big(\sum_k |\epsilon_k| b_k\Big)\, \|\psi\|.$$

Choose a neighborhood $\mathcal{U}$ of 0 in spurion space such that

$$a(\epsilon) := \sum_k |\epsilon_k| a_k \;<\; 1 \qquad \text{for all } \epsilon \in \mathcal{U}.$$

Thus $\mathbb{V}(\epsilon)$ is $\mathbb{K}_0$-bounded with relative bound $a(\epsilon) < 1$ and bound $b(\epsilon) := \sum_k |\epsilon_k| b_k$.

Step 2: Self-adjointness and common domain for the sum. By the Kato–Rellich theorem, the operator

$$\mathbb{K}(\epsilon) \;:=\; \mathbb{K}_0 + \mathbb{V}(\epsilon)$$

with domain $D(\mathbb{K}(\epsilon)) = \mathcal{D}$ is self-adjoint for all $\epsilon \in \mathcal{U}$; moreover $\mathcal{D}$ is a *common* operator domain for the whole family $\{\mathbb{K}(\epsilon)\}_{\epsilon \in \mathcal{U}}$, and any core of $\mathbb{K}_0$ is a core for $\mathbb{K}(\epsilon)$.

Step 3: Restriction to the physical sector and band preparation. Let $\mathsf{P}_{\mathrm{phys}}$ be the orthogonal projector onto $\mathcal{H}_{\mathrm{phys}}$. Stage–I (BRST anomaly–free) implies $[\mathbb{K}(\epsilon), \mathsf{P}_{\mathrm{phys}}] = 0$ (the dynamics

preserves the physical subspace). Therefore the restriction $\mathbb{K}(\epsilon)\restriction_{\mathcal{H}_{\rm phys}}$ is self-adjoint on $\mathcal{D}$ (which we assumed $\subset \mathcal{H}_{\rm phys}$).

The UV/IR taggers $P_x(\lambda_{\rm UV})$ and $K_{\rm IR}^{(\ell)}$ act by bounded c-number spacetime convolution and commute with the local differential/polynomial structure of $\mathbb{K}_0$ and of each $\mathbb{V}_k$ (cf. Definition 7.551 and the locality assumptions). Hence $[P_x, \mathbb{K}(\epsilon)] = [K_{\rm IR}^{(\ell)}, \mathbb{K}(\epsilon)] = 0$ and both operators map $\mathcal{D}$ into itself. Consequently the band-prepared generator,

$$\mathbb{K}^{(x)}(\epsilon) \;:=\; K_{\rm IR}^{(\ell)}\, P_x\, \mathbb{K}(\epsilon)\, P_x\, K_{\rm IR}^{(\ell)},$$

is the restriction of $\mathbb{K}(\epsilon)$ to a reducing subspace (since $P_x K_{\rm IR}^{(\ell)}$ commutes with $\mathbb{K}(\epsilon)$); therefore $\mathbb{K}^{(x)}(\epsilon)$ is self-adjoint on the *same* domain $\mathcal{D}$.

Step 4: The band Hessian $\mathbb{H}^{(x)}(\epsilon)$. The band Hessian $\mathbb{H}^{(x)}(\epsilon)$ (mass/mixing ledger) is obtained as the second variation of the band energy/action functional around the vacuum and is (by construction) a self-adjoint operator on the *form* domain of $\mathbb{K}_0$. In the present setting, each quadratic form perturbation induced by $\mathbb{V}_k$ is *form-bounded* with respect to $\mathbb{K}_0$ with relative bound < 1 (same locality/polynomial assumptions). Hence the KLMN theorem (Kato–Lions–Milgram–Nelson) yields a unique self-adjoint operator associated with the form sum, with *common form domain* equal to that of $\mathbb{K}_0$. Since in our hypotheses we already have (7.740) at the operator level, we can equivalently conclude via Kato–Rellich that $\mathbb{H}^{(x)}(\epsilon)$ is self-adjoint on the *same operator domain* $\mathcal{D}$ (after the same band preparation as in Step 3, which commutes with the dynamics and preserves $\mathcal{D}$).

Step 5: Gauge/BRST robustness. The commuting properties used above stem from the BRST completion and the fact that the taggers act by bounded spacetime convolutions that commute with internal (G) and BRST actions; expectations and domains are taken on $\mathcal{H}_{\rm phys}$. Therefore the statements are gauge-parameter independent and Nielsen-stable.

Combining the steps proves that, for all ϵ in a neighborhood of 0, both $\mathbb{K}^{(x)}(\epsilon)$ and $\mathbb{H}^{(x)}(\epsilon)$ are self-adjoint on the *same* domain $\mathcal{D}$. □

Proposition 7.642 (Type-A analyticity in the spurions)**.** *The family $\epsilon \mapsto \mathbb{K}^{(x)}(\epsilon)$ (and its equal-time reduction $\mathbb{H}^{(x)}(\epsilon)$) is an analytic family of type (A) in the sense of Kato: the domain is ϵ-independent and the map is norm-analytic on $\mathcal{D}$ (polynomial in ϵ). Consequently, the resolvent $(z - \mathbb{K}^{(x)}(\epsilon))^{-1}$ is analytic in ϵ for z off the real axis, and for every simple isolated eigenvalue $\lambda_j^{(x)}(\epsilon)$ the eigenvalue and Riesz projector are real-analytic in ϵ.*

Proof. Step 1: Common domain (Kato–Rellich). By Lemma 7.641, $\mathbb{K}^{(x)}(\epsilon)$ is self-adjoint on the *same* dense domain $\mathcal{D} \subset \mathcal{H}_{\rm phys}$ for all ϵ in a neighbourhood of 0. Thus the family has a ϵ-independent domain.

Step 2: Affine (hence analytic) dependence on ϵ. Before band preparation, write

$$\mathbb{K}(\epsilon) = \mathbb{K}_0 + \sum_{k=1}^{K} \epsilon_k\, \mathbb{V}_k,$$

with each $\mathbb{V}_k$ symmetric and $\mathbb{K}_0$-bounded with relative bound < 1. Band preparation acts by bounded operators that commute with the dynamics on $\mathcal{H}_{\rm phys}$ (Definition 7.551

and Lemma 7.641), so

$$\mathbb{K}^{(x)}(\epsilon) \;=\; B^{(x)}\left(\mathbb{K}_0 + \sum_{k=1}^{K} \epsilon_k\, \mathbb{V}_k\right) B^{(x)}\Big|_{\mathcal{H}_{\mathrm{phys}}}, \qquad B^{(x)} := K_{\mathrm{IR}}^{(\ell)} P_x,$$

and therefore still

$$\mathbb{K}^{(x)}(\epsilon) \;=\; \mathbb{K}_0^{(x)} + \sum_{k=1}^{K} \epsilon_k\, \mathbb{V}_k^{(x)} \quad \text{on } \mathcal{D},$$

with $\mathbb{K}_0^{(x)} := B^{(x)}\mathbb{K}_0 B^{(x)}$ and $\mathbb{V}_k^{(x)} := B^{(x)}\mathbb{V}_k B^{(x)}$. Hence for every $\psi \in \mathcal{D}$ the map $\epsilon \mapsto \mathbb{K}^{(x)}(\epsilon)\psi$ is *affine* (polynomial of degree 1) in ϵ, i.e. entire vector-valued analytic. Equivalently, with the graph norm $\|\psi\|_{\mathcal{D}} := \|\psi\| + \|\mathbb{K}_0^{(x)}\psi\|$, $\epsilon \mapsto \mathbb{K}^{(x)}(\epsilon) \in \mathcal{L}(\mathcal{D}, \mathcal{H}_{\mathrm{phys}})$ is norm-analytic (indeed, norm-polynomial).

Step 3: Type-(A) analyticity and resolvent analyticity. A family with fixed domain and operator-valued analytic dependence is a Kato type-(A) family (see, e.g., Kato, *Perturbation Theory for Linear Operators*, Ch. VII). Therefore, for any z in the resolvent set of $\mathbb{K}^{(x)}(\epsilon)$ (in particular, any $z \in \mathbb{C} \setminus \mathbb{R}$ for self-adjoint $\mathbb{K}^{(x)}(\epsilon)$), the resolvent $R^{(x)}(z,\epsilon) := (z - \mathbb{K}^{(x)}(\epsilon))^{-1}$ is analytic in ϵ. Concretely, for $z \notin \mathbb{R}$ and ϵ small enough,

$$R^{(x)}(z,\epsilon) = R_0^{(x)}(z)\left(\mathbf{1} - \sum_k \epsilon_k\, \mathbb{V}_k^{(x)} R_0^{(x)}(z)\right)^{-1} = \sum_{m=0}^{\infty} R_0^{(x)}(z)\Big(\sum_k \epsilon_k\, \mathbb{V}_k^{(x)} R_0^{(x)}(z)\Big)^m,$$

with $R_0^{(x)}(z) := (z - \mathbb{K}_0^{(x)})^{-1}$, which converges in operator norm by $\|(z - \mathbb{K}_0^{(x)})^{-1}\| \le |\operatorname{Im} z|^{-1}$ and smallness of ϵ; this exhibits holomorphy via a Neumann series.

Step 4: Analyticity of isolated eigenvalues and Riesz projectors. Let $\Sigma(\epsilon)$ be a compact, isolated part of the spectrum of $\mathbb{K}^{(x)}(\epsilon)$ (e.g. a simple eigenvalue $\lambda_j^{(x)}(\epsilon)$) with a contour Γ that encloses $\Sigma(\epsilon)$ and no other spectral points for ϵ in a small neighbourhood. The Riesz projector

$$\mathsf{P}_j^{(x)}(\epsilon) \;=\; \frac{1}{2\pi i} \oint_{\Gamma} (z - \mathbb{K}^{(x)}(\epsilon))^{-1}\, dz$$

is analytic in ϵ because the integrand is analytic jointly in (z,ϵ) and the contour is fixed. If the enclosed eigenvalue is simple, then the eigenvalue $\lambda_j^{(x)}(\epsilon)$ and the corresponding (normalized) eigenvector/eigenprojection depend real-analytically on ϵ (Kato's analytic perturbation theory; eigenvalue/eigenprojection are given by holomorphic functionals of the resolvent).

Step 5: Equal-time reduction $\mathbb{H}^{(x)}(\epsilon)$. The equal-time band Hessian (mass/mixing ledger) has the same analytic structure:

$$\mathbb{H}^{(x)}(\epsilon) \;=\; \mathbb{H}_0^{(x)} \;+\; \sum_k \epsilon_k\, \mathbb{W}_k^{(x)} \;+\; \sum_{k,\ell} \epsilon_k \epsilon_\ell\, \mathbb{W}_{k\ell}^{(x)} \;+\; \cdots,$$

where each coefficient operator is $\mathbb{H}_0^{(x)}$-bounded (arising from local polynomial interactions and finite-order counterterms on $\mathcal{H}_{\mathrm{phys}}$). This yields a power-series (hence analytic) dependence on ϵ with fixed domain; all conclusions above (resolvent/eigenvalue/projector analyticity) apply verbatim.

Combining Steps 1–5 establishes that $\epsilon \mapsto \mathbb{K}^{(x)}(\epsilon)$ and $\epsilon \mapsto \mathbb{H}^{(x)}(\epsilon)$ are analytic families of type (A), and proves the stated consequences. □

Lemma 7.643 (Gauge-parameter flow is BRST-exact on $\mathcal{H}_{\mathrm{phys}}$)**.** *Let α_{gf} denote any gauge-fixing parameter. Then*

$$\partial_{\alpha_{\mathrm{gf}}} \mathbb{K}^{(x)}(\epsilon, \alpha_{\mathrm{gf}}) \;=\; \zeta\Big(\mathbb{B}^{(x)}_{\alpha_{\mathrm{gf}}}\Big) \;+\; \partial_\mu(\cdots),$$

for some local insertion $\mathbb{B}^{(x)}_{\alpha_{\mathrm{gf}}}$ (Nielsen identity, Proposition 7.556), where the total-derivative improvement is invisible in spectral data on $\mathcal{H}_{\mathrm{phys}}$.

Proof. Step 1: BRST doublet and gauge fermion. Work in the algebraic-renormalization framework with nilpotent BRST differential ζ (Stage-I gate). Introduce the *gauge fermion* $\Psi(\alpha_{\mathrm{gf}})$ so that the gauge-fixing+ghost action is $S_{\mathrm{gf+gh}} = \zeta\,\Psi(\alpha_{\mathrm{gf}})$. The gauge parameter α_{gf} enters as a BRST doublet with an external source χ (of opposite statistics): $\zeta\,\alpha_{\mathrm{gf}} = \chi$, $\zeta\,\chi = 0$. Hence

$$\partial_{\alpha_{\mathrm{gf}}} S_{\mathrm{gf+gh}} = \partial_{\alpha_{\mathrm{gf}}}\,\zeta\Psi = \zeta\,\Big(\partial_{\alpha_{\mathrm{gf}}}\Psi\Big), \tag{7.741}$$

which is the off-shell (algebraic) content behind the Nielsen identity; see [117].

Step 2: From action to generators (operator statement). Passing to the operator formalism, variations of the microscopic generator (Hamiltonian/Schwinger generator) with respect to α_{gf} are insertions of the local composite operator obtained by the rule (7.741). Thus there exists a local $\mathbb{B}_{\alpha_{\mathrm{gf}}}$ such that

$$\partial_{\alpha_{\mathrm{gf}}} \mathbb{K}(\epsilon, \alpha_{\mathrm{gf}}) \;=\; \zeta\Big(\mathbb{B}_{\alpha_{\mathrm{gf}}}\Big) \;+\; \partial_\mu(\cdots). \tag{7.742}$$

The divergence term is a Noether/improvement piece (total derivative) that does not affect equal-time spectral data and, after spacetime smearing, integrates to boundary terms.

Step 3: Band descent preserves exactness. Band preparation uses the bounded, cone-preserving taggers $B^{(x)} := K^{(\ell)}_{\mathrm{IR}} P_x$ and restriction to the physical subspace by the orthogonal projector $\mathsf{P}_{\mathrm{phys}}$. By construction, $[B^{(x)}, \zeta] = 0$ and $[B^{(x)}, \partial_\mu] = 0$ (Definition 7.551 and Proposition 7.573), and Stage-I implies that $\mathsf{P}_{\mathrm{phys}}$ commutes with both ζ and the dynamics on $\mathcal{H}_{\mathrm{phys}}$. Therefore, differentiating the band generator $\mathbb{K}^{(x)} := \Big(B^{(x)}\,\mathbb{K}\,B^{(x)}\Big)\restriction_{\mathcal{H}_{\mathrm{phys}}}$ gives

$$\partial_{\alpha_{\mathrm{gf}}}\,\mathbb{K}^{(x)}(\epsilon, \alpha_{\mathrm{gf}}) = \Big(B^{(x)}\Big[\partial_{\alpha_{\mathrm{gf}}}\mathbb{K}(\epsilon, \alpha_{\mathrm{gf}})\Big]B^{(x)}\Big)\restriction_{\mathcal{H}_{\mathrm{phys}}} = \zeta\Big(B^{(x)}\mathbb{B}_{\alpha_{\mathrm{gf}}}B^{(x)}\Big) + \;\partial_\mu(\cdots).$$

Define $\mathbb{B}^{(x)}_{\alpha_{\mathrm{gf}}} := B^{(x)}\mathbb{B}_{\alpha_{\mathrm{gf}}}B^{(x)}$. This establishes the displayed identity in the lemma.

Step 4: Vanishing insertions on $\mathcal{H}_{\mathrm{phys}}$. Let $|\Phi\rangle, |\Psi\rangle \in \mathcal{H}_{\mathrm{phys}}$ be BRST-closed (physical) states: $\zeta\,|\Phi\rangle = 0 = \zeta\,|\Psi\rangle$. For any local operator $\mathbb{X}$,

$$\langle\Phi|\;\zeta(\mathbb{X})\;|\Psi\rangle = \langle\Phi|\;[Q_{\mathrm{BRST}}, \mathbb{X}\}_{\pm}\;|\Psi\rangle = 0,$$

since Q_{BRST} annihilates physical states and the graded commutator reduces to boundary terms that vanish on $\mathcal{H}_{\mathrm{phys}}$. Thus *BRST-exact* variations do not change physical matrix elements. The improvement $\partial_\mu(\cdots)$ is also invisible in the spectral data we use: (i) for equal-time Hessians it drops out as a total divergence; (ii) for retarded correlators it becomes a boundary term annihilated by cone-preserving smearing (Proposition 7.612). Consequently, physical spectral quantities (resolvent matrix elements, eigenvalues, Riesz projectors restricted to $\mathcal{H}_{\mathrm{phys}}$) are independent of α_{gf} to all orders consistent with renormalization (Proposition 7.556).

Step 5: Compatibility with band analyticity and plateau certification. Because $\partial_{\alpha_{\rm gf}}\mathbb{K}^{(x)}$ is BRST-exact plus a divergence, it preserves the domain and the type-(A) analytic structure in the spurions (Lemma 7.641 and Proposition 7.642). Certified plateaus ensure uniform bounds that justify exchanging $\partial_{\alpha_{\rm gf}}$ with spectral limits and tomographic smearing used elsewhere.

Combining Steps 1–5 proves the claim. □

Proposition 7.644 (Nielsen (gauge) independence of pole positions and residues)**.** *Let $\lambda_j^{(x)}(\epsilon)$ be an isolated eigenvalue of $\mathbb{H}^{(x)}(\epsilon)$ with normalized eigenvector $|\psi_j^{(x)}(\epsilon)\rangle \in \mathcal{D}$. Then*

$$\partial_{\alpha_{\rm gf}}\,\lambda_j^{(x)}(\epsilon) \;=\; 0, \qquad \partial_{\alpha_{\rm gf}}\left\langle \Omega^{(x)}\right|\bar{J}^{(x)\mu}_{a,\rm imp}\left|\psi_j^{(x)}(\epsilon)\right\rangle \;=\; 0,$$

i.e. pseudo–NG masses and current residues are gauge-parameter independent on $\mathcal{H}_{\rm phys}$.

Proof. Step 1: Differentiability and Hellmann–Feynman. By type-(A) analyticity (Proposition 7.642), $\epsilon \mapsto \mathbb{H}^{(x)}(\epsilon)$ is analytic with an ϵ-independent domain $\mathcal{D}$. Hence eigenpairs $(\lambda_j^{(x)}(\epsilon), |\psi_j^{(x)}(\epsilon)\rangle)$ of an isolated simple pole are real–analytic in any auxiliary parameter for which the generator varies smoothly, such as $\alpha_{\rm gf}$ (Kato's theorem [115]). Differentiating the eigenvalue equation and using the Hellmann–Feynman identity gives

$$\partial_{\alpha_{\rm gf}}\lambda_j^{(x)}(\epsilon) = \left\langle \psi_j^{(x)}(\epsilon)\right|\partial_{\alpha_{\rm gf}}\mathbb{H}^{(x)}(\epsilon,\alpha_{\rm gf})\left|\psi_j^{(x)}(\epsilon)\right\rangle.$$

Step 2: Nielsen identity ⇒ BRST-exact variation. By the algebraic–renormalization Nielsen identity, variations in the gauge-fixing parameters form BRST doublets and generate ζ–exact insertions (plus improvements) [117, 120, 121, 108]. At the band level,

$$\partial_{\alpha_{\rm gf}}\,\mathbb{H}^{(x)}(\epsilon,\alpha_{\rm gf}) = \zeta\Big(\mathbb{C}^{(x)}_{\alpha_{\rm gf}}\Big) \;+\; \partial_\mu(\cdots),$$

and likewise for the time–evolution generator (Lemma 7.643 and Proposition 7.556). Since matrix elements on $\mathcal{H}_{\rm phys}$ kill BRST–exact insertions and total derivatives (Lemma 7.552 and Proposition 7.612), we obtain

$$\partial_{\alpha_{\rm gf}}\lambda_j^{(x)}(\epsilon) = 0.$$

Step 3: Residues—set up and Kato gauge. Define the residue (current coupling) $R_j^{(x)\mu a}(\alpha_{\rm gf}) := \langle\Omega^{(x)}|\,\bar{J}^{(x)\mu}_{a,\rm imp}\,|\psi_j^{(x)}(\epsilon)\rangle$. Choose Kato's parallel–transport gauge in $\alpha_{\rm gf}$ so that $\langle\psi_j^{(x)}\rangle\,\partial_{\alpha_{\rm gf}}\psi_j^{(x)} = 0$ (Proposition 7.620). Then

$$\partial_{\alpha_{\rm gf}}R_j^{(x)\mu a} = \underbrace{\langle\partial_{\alpha_{\rm gf}}\Omega^{(x)}|\,\bar{J}^{(x)\mu}_{a,\rm imp}\,|\psi_j^{(x)}\rangle}_{(A)} + \underbrace{\langle\Omega^{(x)}|\,\partial_{\alpha_{\rm gf}}\bar{J}^{(x)\mu}_{a,\rm imp}\,|\psi_j^{(x)}\rangle}_{(B)} + \underbrace{\langle\Omega^{(x)}|\,\bar{J}^{(x)\mu}_{a,\rm imp}\,|\partial_{\alpha_{\rm gf}}\psi_j^{(x)}\rangle}_{(C)}.$$

Step 4: Vanishing of (B). By the Nielsen identity for composite operators, the gauge–parameter derivative of any BRST–improved, conserved current is BRST–exact up to a divergence [117]:

$$\partial_{\alpha_{\rm gf}}\bar{J}^{(x)\mu}_{a,\rm imp} = \zeta\Big(\mathbb{U}^{(x)\mu}_{a,\alpha_{\rm gf}}\Big) + \partial_\nu(\cdots).$$

Thus $(B) = 0$ on $\mathcal{H}_{\rm phys}$ (Lemma 7.552).

Step 5: Vanishing of (A) *and* (C). For the vacuum, the Nielsen identity implies the *state-level* BRST doublet relation

$$\partial_{\alpha_{\rm gf}} |\Omega^{(x)}\rangle = \zeta \, |\eta^{(x)}_{\alpha_{\rm gf}}\rangle \quad \text{with} \quad \mathfrak{g}\big(\eta^{(x)}_{\alpha_{\rm gf}}\big) = -1,$$

up to improvement terms whose matrix elements vanish [117, 108]. Hence $(A) = 0$ because $\bar{J}^{(x)}_{a,\rm imp}$ is BRST–invariant modulo a divergence (again invisible between physical states).

For (C), differentiate the eigenvalue equation $\mathbb{H}^{(x)} |\psi^{(x)}_j\rangle = \lambda^{(x)}_j |\psi^{(x)}_j\rangle$ with respect to $\alpha_{\rm gf}$ and project onto the orthogonal complement of $|\psi^{(x)}_j\rangle$; Kato perturbation theory gives

$$(\mathbf{1} - \mathsf{P}^{(x)}_j) \, |\partial_{\alpha_{\rm gf}} \psi^{(x)}_j\rangle = (\mathbf{1} - \mathsf{P}^{(x)}_j) \left(\mathbb{H}^{(x)} - \lambda^{(x)}_j\right)^{-1} \left(\partial_{\alpha_{\rm gf}} \mathbb{H}^{(x)}\right) |\psi^{(x)}_j\rangle \,,$$

where $\mathsf{P}^{(x)}_j$ is the Riesz projector (Proposition 7.642). Using $\partial_{\alpha_{\rm gf}} \mathbb{H}^{(x)} = \zeta(\mathbb{C}^{(x)}_{\alpha_{\rm gf}}) + \partial_\mu(\cdots)$, the BRST charge commutes with the dynamics ($[\zeta, \mathbb{H}^{(x)}] = 0$), hence with the reduced resolvent; therefore the right-hand side is $\zeta(\,\cdot\,)$ plus an improvement. Consequently,

$$(C) = \langle \Omega^{(x)}| \, \bar{J}^{(x)\mu}_{a,\rm imp} (\mathbf{1} - \mathsf{P}^{(x)}_j) \, |\partial_{\alpha_{\rm gf}} \psi^{(x)}_j\rangle = 0$$

on $\mathcal{H}_{\rm phys}$, because BRST–exact vectors have zero matrix elements against BRST–invariant insertions (modulo total derivatives), cf. Lemma 7.552 and Proposition 7.612.

Step 6: Conclusion. All three contributions vanish, so $\partial_{\alpha_{\rm gf}} R^{(x)\mu a}_j = 0$. Together with Step 2 this establishes the gauge–parameter independence of both pole positions and residues on $\mathcal{H}_{\rm phys}$.

Proposition 7.645 (Analytic tracking of mixing angles)**.** *Let* $\mathcal{E}^{(x)}(\epsilon)$ *be an isolated spectral subspace (possibly multi-dimensional) of* $\mathbb{H}^{(x)}(\epsilon)$ *separated by a gap along* $\epsilon \in U \subset \mathbb{R}^n$*. Then the Riesz projector*

$$\mathsf{P}^{(x)}_{\mathcal{E}}(\epsilon) = \frac{1}{2\pi i} \oint_\gamma (z - \mathbb{H}^{(x)}(\epsilon))^{-1} dz$$

is analytic in ϵ *(fixed contour* γ*). Any orthonormal frame obtained by Kato parallel transport in* $\operatorname{Ran} \mathsf{P}^{(x)}_{\mathcal{E}}(\epsilon)$ *varies real-analytically; "mixing angles'' extracted by comparing this frame to a fixed reference basis are analytic functions of* ϵ *(up to constant phases). Gauge independence holds by Proposition 7.644.*

Proof. Step 1: Analyticity of the Riesz projector. By Proposition 7.642, $\epsilon \mapsto \mathbb{H}^{(x)}(\epsilon)$ is a Kato type-(A) analytic family with ϵ-independent domain. Therefore $(z - \mathbb{H}^{(x)}(\epsilon))^{-1}$ is operator-analytic in ϵ for z off the real axis. If $\mathcal{E}^{(x)}(\epsilon)$ is isolated by a fixed contour γ that does not cross the spectrum along $\epsilon \in U$, then

$$\mathsf{P}^{(x)}_{\mathcal{E}}(\epsilon) = \frac{1}{2\pi i} \oint_\gamma (z - \mathbb{H}^{(x)}(\epsilon))^{-1} \, dz$$

is analytic in ϵ by dominated convergence/holomorphic functional calculus (see, e.g., [115], Ch. VII).

Step 2: Kato parallel transport and analytic frames. Fix $\epsilon_0 \in U$ and choose an orthonormal frame $\{|\phi_\ell\rangle\}_{\ell=1}^r$ spanning $\operatorname{Ran} \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon_0)$. Define the Kato parallel-transported frame $\{|\psi_\ell(\epsilon)\rangle\}_{\ell=1}^r$ by the ODE

$$\partial_{\epsilon_j} |\psi_\ell(\epsilon)\rangle = \left[\partial_{\epsilon_j} \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon),\, \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon)\right] |\psi_\ell(\epsilon)\rangle\,, \qquad |\psi_\ell(\epsilon_0)\rangle = |\phi_\ell\rangle\,.$$

Since $\epsilon \mapsto \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon)$ is analytic and bounded, the right-hand side is analytic, and standard ODE theory in Banach spaces yields a *real-analytic* solution $\epsilon \mapsto |\psi_\ell(\epsilon)\rangle$; orthonormality and spanning of $\operatorname{Ran} \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon)$ are preserved (Kato's selection theorem, [115]).

Step 3: Overlap matrix and principal (mixing) angles. Let $\Phi = [|\phi_1\rangle \ \cdots \ |\phi_r\rangle]$ and $\Psi(\epsilon) = [|\psi_1(\epsilon)\rangle \ \cdots \ |\psi_r(\epsilon)\rangle]$ be isometries $\mathbb{C}^r \to \mathcal{H}_{\text{phys}}$. The $r \times r$ *overlap matrix*

$$M(\epsilon) := \Phi^\dagger \Psi(\epsilon)$$

is analytic in ϵ (finite-dimensional matrix of analytic scalar products). The (canonical) principal angles $\{\vartheta_\ell(\epsilon)\}_{\ell=1}^r \in [0, \frac{\pi}{2}]$ between the varying subspace $\operatorname{Ran} \Psi(\epsilon)$ and the reference subspace $\operatorname{Ran} \Phi$ are defined by

$$\cos \vartheta_\ell(\epsilon) = \sigma_\ell\Big(M(\epsilon)\Big),$$

the singular values of $M(\epsilon)$ in nonincreasing order. Alternatively (and more invariantly), consider the positive operator on the reference subspace,

$$\mathcal{A}(\epsilon) := \Phi^\dagger \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon)\, \Phi \in \mathbb{C}^{r\times r}, \qquad \text{self-adjoint and analytic in } \epsilon,$$

whose eigenvalues are $\cos^2 \vartheta_\ell(\epsilon)$ (spectral theorem for principal angles).

Step 4: Analyticity of mixing angles. Since $\mathcal{A}(\epsilon)$ is a finite-dimensional self-adjoint analytic family, its eigenvalues admit *real-analytic* parameterizations on U provided they remain simple (Kato's theory, [115], Thm. 6.1). Thus, away from accidental degeneracies, we can label $\lambda_\ell(\epsilon) = \cos^2 \vartheta_\ell(\epsilon)$ analytically; composition with the analytic map $\vartheta \mapsto \arccos \sqrt{\vartheta}$ on $(0, 1)$ yields real-analytic $\vartheta_\ell(\epsilon)$. In the presence of degeneracies, analytic labeling is still possible for each *isolated eigenvalue cluster* (Riesz projectors for $\mathcal{A}(\epsilon)$ are analytic by Step 1), and within such a cluster one can choose an analytic orthonormal basis (Kato selection); the corresponding angles are then analytic up to a relabeling within the degenerate block. Hence the "mixing angles'' extracted from $M(\epsilon)$ or $\mathcal{A}(\epsilon)$ are real-analytic functions of ϵ (up to constant phases and, in degenerate cases, up to analytic rotations inside the degenerate eigenspaces).

Step 5: Gauge independence. By Proposition 7.644, spectral projectors associated with isolated parts of the spectrum are gauge-parameter independent on $\mathcal{H}_{\text{phys}}$; hence $\mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon)$, $\mathcal{A}(\epsilon)$, and the resulting principal angles are Nielsen-stable.

Combining Steps 1–5 proves the proposition. □

Theorem 7.646 (Gauge/BRST safety and analytic spectral shifts on plateaus)**.** *Assume the Stage-I gate (BRST anomaly-free), the QIV hypotheses, and a certified plateau* $\mathfrak{P}$*. Then, for every* $x \in \mathfrak{P}$*:*

Type-A analyticity.
$\mathbb{H}^{(x)}(\epsilon)$ *forms a self-adjoint analytic family; each isolated pseudo–NG eigenvalue and its Riesz projector are real-analytic in* ϵ *(Proposition 7.642).*

Nielsen independence.
Pseudo–NG masses and current residues are gauge-parameter independent on $\mathcal{H}_{\text{phys}}$ *(Proposition 7.644).*

Mixing reliability.
Mixing angles within any isolated pseudo–NG cluster are real-analytic in ϵ *and gauge independent (Proposition 7.645).*

Uniformity across $x \in \mathfrak{P}$ *follows from plateau tolerances (Definition 6.300) and the band-commutation properties of Definition 7.551; BRST/Nielsen robustness is by Lemma 7.552 and Proposition 7.556.*

Proof. Step 1: Common domain and Type-(A) analyticity. By Lemma 7.641, the band-prepared generators $\mathbb{K}^{(x)}(\epsilon)$ and equal-time band Hessians $\mathbb{H}^{(x)}(\epsilon)$ are self-adjoint on a *common*, ϵ–independent dense domain $\mathcal{D} \subset \mathcal{H}_{\text{phys}}$ for all small spurions. Their ϵ–dependence is affine (polynomial) after the bounded $P_x, K_{\text{IR}}^{(\ell)}$ sandwich and restriction to $\mathcal{H}_{\text{phys}}$ (Definition 7.551), so $\epsilon \mapsto \mathbb{H}^{(x)}(\epsilon)$ is a Kato type-(A) family with fixed domain. Hence the resolvent and any isolated spectral data (eigenvalues, Riesz projectors) are real-analytic in ϵ (Proposition 7.642).

Step 2: Gauge/Nielsen independence of spectral poles and residues. Gauge-parameter flow is BRST-exact up to improvements at the band level (Lemma 7.643). Therefore, for any isolated, normalized eigenpair $(\lambda_j^{(x)}, |\psi_j^{(x)}\rangle)$, Hellmann–Feynman on $\mathcal{H}_{\text{phys}}$ gives $\partial_{\alpha_{\text{gf}}} \lambda_j^{(x)} = \langle \psi_j^{(x)} | \partial_{\alpha_{\text{gf}}} \mathbb{H}^{(x)} | \psi_j^{(x)} \rangle = 0$, since BRST-exact and total-derivative insertions vanish between physical states (Lemma 7.552). The same BRST-exactness and a Kato gauge choice for $|\psi_j^{(x)}\rangle$ imply that current residues $\langle \Omega^{(x)} | \, \bar{J}_{a,\text{imp}}^{(x)\mu} \, | \psi_j^{(x)} \rangle$ are α_{gf}–independent as well (Proposition 7.644). This establishes Item (2).

Step 3: Analytic and gauge-stable mixing angles. Let $\mathcal{E}^{(x)}(\epsilon)$ be an isolated pseudo–NG cluster along ϵ. By Step 1, the Riesz projector $\mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon) = \frac{1}{2\pi i} \oint_\gamma (z - \mathbb{H}^{(x)}(\epsilon))^{-1} dz$ is analytic in ϵ for a fixed contour γ. Kato's parallel-transport ODE inside $\operatorname{Ran} \mathsf{P}_{\mathcal{E}}^{(x)}(\epsilon)$ yields an orthonormal frame that depends real-analytically on ϵ; principal (mixing) angles obtained from overlaps with a fixed reference frame are then real-analytic functions of ϵ (up to constant phases). Gauge independence of $\mathsf{P}_{\mathcal{E}}^{(x)}$ by Proposition 7.644 implies gauge independence of the mixing angles, proving Item (3) (see Proposition 7.645).

Step 4: Uniformity on certified plateaus. Certified plateaus $\mathfrak{P}$ (Definition 6.300) provide: (i) compactness of the accepted mask; (ii) uniform bounds on tagger norms and commutators with BRST/G (Definition 7.551); and (iii) an oscillation envelope $\eta_{\mathfrak{P}}$ controlling cross-x variations. Consequently, the analyticity radii, spectral gaps defining the isolated clusters, and conditioning constants for the Riesz projectors can be chosen uniformly in $x \in \mathfrak{P}$. By

the plateau uniformization principle (Lemma 7.579), all statements in Items (1)–(3) hold uniformly across $\mathfrak{P}$, with any residual x–dependence bounded by $O(\eta_{\mathfrak{P}})$. BRST/Nielsen robustness of all constructions follows from Lemma 7.552 and Proposition 7.556.

Items (1)–(3) and the uniformity claim are thus established. □

Corollary 7.647 (Operational consequence)**.** *As ϵ is dialed on $\mathfrak{P}$, (i) pseudo–NG masses $m^2_{\pi_b}(x,\epsilon)$ admit convergent Taylor fits in ϵ whose linear terms match the GMOR coefficients of Theorem 7.630; (ii) mixing angles admit smooth (real-analytic) drifts with ϵ; (iii) none of these fits change under gauge-parameter variations (within numerical tolerance).*

Proof. (i) Taylor fits and GMOR linear term. Fix $x \in \mathfrak{P}$ and a pseudo–NG mode b. By Item (1) of Theorem 7.646 (Type-A analyticity), the isolated eigenvalue $m^2_{\pi_b}(x,\epsilon)$ is a real-analytic function of ϵ in a neighbourhood of $\epsilon = 0$. Hence there exists $r(x) > 0$ such that the multivariate Taylor series

$$m^2_{\pi_b}(x,\epsilon) \;=\; m^2_{\pi_b}(x,0) \;+\; \sum_j \left(\partial_{\epsilon_j} m^2_{\pi_b}\right)\Big|_{\epsilon=0} \epsilon_j \;+\; \mathcal{O}(\|\epsilon\|^2)$$

converges for $\|\epsilon\| < r(x)$. In the exact-symmetry limit, $m^2_{\pi_b}(x,0) = 0$. By Theorem 7.630 (Ward–mass link), the linear coefficients equal the GMOR slopes:

$$\left(\partial_{\epsilon_j} m^2_{\pi_b}\right)\Big|_{\epsilon=0} \;=\; \alpha^{(x)}_{bj} \;=\; \frac{1}{f^2_{\pi_b}(x)} \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{j,b} \right\rangle_{\mathbf{\Psi}},$$

so the fitted linear term matches GMOR. By the plateau uniformization principle (Lemma 7.579) and the uniform analytic control on $\mathfrak{P}$ provided in Theorem 7.646, the radius and the $\mathcal{O}(\|\epsilon\|^2)$ remainder can be chosen uniformly up to the tolerance $\eta_{\mathfrak{P}}$ on the certified mask.

(ii) Analytic drift of mixing angles. Let $\mathcal{E}^{(x)}(\epsilon)$ be the isolated pseudo–NG cluster containing π_b. By Proposition 7.645, the Riesz projector $\mathsf{P}^{(x)}_{\mathcal{E}}(\epsilon)$ and any Kato parallel-transported orthonormal frame inside $\operatorname{Ran}\mathsf{P}^{(x)}_{\mathcal{E}}(\epsilon)$ are real-analytic in ϵ; principal (mixing) angles obtained by comparing this frame against a fixed reference basis are thus real-analytic functions of ϵ (up to constant phases). Therefore, operationally, mixing angles exhibit smooth (real-analytic) drifts as ϵ varies on $\mathfrak{P}$.

(iii) Gauge-parameter independence of the fits. By Item (2) of Theorem 7.646 and Proposition 7.644, both pseudo–NG masses (hence their Taylor coefficients) and residues are gauge-parameter independent on $\mathcal{H}_{\mathrm{phys}}$; Proposition 7.645 further gives gauge independence of mixing angles. Consequently, any regression (e.g. linear or polynomial in ϵ within the analytic radius) fitted to $m^2_{\pi_b}(x,\epsilon)$ or to the mixing angles is invariant under variations of the gauge-fixing parameter α_{gf}, up to the numerical/plateau tolerance budget $\eta_{\mathfrak{P}}$.

These three statements together yield the claimed operational consequences on $\mathfrak{P}$. □

7.9.14 Gauge–flatness Audit and Analytic Tracking Window in $\{\epsilon_k\}$

Context. On the physical sector, poles and residues vary analytically in the explicit couplings (type–A) and are gauge–parameter independent (Nielsen flat) (Propositions 7.642 and 7.644

and Theorem 7.646). We now (i) turn these into *operational tests* at each band point $x \in \mathfrak{P}$, and (ii) define a *certified window* in spurion space where the quadratic Taylor model passes lack-of-fit tests.

Definition 7.648 (Gauge path and stencil)**.** Let $\alpha_{\rm gf} \in \mathbb{R}^q$ denote gauge–fixing parameters. Around a nominal setting α_0 we probe one-dimensional coordinate lines $\alpha_0 \pm h_\alpha \mathbf{e}_\ell$ and $\alpha_0 \pm 2h_\alpha \mathbf{e}_\ell$, $\ell = 1, \dots, q$. Use the 5-point, order-h_α^4 central stencil for a scalar observable $f(\alpha)$:

$$\partial_{\alpha_\ell} f(\alpha_0) \;\approx\; \frac{-f(\alpha_0+2h_\alpha\mathbf{e}_\ell) + 8f(\alpha_0+h_\alpha\mathbf{e}_\ell) - 8f(\alpha_0-h_\alpha\mathbf{e}_\ell) + f(\alpha_0-2h_\alpha\mathbf{e}_\ell)}{12\,h_\alpha}.$$

For complex matrix elements, apply the stencil to Re and Im parts separately and combine in the Euclidean norm.

Definition 7.649 (Step size and tolerance)**.** Choose a dimensionless step $h_\alpha = \eta_{\mathfrak{P}}^{1/2}$ (with a floor $h_\alpha^{\min} = 10^{-3}$) so that truncation error $O(h_\alpha^4)$ is negligible vs. the plateau tolerance $\eta_{\mathfrak{P}}$ while round-off remains small. Define the *Nielsen slope threshold*

$$\epsilon_{\rm Nielsen} \;:=\; c_{\rm N}\,\eta_{\mathfrak{P}}, \qquad c_{\rm N} \in [5, 10].$$

Definition 7.650 (Operational Nielsen slope test)**.** At $x \in \mathfrak{P}$, let $\{\lambda_j^{(x)}\}$ be the tracked poles (eigenvalues) and $\{R_{a,j}^{(x)}\} = \{\langle\Omega|\bar{J}_{a,\rm imp}|\psi_j\rangle\}$ the residues for broken currents a. Compute

$$S_{\rm Nielsen}(x) \;:=\; \max_{j,\ell} \left|\partial_{\alpha_\ell}\lambda_j^{(x)}\right| \;\vee\; \max_{a,j,\ell} \left|\partial_{\alpha_\ell} R_{a,j}^{(x)}\right|$$

with the stencil of Definition 7.648. *Pass* if $S_{\rm Nielsen}(x) \le \epsilon_{\rm Nielsen}$; otherwise *fail*.

Proposition 7.651 (Stability and BRST/Nielsen safety)**.** *The derivatives in Definition 7.650 are computed on $\mathcal{H}_{\rm phys}$ with band taggers that commute with ζ and the G-action (Definition 7.551); therefore the test is BRST-safe (Lemma 7.552) and its acceptance decision is gauge-parameter independent in the ideal limit (Proposition 7.644). Finite h_α and readout noise are controlled by Definition 7.649.*

Proof. Step 1: Objects whose slopes are tested. Let $\mathscr{F}^{(x)}(\alpha_{\rm gf})$ denote any of the observables covered by Definition 7.650 (e.g. pseudo–NG eigenvalues of $\mathbb{H}^{(x)}$, Riesz-projector–based mixing angles, current residues, or any band-limited spectral functional built from resolvents and matrix elements). By construction, all such readouts are formed after band descent with $B^{(x)} := K_{\rm IR}^{(\ell)} P_x$ and evaluated on $\mathcal{H}_{\rm phys}$.

Step 2: Commutation with BRST/G and differentiability. The taggers are bounded spacetime convolutions that commute with BRST and the G-action (Definition 7.551 and Proposition 7.573); hence $[B^{(x)}, \zeta] = [B^{(x)}, \delta_a] = 0$ and $B^{(x)}$ preserves $\mathcal{H}_{\rm phys}$. By type-(A) analyticity (Proposition 7.642), the families $\epsilon \mapsto \mathbb{K}^{(x)}, \mathbb{H}^{(x)}$ and all resolvent functionals are differentiable in any smooth external parameter, in particular $\alpha_{\rm gf}$.

Step 3: BRST-exact gauge flow ⇒ vanishing ideal slopes. The Nielsen identity at the band level (Lemma 7.643) gives $\partial_{\alpha_{\rm gf}} \mathbb{H}^{(x)} = \zeta(\mathbb{C}_{\alpha_{\rm gf}}^{(x)}) + \partial_\mu(\cdots)$. For any physical matrix element $\langle\Phi| \cdot |\Psi\rangle$

with $|\Phi\rangle, |\Psi\rangle \in \mathcal{H}_{\text{phys}}$, BRST-exact insertions and total derivatives vanish (Lemma 7.552 and Proposition 7.612). Therefore, by Hellmann–Feynman and the resolvent calculus,

$$\partial_{\alpha_{\text{gf}}} m_{\pi_b}^2(x) = 0, \quad \partial_{\alpha_{\text{gf}}} \mathsf{P}_{\mathcal{E}}^{(x)}(x) = 0, \quad \partial_{\alpha_{\text{gf}}} \left\langle \Omega^{(x)} \middle| \bar{J}_{a,\text{imp}}^{(x)} \middle| \psi_j^{(x)} \right\rangle = 0,$$

and similarly for any $\mathscr{F}^{(x)}$ built from these spectral objects (chain rule). Thus, in the *ideal* (continuum, noiseless) limit, the true slope $\partial_{\alpha_{\text{gf}}} \mathscr{F}^{(x)}(\alpha_{\text{gf}}) = 0$. This is the content of Nielsen independence (Proposition 7.644) specialized to the observables of the test.

Step 4: Finite-difference estimator, bias and variance. The operational slope uses a finite difference with step h_α from Definition 7.649:

$$\widehat{\partial_\alpha \mathscr{F}^{(x)}} := \begin{cases} \dfrac{\mathscr{F}^{(x)}(\alpha+h_\alpha) - \mathscr{F}^{(x)}(\alpha-h_\alpha)}{2h_\alpha}, & \text{(central)}, \\ \dfrac{\mathscr{F}^{(x)}(\alpha+h_\alpha) - \mathscr{F}^{(x)}(\alpha)}{h_\alpha}, & \text{(forward)}. \end{cases}$$

Since $\mathscr{F}^{(x)}$ is C^3 in α (Step 2), the truncation bias is $O(h_\alpha^2)$ for the central scheme and $O(h_\alpha)$ for the forward scheme, uniformly on the certified mask (plateau compactness). With readout noise level σ_{rd} per evaluation, the variance scales as $\text{Var}(\widehat{\partial_\alpha \mathscr{F}}) \sim c\, \sigma_{\text{rd}}^2 / h_\alpha^2$ for either scheme (with an $O(1)$ constant c depending on whether two or three evaluations are used). The step/tolerance prescription in Definition 7.649 balances these errors so that the combined RMS is $\lesssim \sigma_{\text{tol}}$ and $\sigma_{\text{tol}} \gg \eta_{\mathfrak{P}}$ (to clear the plateau envelope), ensuring stability of the accept/reject decision.

Step 5: Gauge-parameter independence of the acceptance decision. Because the ideal slope vanishes (Step 3), any two gauge-parameter choices yield the *same* acceptance outcome in the limit $h_\alpha \to 0$ and $\sigma_{\text{rd}} \to 0$. With finite h_α and noise, the probability of a flip in the decision is controlled by the RMS error derived in Step 4 and is made negligible by the thresholds stipulated in Definition 7.649. Hence the operational test is BRST-safe and Nielsen-stable as stated.

The proposition follows. □

Remark 7.652 (Practical audit)**.** (i) Verify stencil consistency by halving h_α once; require derivative estimates to agree within $O(h_\alpha^4) + O(\eta_{\mathfrak{P}})$. (ii) Report the per-mode slopes and the maximum $S_{\text{Nielsen}}(x)$. (iii) If the test fails on a subregion of $\mathfrak{P}$, refine the mask or check for anomaly filters (Definition 7.613).

Definition 7.653 (Quadratic Taylor model in the spurions)**.** Along a spurion ray $\epsilon(t) = \epsilon^{(0)} + t\,\hat{\mathbf{v}}$ with small t, model an eigenvalue (or a residue component) $g(t)$ by

$$g(t) \;=\; g_0 \;+\; a\,t \;+\; \tfrac{1}{2}\,b\,t^2 \;+\; \rho(t), \qquad \rho(t) = O(t^3),$$

with WLS (weights from readout errors). For multi-parameter tracking, use $g(\epsilon) = g_0 + \mathbf{a}^\top \epsilon + \frac{1}{2}\,\epsilon^\top B\,\epsilon + \rho(\epsilon)$.

Definition 7.654 (Analytic tracking window)**.** Let $I = [-t_{\max}, t_{\max}]$ be the largest symmetric interval such that:

1. (Lack-of-fit) The quadratic model passes an F-test against a cubic extension at level $1-\beta$ (e.g. 95%), and the normalized residual $\mathcal{R}_{\text{quad}} = \|W^{1/2}\mathbf{r}\|_2/(\sqrt{N}\,\eta_{\mathfrak{P}}) \le 1$.
2. (Coefficient stability) Refit on the halves $[0, t_{\max}]$, $[-t_{\max}, 0]$; require relative drifts of a, b below $c_{\text{stab}}\eta_{\mathfrak{P}}$ (e.g. $c_{\text{stab}} = 5$).
3. (Consistency across directions) For a basis of spurion directions $\{\hat{\mathbf{e}}_k\}$, the unions of their intervals define a polydisc $\mathcal{B}_\epsilon = \{\epsilon : \ |\epsilon_k - \epsilon_k^{(0)}| \le \epsilon_k^{\max}\}$, each $\epsilon_k^{\max}$ coming from $t_{\max}$ on $\hat{\mathbf{e}}_k$.

We call $\mathcal{B}_\epsilon$ the *analytic tracking window* at x.

Proposition 7.655 (Type–A consistency of the window)**.** *By Proposition 7.642, $g(\epsilon)$ is analytic near $\epsilon^{(0)}$; hence a non-empty window $\mathcal{B}_\epsilon$ exists. If $\mathcal{R}_{\text{quad}} \le 1$ and the cubic model is not favored (by AIC_c or an F-test) on $\mathcal{B}_\epsilon$, the quadratic coefficients provide an accurate local parametric tracker for poles/residues, uniformly on $\mathfrak{P}$ up to $O(\eta_{\mathfrak{P}})$.*

Proof. Step 1: Analyticity ⇒ Taylor control and existence of a window. Fix $x \in \mathfrak{P}$ and let $g(\epsilon)$ denote any scalar component of an isolated pole/residue (eigenvalue, current matrix element, or a coordinate of a mixing-angle chart). By Proposition 7.642, g is real–analytic in a ball $B_r(\epsilon^{(0)})$. Write $\Delta\epsilon := \epsilon - \epsilon^{(0)}$. Taylor's theorem with integral remainder gives, for some $M_3(x) < \infty$,

$$g(\epsilon) \ = \ g_0 \ + \ J\cdot\Delta\epsilon \ + \ \tfrac{1}{2}\,\Delta\epsilon^{\top} H\,\Delta\epsilon \ + \ R_3(\epsilon), \qquad |R_3(\epsilon)| \ \le \ M_3(x)\,\|\Delta\epsilon\|^3, \tag{7.743}$$

for all $\epsilon \in B_r$. Choose a radius $0 < \rho \le r$ small enough that $M_3(x)\rho^3$ is within the target truncation budget (fixed below), and define the *window* $\mathcal{B}_\epsilon := \{\epsilon : \|\Delta\epsilon\| \le \rho\}$. Thus $\mathcal{B}_\epsilon \neq \varnothing$ by analyticity.

Step 2: Quadratic WLS as a local parametric tracker. Collect measurements $\{(\epsilon^{(n)}, y_n)\}_{n=1}^N$ with $\epsilon^{(n)} \in \mathcal{B}_\epsilon$, where

$$y_n \ = \ g(\epsilon^{(n)}) \ + \xi_n, \qquad \mathbb{E}[\xi_n] = 0, \quad \operatorname{Var}(\xi_n) = \sigma_n^2,$$

and the noise envelope (systematic+statistical) is controlled at $O(\eta_{\mathfrak{P}})$ by the plateau certification (Definition 6.300, cf. the usage in Proposition 7.592). Fit the quadratic model $q(\epsilon) := \alpha + J\cdot\Delta\epsilon + \frac{1}{2}\Delta\epsilon^{\top}H\,\Delta\epsilon$ by weighted least squares (full-rank design). Standard regression theory with deterministic model misspecification (7.743) yields the coefficient bias

$$\|\widehat{\alpha} - g_0\| + \|\widehat{J} - J\| + \|\widehat{H} - H\| \ = \ O(\rho^3) \ + \ O_{\mathbb{P}}\Big(\max_n \sigma_n\Big),$$

where the $O(\rho^3)$ term comes from the uniform cubic remainder and the stochastic term is controlled by the weights ($\sigma_n = O(\eta_{\mathfrak{P}})$ on a certified mask). Hence, provided ρ is chosen so that $M_3(x)\rho^3 \lesssim \eta_{\mathfrak{P}}$, the quadratic coefficients track the true local Taylor coefficients up to $O(\eta_{\mathfrak{P}})$.

Step 3: Role of $\mathcal{R}_{\text{quad}}$ and the cubic model comparison. Let RSS_2 (resp. RSS_3) be the weighted residual sum of squares for the quadratic (resp. cubic) fit on $\mathcal{B}_\epsilon$. From (7.743), the *best possible* reduction in residual by adding cubic terms is $O(\rho^6)$ (since the neglected signal is

$O(\rho^3)$ in amplitude). Therefore, if the noise floor is $\gtrsim O(\eta_{\mathfrak{P}})$ and the normalization $\mathcal{R}_{\text{quad}} \le 1$ holds (i.e., the quadratic residual sits within the plateau budget), the expected improvement $\text{RSS}_2 - \text{RSS}_3$ is not statistically significant on $\mathcal{B}_\epsilon$. Concretely, AIC_c penalizes the extra cubic parameters by a constant that dominates an $O(\rho^6)$ gain for small enough ρ, and the classical F-test likewise fails to reject the quadratic null once the signal-to-noise is calibrated to the plateau budget. By hypothesis, both diagnostics *do not* favor the cubic model; thus the quadratic specification is operationally consistent on $\mathcal{B}_\epsilon$.

Step 4: Uniformity on $\mathfrak{P}$. On a certified plateau, the analyticity radius and derivative bounds can be chosen uniformly: compactness of the mask and the spectral isolation hypotheses imply $\sup_{x\in\mathfrak{P}} M_3(x) =: M_3 < \infty$ (Lemma 7.619 and Propositions 7.620 and 7.642). Choosing a single $\rho \le \min_{x\in\mathfrak{P}} r(x)$ such that $M_3\rho^3 \lesssim \eta_{\mathfrak{P}}$ makes the remainder control uniform, and the plateau uniformization principle (Lemma 7.579) bounds the cross-x drift of the fitted coefficients by $O(\eta_{\mathfrak{P}})$. Therefore the quadratic coefficients furnish an *accurate, uniform* local tracker for poles/residues on $\mathfrak{P}$, up to $O(\eta_{\mathfrak{P}})$.

Combining the steps proves the proposition. □

Remark 7.656 (Reporting rules)**.** For each $x \in \mathfrak{P}$: (i) report $S_{\text{Nielsen}}(x)$ and pass/fail; (ii) give the window $\mathcal{B}_\epsilon$ (component radii $\epsilon_k^{\max}$), the quadratic coefficients with CIs, the normalized residual $\mathcal{R}_{\text{quad}}$, and the F-test/AIC_c outcomes; (iii) if the window collapses or Nielsen slopes exceed $\epsilon_{\text{Nielsen}}$, shrink the mask or reduce the spurion span and re-audit.

7.9.15 Plateau–mask Certification (Report Only Where Robust)

We formalize the certification protocol that selects *where* in the $(\lambda_{\text{UV}}, \ell)$–grid our readouts are instrument–robust (gauge/basis/scheme safe) and stable under mesh refinement. All diagnostics reported for QIV (§7.9) are then restricted to this certified mask.

Definition 7.657 (Grid and mask)**.** Let $\mathcal{G} = \{\ (\lambda_{\text{UV}}^{(i)}, \ell^{(j)})\ \}$ be the finite sampling grid in scale space, ordered so that $\ell^{(j+1)} > \ell^{(j)}$. A *plateau mask* is a subset $\mathfrak{M}_{\text{mask}} \subset \mathcal{G}$ such that the plateau tolerances of Definition 6.300 hold on every connected component, and all quantities below satisfy the improving–physicality constraints in Definition 7.659.

Definition 7.658 (Physical margins on $\mathcal{H}_{\text{phys}}$)**.** At a band point $x = (\lambda_{\text{UV}}, \ell)$ let:

1. **Mass margin** $\mu(x)$ be the smallest eigenvalue of the pseudo–NG block $M_\pi^2(x)$ of the band Hessian on $\mathcal{H}_{\text{phys}}$ (cf. Section 7.9 and Theorem 7.630). Thus $\mu(x) > 0$ in QIV.
2. **Hyperbolicity margin** $\chi(x)$ be the infimum, over unit covectors $\hat{\mathbf{n}}$, of the minimal positive eigenvalue of the principal symbol of the kinetic operator (time–derivative block) after band descent and physical projection:
$$\chi(x) \ := \ \inf_{\|\hat{\mathbf{n}}\|=1} \ \lambda_{\min}^{+}\Big(\sigma_{\text{prin}}^{(x)}(\hat{\mathbf{n}})\Big),$$
ensuring well–posedness/positivity of the quadratic form (relativistic z=1 or finite z).
3. **Spectral floor (T–odd)** $s_{\text{floor}}(x)$ be the certified low–frequency T–odd weight tied to the Ward source:
$$s_{\text{floor}}(x) \ := \ \kappa_{\text{spec}}(x)\, c_0(x) \max_{a\in\mathfrak{g}_{\text{br}}} \big|\mathcal{R}_a^{(x)}\big|,$$

with $\kappa_{\mathrm{spec}}(x)$ and $c_0(x)$ from Proposition 7.609 and Lemma 7.608, and $\mathcal{R}_a^{(x)}$ from eq. (7.665).

All three margins are computed on $\mathcal{H}_{\mathrm{phys}}$ and are gauge–parameter independent by Propositions 7.556 and 7.644; continuity in the mask follows from Proposition 7.642 and Lemma 7.579.

Definition 7.659 (Improving physicality with ℓ)**.** Given a fixed λ_{UV}, a sequence $\{x_j = (\lambda_{\mathrm{UV}}, \ell^{(j)})\}_{j_0 \le j \le j_1}$ satisfies *improving physicality* if

$$\mu(x_{j+1}) \;\ge\; \mu(x_j) - \eta_{\mathfrak{P}}, \qquad \chi(x_{j+1}) \;\ge\; \chi(x_j) - \eta_{\mathfrak{P}}, \qquad s_{\mathrm{floor}}(x_{j+1}) \;\ge\; s_{\mathrm{floor}}(x_j) - \eta_{\mathfrak{P}},$$

for the plateau tolerance $\eta_{\mathfrak{P}}$ of Definition 6.300. Equivalently, upon tightening tolerances one may enforce monotone nondecreasing behavior.

Definition 7.660 (Instrument–robust observables on the mask)**.** On $\mathfrak{M}_{\mathrm{mask}}$, report only:

- law/state visibilities and their channel splits (holosymmetric overlays, Definition 6.275 and Proposition 7.555);
- exponents and amplitudes from visibility fits (Theorem 7.580 and Corollary 7.581);
- pseudo–NG masses/mixings and GMOR coefficients (Theorem 7.630 and Corollary 7.631);
- T–odd tomography summaries (Definition 7.607 and Theorem 7.614);
- the margins $\mu, \chi, s_{\mathrm{floor}}$ of Definition 7.658.

All are computed on $\mathcal{H}_{\mathrm{phys}}$ (BRST descent Lemma 7.552) and are Nielsen–stable (Propositions 7.556 and 7.644).

Lemma 7.661 (Gauge/basis/scheme robustness on $\mathfrak{M}_{\mathrm{mask}}$)**.** *Let α_{gf} be any gauge–fixing parameter, and let $\mathcal{R}$ denote admissible basis/scheme changes that act by bounded, BRST–compatible similarity transforms after band descent. Then, for $x \in \mathfrak{M}_{\mathrm{mask}}$,*

$$\partial_{\alpha_{\mathrm{gf}}}\{\mu, \chi, s_{\mathrm{floor}}, \Lambda_\bullet, M_\pi^2, F\} \;=\; 0, \qquad \delta_{\mathcal{R}}\{\mu, \chi, s_{\mathrm{floor}}, \Lambda_\bullet, M_\pi^2, F\} \;=\; \mathcal{O}(\eta_{\mathfrak{P}}),$$

i.e. the reported values are gauge–independent and scheme–stable within plateau tolerances.

Proof. Gauge independence. All quantities are computed on $\mathcal{H}_{\mathrm{phys}}$ after band descent by the bounded taggers $B^{(x)} := K_{\mathrm{IR}}^{(\ell)} P_x$, which commute with BRST and the G–action (Definition 7.551 and Proposition 7.573). Gauge–parameter flow is BRST–exact (plus total derivatives) at the band level by the Nielsen identity (Lemma 7.643). Hence any physical matrix element of $\partial_{\alpha_{\mathrm{gf}}}$ of these objects vanishes (Lemma 7.552 and Proposition 7.556):

- μ, χ are spectral margins of the (band) principal symbol/Hessian; their values are spectral data and thus Nielsen–independent (Proposition 7.644).
- M_π^2 (pseudo–NG masses) and F (decay–constant matrix) are isolated spectral poles and residues, already covered by Proposition 7.644.
- s_{floor} and the tomographic kernel floor κ_{spec} are constructed from $\widehat{\kappa}_x$ (taggers) by positive quadratures (Lemma 7.575 and Proposition 7.602); since the taggers commute with BRST/G, these floors are gauge–parameter independent.

- $\Lambda_\bullet$ (state/law overlaps and their T–odd/T–even parts) are built from resolvents and band–descended matrix elements; BRST–exact insertions and improvements drop out on $\mathcal{H}_{\mathrm{phys}}$, hence no gauge dependence (Proposition 7.556).

Therefore $\partial_{\alpha_{\mathrm{gf}}}\{\cdots\} = 0$ on $\mathcal{H}_{\mathrm{phys}}$.

Basis/scheme robustness. Let $\mathcal{R}$ act by a bounded, BRST–compatible similarity S on the band–prepared physical space, $S : \mathcal{H}_{\mathrm{phys}} \to \mathcal{H}_{\mathrm{phys}}$, with S invertible, $[S, \zeta] = 0$, and with the tagger class mapped into itself (admissible scheme change). Then:

- Spectra and spectral gaps are invariant under similarity: $\mathrm{spec}(S^{-1}\mathbb{H}^{(x)}S) = \mathrm{spec}(\mathbb{H}^{(x)})$, hence μ, χ, M_π^2 are unchanged.
- Residues transform covariantly, but their *numerical values* in a fixed physical normalization are invariant because both interpolating operators and states are pushed forward by S; any difference arises only from the *finite* tagger/mesh implementations used in practice.
- s_{floor} and κ_{spec} are positive quadratic functionals of $\widehat{\kappa}_x$; admissible scheme changes preserve the tagger class, so the ideal values are invariant.

On certified masks, the only discrepancies come from discretization and plateau reweightings; these are controlled by the oscillation envelope in Definition 6.300 (uniformization) and by the acceptance/convergence gates (§ "Grid–refinement schedule"): any scheme/basis induced drift of reported numbers is bounded by the budget $O(\eta_{\mathfrak{P}})$ (see also Lemma 7.588, the robustness statements following Proposition 7.594, and the mask thresholds discussion). Hence $\delta_{\mathcal{R}}\{\cdots\} = \mathcal{O}(\eta_{\mathfrak{P}})$.

Combining both parts proves the lemma. □

Lemma 7.662 (Finite–mesh audit: convergence under grid refinement)**.** *Let $\mathcal{G}_h$ be a sequence of grids with mesh size $h \to 0$, and let $\mathfrak{M}_{\mathrm{mask}}^{(h)}$ be the certified masks. If the oscillation bound of Definition 6.300 holds uniformly, then every compact subset of the limiting plateau set is eventually contained in $\mathfrak{M}_{\mathrm{mask}}^{(h)}$, and the reported observables converge uniformly on that subset.*

Proof. Step 1: Equicontinuity and uniform boundedness (plateau envelope). For each observable $Q \in \{\mu, \chi, s_{\mathrm{floor}}, \Lambda_\bullet, M_\pi^2, F, \ldots\}$ define its mesh–h version $Q^{(h)}(x)$ computed on $\mathfrak{M}_{\mathrm{mask}}^{(h)}$. The certified plateau hypothesis gives, for all sufficiently fine h and all x, y in a common certified mask,

$$|Q^{(h)}(x) - Q^{(h)}(y)| \;\le\; \eta_{\mathfrak{P}}\, d(x,y) \quad \text{(after a fixed rescaling of } d),$$

and $|Q^{(h)}(x)| \le C_Q$ uniformly (finite–energy window, tagger bounds). Thus $\{Q^{(h)}\}_h$ is an equicontinuous and uniformly bounded family on any compact K contained in the limiting plateau set.

Step 2: Cauchy property from the refinement gate. Between successive refinement levels the *convergence gate* on the common submask ensures

$$\|Q^{(h)} - Q^{(h/\rho)}\|_{L^\infty(K \cap \mathfrak{M}_{\mathrm{mask}}^{(h)} \cap \mathfrak{M}_{\mathrm{mask}}^{(h/\rho)})} \;\le\; c_{\mathrm{conv}}\, \eta_{\mathfrak{P}} \qquad (c_{\mathrm{conv}} = 2),$$

and the "improving physicality'' inequalities (monotone $\mu, \chi, s_{\text{floor}}$ with refinement) prevent loss of certification under further refinement. Iterating along a geometric mesh sequence shows $\{Q^{(h)}\}_h$ is Cauchy in the sup–norm on K up to the fixed plateau budget; hence there exists a uniform limit $Q^{(\infty)}$ on K.

Step 3: Eventual inclusion of compact subsets. Let K be a compact subset of the limiting plateau. By definition of the limiting set and the monotone "improving physicality'' gate, for all sufficiently small h the margin inequalities and floors (§ "Why these thresholds are not arbitrary", hyperbolicity/mass–gap/spectral floors) continue to hold at the refined resolution on K; therefore $K \subset \mathfrak{M}^{(h)}_{\text{mask}}$ eventually. (Intuitively: the discretization buffer in δ_{gap} scales like $3\,\Delta\lambda_{\text{grid}}(h)$ and shrinks under refinement, so once eligible, points remain eligible; see the monotonicity discussion in that section.)

Step 4: Uniform convergence on K. By Step 1 (equicontinuity) and Step 2 (Cauchy), the Arzelà–Ascoli theorem yields uniform convergence of $Q^{(h)}$ to $Q^{(\infty)}$ on K. The certification inequalities (mass/hyperbolicity margins, spectral floors) are closed under uniform limits, so $Q^{(\infty)}$ remains admissible and the mask stabilizes on K.

Therefore every compact K in the limiting plateau is eventually contained in $\mathfrak{M}^{(h)}_{\text{mask}}$, and all reported observables converge uniformly on K. □

Proposition 7.663 (Construction of the plateau mask)**.** *Given $\mathcal{G}$ and tolerances $(\eta_{\mathfrak{P}}$, fit tolerances$)$, the iterative procedure is as follows:*

- **(i)** *Select all points satisfying the plateau bounds of Definition 6.300.*
- **(ii)** *Prune points that violate Definition 7.659 along any fixed λ_{UV}–line.*
- **(iii)** *Prune isolated points that fail the finite–difference consistency checks for exponents/-margins.*

This produces a nonempty mask $\mathfrak{M}_{\text{mask}}$ such that all observables in Definition 7.660 are instrument–robust (Lemma 7.661) and mesh–convergent (Lemma 7.662).

Proof. Notation. For each grid point $x \in \mathcal{G}$ let $Q(x)$ denote any observable in Definition 7.660 (e.g. $\mu, \chi, s_{\text{floor}}, \Lambda_\bullet, M_\pi^2, F$) computed after band descent. Write

$$\mathcal{S}_1 := \{x \in \mathcal{G} : x \text{ satisfies Definition 6.300}\},$$
$$\mathcal{S}_2 := \{x \in \mathcal{S}_1 : x \text{ satisfies Definition 7.659 along its } \lambda_{\text{UV}}\text{-line}\}.$$

and let $\mathcal{S}_3$ be the subset of $\mathcal{S}_2$ left after removing points that fail the local finite–difference consistency checks (slopes/exponents/margins) with the stated fit tolerances. The algorithm outputs $\mathfrak{M}_{\text{mask}} := \mathcal{S}_3$.

1) Nonemptiness. By Definition 6.300 there exists a certified plateau $\mathfrak{P} \neq \varnothing$ on which the channel oscillations are bounded by $\eta_{\mathfrak{P}}$. All mask observables are continuous (indeed, real–analytic) in the control parameters by type–(A) analyticity and spectral isolation (Propositions 7.620 and 7.642 and Lemma 7.619); hence the acceptance inequalities of Definition 6.300 hold on an open neighbourhood of $\mathfrak{P}$. For any sufficiently fine grid $\mathcal{G}$, there exists at least one $x \in \mathcal{G} \cap \mathfrak{P}$, so $\mathcal{S}_1 \neq \varnothing$.

The inequalities in Definition 7.659 (monotone margins $\mu, \chi, s_{\text{floor}}$ along the λ_{UV}–line) are ensured by the *construction* of the thresholds and the refinement gate: the mass–gap and hyperbolicity reserves are pegged to $5\eta_{\mathfrak{P}}$ and the discretization buffer $3\Delta\lambda_{\text{grid}}$ shrinks geometrically (§ "Why these thresholds are not arbitrary"; see the "Refinement stability" bullet and Proposition 7.602 and Lemma 7.575). Thus, within $\mathcal{S}_1$ there is a nonempty subregion where these inequalities already hold and are preserved under refinement, so $\mathcal{S}_2 \neq \varnothing$.

Finally, by type–(A) analyticity the true derivatives/slopes exist and the finite–difference estimators are consistent on $\mathcal{S}_2$; choosing the fit tolerances as in the slope/visibility tests (Propositions 7.592, 7.594 and 7.599) removes only spurious, noise–induced outliers. Hence $\mathcal{S}_3 \neq \varnothing$.

2) Closure under the certification gates. Membership in $\mathcal{S}_1$ is defined by inequalities stable under $O(\eta_{\mathfrak{P}})$ perturbations and therefore is closed on $\mathcal{G}$ with respect to the plateau envelope; the pruning step (2) enforces additional *monotone* inequalities that are hereditary along each λ_{UV}–line (once satisfied, they remain satisfied under further geometric refinement because the discretization buffer decreases). Step (3) removes points that contradict the local analytic model (quadratic/cubic WLS in ϵ or ℓ); since Proposition 7.655 guarantees a nonempty analytic window where the quadratic tracker is valid and *not* improved by cubic terms, the pruning cannot delete that window. Thus the algorithm stabilizes on a nonempty certified set $\mathfrak{M}_{\text{mask}}$.

3) Instrument robustness on $\mathfrak{M}_{\text{mask}}$. On $\mathfrak{M}_{\text{mask}}$ all quantities are evaluated on $\mathcal{H}_{\text{phys}}$ with taggers that commute with BRST/G (Definition 7.551 and Proposition 7.573). Gauge–parameter variations are BRST–exact (Lemma 7.643), so physical matrix elements, spectra and residues are Nielsen–independent (Proposition 7.644). Admissible basis/scheme changes act by bounded similarities and preserve the ideal values; the only deviations are discretization/-tagger artefacts controlled by the plateau envelope. Consequently, Lemma 7.661 applies and yields instrument–robustness of all observables in Definition 7.660, with scheme drifts $\mathcal{O}(\eta_{\mathfrak{P}})$.

4) Mesh convergence. Because every $x \in \mathfrak{M}_{\text{mask}}$ satisfies Definition 6.300 uniformly and step (2) enforces "improving physicality," the hypotheses of Lemma 7.662 hold: the family of mesh–level observables is equicontinuous and uniformly bounded on compact subsets of the limiting plateau, and the convergence gate on the common submask makes the sequence Cauchy. Hence the reported observables converge uniformly on any compact subset of the limiting plateau and the certified masks eventually contain those subsets (Lemma 7.662).

5) Compatibility with GMOR/visibility diagnostics. Step (3) uses finite–difference and model–selection checks that are precisely those guaranteed by the analytic spectral/GMOR theory on plateaus (Theorems 7.630 and 7.646 and Proposition 7.655): accepted points are exactly those for which the quadratic (or linear-in–spurion) model is adequate within the plateau budget and for which no spurious IR–improvement (QIII) is detected (Proposition 7.599). Therefore the final mask satisfies all consistency requirements used elsewhere in the analysis.

Combining 1)–5) shows that the procedure outputs a nonempty $\mathfrak{M}_{\text{mask}}$ with instrument–robust and mesh–convergent observables, as claimed. □

Theorem 7.664 (Certified reporting on $\mathfrak{M}_{\text{mask}}$)**.** *On the certified mask $\mathfrak{M}_{\text{mask}}$ the following hold uniformly:*

Instrument robustness.
All reported visibilities, exponents, masses/mixings, GMOR slopes, and physical margins are gauge–independent and scheme–stable within $\mathcal{O}(\eta_{\mathfrak{P}})$ (Lemma 7.661).

Improving physicality with ℓ.
μ, χ, s_{floor} are nondecreasing in ℓ up to $\eta_{\mathfrak{P}}$ (Definition 7.659); in particular, $\mu > 0$ (no exact NG) and the T–odd floor persists (QIV law–deficit), consistent with Theorems 7.580 and 7.614.

Mesh convergence.
Reported values converge under grid refinement (Lemma 7.662).

Therefore, all quoted results are restricted to $\mathfrak{M}_{\mathrm{mask}}$, *ensuring that QIV conclusions (persistent law–deficit; unique–vacuum state channel; GMOR linear scaling) are made only where the instrumentation guarantees robustness on $\mathcal{H}_{\mathrm{phys}}$.*

Proof. Preliminaries. The mask $\mathfrak{M}_{\mathrm{mask}}$ is produced by the selection/pruning procedure of Proposition 7.663. Hence every $x \in \mathfrak{M}_{\mathrm{mask}}$ simultaneously satisfies: (i) the plateau envelope and channel oscillation bounds of Definition 6.300; (ii) the *improving physicality* inequalities along each λ_{UV}–line (Definition 7.659); and (iii) local finite–difference/fit consistency with the type–(A) analytic model and the QIV diagnostics (GMOR/visibility), so spurious outliers have been pruned.

(1) Instrument robustness. By Lemma 7.661, all reported observables on $\mathfrak{M}_{\mathrm{mask}}$

$$Q \in \{\mu, \chi, s_{\mathrm{floor}}, \Lambda_{\bullet}, M_{\pi}^2, F, \text{ visibilities/exponents/GMOR slopes}\}$$

are computed after band descent with taggers commuting with BRST/G, and their values are (i) gauge–parameter independent on $\mathcal{H}_{\mathrm{phys}}$ (Nielsen independence) and (ii) stable under admissible basis/scheme changes, up to $\mathcal{O}(\eta_{\mathfrak{P}})$ induced by finite mesh/tagger differences bounded by the plateau envelope. Therefore Item (1) holds uniformly on the mask.

(2) Improving physicality and persistence of the QIV signature. Membership in $\mathfrak{M}_{\mathrm{mask}}$ includes the monotonicity requirements of Definition 7.659: along increasing ℓ (IR coarse–graining) the margins μ (mass gap in the would–be NG sector), χ (hyperbolicity reserve), and the T–odd spectral floor s_{floor} are nondecreasing up to the plateau tolerance $\eta_{\mathfrak{P}}$. In particular, $\mu > 0$ everywhere on the mask, excluding exact NG modes and ensuring QIV (explicit breaking) rather than QII (SSB) behaviour; and $s_{\mathrm{floor}} > 0$ persists, providing a stable law–deficit in the T–odd channel. These statements are precisely the operational content of the QIV diagnostics recorded in Theorem 7.580 and are compatible with the non–signalling/tomographic completion in Theorem 7.614. Hence Item (2) follows.

(3) Mesh convergence. By construction (Proposition 7.663), the certified masks at successive refinement levels obey the convergence gate and "improving physicality'' monotonicity. The hypotheses of Lemma 7.662 are therefore satisfied: uniform oscillation control on the certified sets yields equicontinuity and uniform boundedness of all reported observables; the refinement gate provides a Cauchy property on common submasks; consequently the reported values converge uniformly on compact subsets of the limiting plateau. This proves Item (3).

Conclusion. Items (1)–(3) together imply that all reported QIV conclusions are made *only* on $\mathfrak{M}_{\mathrm{mask}}$, where (i) gauge/BRST robustness and scheme stability are guaranteed within

$\mathcal{O}(\eta_{\mathfrak{P}})$, (ii) physicality margins strengthen with IR scale so that the QIV T–odd signature persists, and (iii) mesh refinement does not change the reported values beyond the plateau budget. This is the claimed certified reporting property. □

7.9.16 Numerical Thresholds and Grid–refinement Schedule for the Mask

Context. We now *fix numbers* for the plateau tolerance and physicality margins and formalize the mesh–refinement audit that underpins Proposition 7.663 and Theorem 7.664. All statements act on $\mathcal{H}_{\text{phys}}$ and inherit BRST/Nielsen safety from Lemma 7.552 and Proposition 7.556.

Definition 7.665 (Fixed thresholds for the mask)**.** Let $\eta_{\mathfrak{P}} \in (0,1)$ be the plateau oscillation tolerance (Definition 6.300). We fix the following *numeric* thresholds:

1. **Plateau tolerance:** $\eta_{\mathfrak{P}} = 10^{-2}$ (1% envelope) by default. Tight variant for precision runs: $\eta_{\mathfrak{P}} = 5 \times 10^{-3}$.
2. **Gap threshold for the mass margin μ (near–degeneracy control):** Let $\Delta\lambda_{\text{grid}}(x)$ be the spectral resolution (eigenvalue discretization uncertainty) for the band Hessian at x. Set
$$\delta_{\text{gap}}(x) \;:=\; \max\Big\{\, 5\,\eta_{\mathfrak{P}}\,\Lambda_{\text{scale}}(x)\;,\; 3\,\Delta\lambda_{\text{grid}}(x)\,\Big\},$$
where $\Lambda_{\text{scale}}(x)$ is the local spectral scale (e.g. the median of nonzero eigenvalues of $\mathbb{H}^{(x)}$). The mass margin constraint in Definition 7.658 is then $\mu(x) \geq \delta_{\text{gap}}(x)$.
3. **Hyperbolicity margin χ:** Let $\chi(x)$ be the smallest *positive* principal–symbol eigenvalue margin preserving well–posedness (Definition 7.658). Impose
$$\chi(x) \;\geq\; \delta_{\text{hyp}}, \qquad \delta_{\text{hyp}} := 5\,\eta_{\mathfrak{P}}.$$
(For models with dynamical exponent $z \neq 1$, interpret the principal symbol with the anisotropic metric.)
4. **Spectral floor (law channel):** Let $s_{\text{floor}}(x)$ denote the minimal calibrated T–odd spectral weight over $|\omega| \leq \omega_0(x)$ (cf. Definitions 7.607 and 7.636). Require
$$s_{\text{floor}}(x) \;\geq\; s_{\min}, \qquad s_{\min} := 3\,\eta_{\mathfrak{P}},$$
and, correspondingly, the kernel floor $\kappa_{\text{spec}}(x)$ to satisfy $\kappa_{\text{spec}}(x) \geq \kappa_{\min} := 2\,\eta_{\mathfrak{P}}$ (cf. calibration in Proposition 7.602 and Definition 7.603).

A band point x is *mask–eligible* if all four inequalities hold.

Remark 7.666 (Units and normalization)**.** The margins μ, χ scale with the chosen spectral norm; we normalize by the local scale $\Lambda_{\text{scale}}(x)$ so that thresholds are dimensionless. The floors s_{floor} and κ_{spec} are already dimensionless (overlap/spectral–kernel quantities).

Definition 7.667 (Grid–refinement schedule)**.** Let $\mathcal{G}^{(m)}$ be the m–th grid on the $(\lambda_{\mathrm{UV}}, \ell)$ domain with spacings $h_\lambda^{(m)}, h_\ell^{(m)}$. The grid is refined geometrically from an initial grid $\mathcal{G}^{(0)}$ as follows:

$$\begin{aligned} h_\lambda^{(m+1)} &= \rho\, h_\lambda^{(m)}, \\ h_\ell^{(m+1)} &= \rho\, h_\ell^{(m)}, \\ \rho &\in \left[\tfrac{1}{2}, \tfrac{2}{3}\right]. \end{aligned}$$

At each refinement, the mask–eligible set $\mathfrak{M}^{(m)}$ is recomputed using the condition from Definition 7.665.

Definition 7.668 (Convergence metric and acceptance)**.** Consider an observable $Q \in \left\{ \Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}, \dots \right\}$. The Cauchy–type metric between consecutive grids on their common submask, $\mathfrak{M}^{(m+1)} \subseteq \mathfrak{M}^{(m)}$, is defined by:

$$\Delta^{(m)}[Q] \;:=\; \sup_{x \in \mathfrak{M}^{(m+1)}} \left| Q^{(m+1)}(x) - Q^{(m)}(x) \right|.$$

We *accept convergence* at level $m_\star$ if:

$$\Delta^{(m_\star - 1)}[Q] \;\le\; c_{\mathrm{conv}}\, \eta_{\mathfrak{P}} \quad \text{for all such observables } Q, \text{ with } c_{\mathrm{conv}} = 2,$$

and the *improving–physicality* condition holds, i.e., the quantities $\mu, \chi, s_{\mathrm{floor}}$ are *nondecreasing* with m on the nested masks (Definition 7.659).

Proposition 7.669 (Certified refinement and reporting)**.** *If the schedule of Definition 7.667 and thresholds of Definition 7.665 are enforced, and the acceptance criterion of Definition 7.668 holds at $m_\star$, then the mask $\mathfrak{M}_{\mathrm{mask}} := \mathfrak{M}^{(m_\star)}$ is* instrument–robust*: quoted exponents, masses, and deficits on $\mathfrak{M}_{\mathrm{mask}}$ vary by at most $2\eta_{\mathfrak{P}}$ under one further refinement. Certified reporting per Theorem 7.664 follows.*

Proof. Geometric refinement yields a Cauchy sequence in the sup–norm on the nested masks; the acceptance bound controls discretization error at $O(\eta_{\mathfrak{P}})$. Monotone margins ensure no spurious loss of physicality upon refinement. □

Remark 7.670 (Practical defaults)**.** Use $\eta_{\mathfrak{P}} = 10^{-2}$, $\rho = 1/2$, and stop after two successive accepted levels (with identical decisions for QIV/QIII/QII discrimination across the mask). For tougher problems, lower $\eta_{\mathfrak{P}}$ and raise δ_{gap} proportionally.

Why these thresholds are not arbitrary

The thresholds in Section 7.9.16 are fixed by three principles that are already part of the Chapter VII–VIII machinery: (i) a *single accuracy budget* set on certified plateaus $\mathfrak{P}$ (Definition 7.31 and Proposition 6.298), (ii) *dimensionless normalization* against the local spectral scale and the grid's spectral resolution, and (iii) *monotone refinement* with an explicit convergence gate (Definition 7.668, Proposition 7.663, and Theorem 7.664). Each inequality is just these principles written as numbers.

1) One budget to rule them all (plateau envelope). We first fix the plateau oscillation budget $\eta_{\mathfrak{P}}$ on $\mathfrak{P}$ (default 10^{-2}; tight 5×10^{-3}). This is not a knob for "tuning results"; it is the *unit of numerical significance* that already governs acceptance and Nielsen/BRST robustness on $\mathcal{H}_{\text{phys}}$ (Lemma 7.552 and Proposition 7.556). Every downstream gate is expressed as a small integer multiple of $\eta_{\mathfrak{P}}$. That decision ensures two things: (a) the mask is *dimensionless* and scales if we tighten/loosen the target accuracy, and (b) all channels (spectral T–odd, correlational T–even, kinematics) are compared in the *same currency*.

2) Dimensional correctness and dual buffering (near-degeneracy, hyperbolicity). The *mass-gap threshold*

$$\delta_{\text{gap}}(x) = \max\Big\{\, 5\,\eta_{\mathfrak{P}}\,\Lambda_{\text{scale}}(x),\; 3\,\Delta\lambda_{\text{grid}}(x)\Big\}, \qquad \mu(x) \geq \delta_{\text{gap}}(x),$$

is a direct transcription of dimensional and discretization control: $\Lambda_{\text{scale}}(x)$ (e.g. the median nonzero eigenvalue of the band Hessian) furnishes units, while $\Delta\lambda_{\text{grid}}(x)$ captures the grid's spectral granularity. Taking the *max* makes the decision invariant to whether the ambiguity comes from physics scale or from resolution; scaling μ by Λ_{scale} keeps the inequality dimensionless. The companion *hyperbolicity margin*

$$\chi(x) \geq \delta_{\text{hyp}}, \qquad \delta_{\text{hyp}} := 5\,\eta_{\mathfrak{P}},$$

enforces a positive reserve for the smallest principal-symbol eigenvalue in the first-order reduction, so well-posedness is not at the mercy of the plateau envelope; it is the numerical form of the kinematic sanity checks (tachyon/hyperbolicity) that already gate $\mathcal{A}_{\{\text{law,state}\}}$ (eq. (7.10), Definition 7.535, and Section 7.2.7).

3) Floors that come from physics (T–odd and kernel). QIV's law-deficit is *spectral* in origin at low frequency (Proposition 7.673). We therefore enforce a T–odd spectral *floor*

$$s_{\text{floor}}(x) \geq 3\,\eta_{\mathfrak{P}},$$

so the observed Ward-source signal is provably above the instrument envelope (Källén–Lehmann positivity keeps this honest on $\mathcal{H}_{\text{phys}}$). The tomography kernel is simultaneously constrained by

$$\kappa_{\text{spec}}(x) \geq 2\,\eta_{\mathfrak{P}},$$

so the reconstruction itself is never the bottleneck that triggers or suppresses the spectral signature. These two floors formalize the "spectral dominance" statement in Corollary 7.677(i) while keeping the correlational (T–even) readout cleanly quadratic in $\boldsymbol{\epsilon}$ through $C^{(x)}$ (Definition 7.674 and Lemma 7.675).

4) Why the specific multipliers $\{2,3,5\}$? They are *safety factors relative to* $\eta_{\mathfrak{P}}$ chosen to satisfy two monotonicity requirements that are used later in proofs:

- **Instrument clearance order:** kernel floor $2\eta_{\mathfrak{P}}$ < spectral floor $3\eta_{\mathfrak{P}}$ < hyperbolicity/mass-scale reserve $5\eta_{\mathfrak{P}}$. This strict ordering prevents *which* inequality is active from flipping under $\mathcal{O}(\eta_{\mathfrak{P}})$ oscillations on $\mathfrak{P}$ and guarantees that when the T–odd channel is above floor it cannot be "explained away" by kernel noise (Proposition 7.673).

- **Refinement stability:** under geometric refinement $h \mapsto \rho h$ with $\rho \in [1/2, 2/3]$, the discretization buffer $3\,\Delta\lambda_{\text{grid}}$ contracts fast enough that, once $\mu \geq \delta_{\text{gap}}$ holds, it keeps holding at the next level unless the *physical* scale changes—exactly the "improving physicality" criterion ($\mu, \chi, s_{\text{floor}}$ nondecreasing) used by the acceptance gate (Definition 7.668, Proposition 7.663, and Theorem 7.664).

These are the *smallest* integer factors that make the two requirements compatible with the convergence gate $c_{\text{conv}} = 2$ below. In other words: they are not cosmetic; they are the minimal constants that make the later lemmas go through with clean inequalities.

5) How the grid-refinement schedule locks in robustness. At each refinement level we recompute the mask with the *same* thresholds and require two things to accept level $m_\star$: (i) *common-submask agreement*

$$\Delta^{(m_\star - 1)}[Q] \leq c_{\text{conv}} \eta_{\mathfrak{P}}, \qquad c_{\text{conv}} = 2,$$

and (ii) *improving physicality* ($\mu, \chi, s_{\text{floor}}$ nondecreasing with level). The geometric ratio $\rho \in [1/2, 2/3]$ is chosen so that the discretization term in δ_{gap} shrinks fast enough to make the common-submask Cauchy property both *observable* and *independent of the (unknown) order* of the scheme. With $c_{\text{conv}} = 2$ and the safety order $2 < 3 < 5$, a short triangle-inequality argument yields the *Certified Reporting* bound:

> any observable reported on the accepted mask varies by at most $2\,\eta_{\mathfrak{P}}$ under one further refinement (Theorem 7.664).

This is precisely why the same integers $\{2, 3, 5\}$ appear across floors and margins: they are the constants that make the refinement proof close.

6) Defaults and scaling. The defaults $\eta_{\mathfrak{P}} = 10^{-2}$ and $\rho = 1/2$ are *calibration choices*, not physics claims: they give a conservative starting point where the safety order $2 < 3 < 5$ already implies the certified-reporting guarantee. Tightening accuracy simply *rescales all thresholds linearly* with $\eta_{\mathfrak{P}}$; for hard instances lower $\eta_{\mathfrak{P}}$ and raise δ_{gap} proportionally to preserve the same inequalities, so all the theorems and corollaries (Corollary 7.677) continue to apply verbatim.

Net effect. Mask eligibility reduces to four inequalities written in the single unit $\eta_{\mathfrak{P}}$, normalized by Λ_{scale} and buffered by $\Delta\lambda_{\text{grid}}$, then audited by a geometric refinement with a convergence gate. This is why the QIV statistics we report are (i) above instrument floor, (ii) dimensionally robust, (iii) mesh-independent at $\mathcal{O}(\eta_{\mathfrak{P}})$, and (iv) consistent with the channel-resolved narrative: spectral saturation for the law-deficit and correlational stiffness encoded by $C^{(x)}$ with localization via ∇_ϵ (Propositions 7.673 and 7.676, Definition 7.674, and Lemma 7.675).

7.9.17 Channel–resolved Holosymmetric Readout

We now make the channel decomposition *operational* and show how, in QIV, the **T–odd (spectral)** part of the law channel tracks persistent non–conservation (= Ward source), while the **T–even** quadratures encode stiffness / order–parameter responses to the explicit sources.

This both sharpens quadrant discrimination and *localizes* where the explicit breaking lives in the operator basis.

Definition 7.671 (Triadic channel projectors and quadratures)**.** Let $\{\Pi_\alpha\}_{\alpha\in\{\mathrm{corr,vac,spec}\}}$ be the orthogonal channel projectors for the holosymmetric readout (Definition 6.275), commuting with the band taggers (Definition 7.551). For $\bullet \in \{\mathrm{law}, \mathrm{state}\}$ and $x = (\lambda_{\mathrm{UV}}, \ell)$ set

$$\Lambda_\bullet^{(\alpha;x)} \;:=\; \mathrm{Tr}\Big[\Pi_\alpha\,(U_B^{(x)})^\dagger U_A^{(x)}\,\rho_0^{(x)}\Big], \qquad \Lambda_\bullet^{(x)} = \sum_\alpha \Lambda_\bullet^{(\alpha;x)} \quad \text{(Proposition 7.555)}.$$

For a complex readout Z, write its T–*odd* (spectral) quadrature as $-\operatorname{Re} Z$ (our sign convention), and its T–*even* quadrature as $\operatorname{Im} Z$ (Kubo/Taylor expansion aligns with these conventions below).

Definition 7.672 (Spectral (T–odd) tomography recap)**.** At $x \in \mathfrak{P}$, for a broken generator a, the T–odd spectral density $\mathsf{S}_a(x;\omega)$ and positive tomography kernel $\mathsf{K}_{\mathrm{spec}}(x;\omega)$ satisfy the representation

$$-\operatorname{Re}\,\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;=\; \int_{\mathbb{R}} d\omega\; \mathsf{K}_{\mathrm{spec}}(x;\omega)\,\mathsf{S}_a(x;\omega), \tag{7.744}$$

as established in Definition 7.607 and Lemma 7.578. Low–frequency mollifiers extract the Ward source $\mathcal{R}_a^{(x)} = \sum_k \epsilon_k \langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})}\rangle_{\mathbf{\Psi}}$ (Lemma 7.608), and yield the tomographic lower bound (Proposition 7.609 and Corollary 7.610).

Proposition 7.673 (T–odd channel tracks non–conservation (Ward source))**.** *On any certified plateau point $x \in \mathfrak{P}$ and for any broken a,*

$$1 - \left|\Lambda_{\mathrm{law}}^{(x)}\right| \;\geq\; -\operatorname{Re}\,\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;\gtrsim\; \kappa_{\mathrm{spec}}(x)\,c_0(x)\left|\mathcal{R}_a^{(x)}\right| \;-\; O(\eta_{\mathfrak{P}}),$$

with $\kappa_{\mathrm{spec}}(x), c_0(x) > 0$ the kernel floor and probe normalization constants (Proposition 7.609 and Lemma 7.608). Thus the spectral (T–odd) channel provides a linear *low–frequency tracker of the non–conservation fixed by the spurions.*

Proof. Step 1: Modulus deficit vs. T–odd real part. Decompose the law branch overlap into its vacuum/state/spectral/correlational pieces as in the spectral representation (eq. (7.744)). On a certified plateau, the vacuum piece is $1 + O(\eta_{\mathfrak{P}})$ (Theorem 7.589), and the T–even (correlational) contribution affects only the phase at order $O(\eta_{\mathfrak{P}})$ (Lemma 7.675). Hence the pointwise modulus deficit obeys the "gap" estimate

$$1 - \left|\Lambda_{\mathrm{law}}^{(x)}\right| \;\geq\; -\operatorname{Re}\,\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;-\; O(\eta_{\mathfrak{P}}),$$

cf. Lemma 7.578. Dropping the harmless $O(\eta_{\mathfrak{P}})$ term yields the first inequality stated.

Step 2: Tomographic lower bound from the spectral representation. From the spectral representation of the T–odd branch (e.g. eq. (7.706)), the real part satisfies

$$-\operatorname{Re}\,\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} = \int_{\mathbb{R}} \mathsf{K}_{\mathrm{spec}}(x;\omega)\,\mathsf{S}_a^{(x)}(\omega)\,d\omega,$$

with a nonnegative, continuous tomography kernel $\mathsf{K}_{\mathrm{spec}}$ (Definition 7.607) and a nonnegative low–frequency spectral density $\mathsf{S}_a^{(x)}$ (Källén–Lehmann positivity on $\mathcal{H}_{\mathrm{phys}}$). Restricting to

$|\omega| \le \omega_0(x)$ and using the kernel floor $\mathsf{K}_{\mathrm{spec}}(x;\omega) \ge \kappa_{\mathrm{spec}}(x) > 0$ there (Lemma 7.575 and Proposition 7.602), we obtain

$$-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;\ge\; \kappa_{\mathrm{spec}}(x)\int_{-\omega_0(x)}^{\omega_0(x)} \mathsf{S}_a^{(x)}(\omega)\,d\omega.$$

Approximating the sharp window by an even, normalized mollifier χ_τ supported in $[-\omega_0(x),\omega_0(x)]$ and using positivity gives (cf. Proposition 7.609)

$$-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;\ge\; \kappa_{\mathrm{spec}}(x)\,\mathcal{T}_a^{(x)}[\chi_\tau] \;-\; o_\tau(1),$$

where $o_\tau(1)\to 0$ as the bandwidth shrinks (or $\tau\to\infty$).

Step 3: Ward–source tracking at $\omega \approx 0$. By the Ward/PCAC matching at low frequency (Lemma 7.608),

$$\lim_{\tau\to\infty}\mathcal{T}_a^{(x)}[\chi_\tau] \;=\; c_0(x)\,|\mathcal{R}_a^{(x)}|, \qquad c_0(x)>0,$$

and, with the PCAC/LSZ bandwidth schedule, the finite–τ error can be made $O(\eta_{\mathfrak{P}})$ uniformly on $\mathfrak{P}$ (Lemma 7.637 and Proposition 7.638). Combining with Step 2 yields

$$-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;\gtrsim\; \kappa_{\mathrm{spec}}(x)\,c_0(x)\,|\mathcal{R}_a^{(x)}| \;-\; O(\eta_{\mathfrak{P}}),$$

where "$\gtrsim$" absorbs the controllable $o_\tau(1)$ into the plateau budget.

Step 4: Conclusion. Insert the bound from Step 3 into the modulus–deficit estimate from Step 1 to obtain the displayed chain of inequalities. The right–hand side is linear in the Ward source $|\mathcal{R}_a^{(x)}|$ with positive prefactor $\kappa_{\mathrm{spec}}(x)c_0(x)$, proving that the T–odd (spectral) channel *linearly* tracks explicit non–conservation at low frequency on certified plateaus. All steps are BRST/Nielsen safe on $\mathcal{H}_{\mathrm{phys}}$ by Lemma 7.552 and Proposition 7.556. □

Definition 7.674 (Spurion–resolved T–even stiffness tensor)**.** Let $U_B^{(x)\dagger}U_A^{(x)} = \exp\!\big(i\,\varepsilon_{\mathrm{IR}}(x)\,G_x - \tfrac{1}{2}\varepsilon_{\mathrm{IR}}(x)^2 C_x + \cdots\big)$ be the Duhamel/BCH expansion (Proposition 7.616). Define the *T–even stiffness tensor* at x by the quadratic response of the correlational channel,

$$C_{kk'}^{(x)} \;:=\; \int_0^1 ds\int_0^1 dt\;\theta(s-t)\,\Big\langle\{\,\mathcal{S}_k^{(x)}(s),\,\mathcal{S}_{k'}^{(x)}(t)\,\}_c\Big\rangle_{\Psi},$$

where $\{\cdot,\cdot\}_c$ is the connected anticommutator, $\mathcal{S}_k^{(x)}$ are the band–tagged source densities (adjoint indices suppressed), and all operators/states live on $\mathcal{H}_{\mathrm{phys}}$.

Lemma 7.675 (T–even holosymmetric quadrature equals stiffness quadratic form)**.** *To order ϵ^2,*

$$\operatorname{Im}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)} \;=\; -\tfrac{1}{2}\sum_{k,k'}\epsilon_k\,C_{kk'}^{(x)}\,\epsilon_{k'} \;+\; o(\epsilon^2),$$

with $C^{(x)}$ (cf. Definition 7.674) symmetric and positive semidefinite. Hence $\operatorname{Im}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)} \le 0$*, and its magnitude increases with the* stiffness *(static order response) to the explicit sources.*

Proof. Start from the Duhamel/BCH expansion of the holosymmetric branch overlap (see Proposition 7.616):

$$(U_B^{(x)})^\dagger U_A^{(x)} = \mathbf{1} \;+\; i\,\epsilon_k \int_0^1 ds\, \mathcal{S}_k^{(x)}(s) \;-\; \frac{\epsilon_k \epsilon_{k'}}{2} \int_0^1 ds \int_0^1 dt\, \theta(s-t)\, \big\{ \mathcal{S}_k^{(x)}(s), \mathcal{S}_{k'}^{(x)}(t) \big\} \;+\; \mathcal{O}(\epsilon^3),$$

up to the T–odd (commutator) quadratic piece which does not contribute to the correlational/T–even projection. Taking the expectation value in the physical sector $\mathcal{H}_{\text{phys}}$ and projecting onto the correlational (T–even) readout eliminates the $\mathcal{O}(\epsilon)$ term and retains only the anticommutator quadratic piece. By Definition 7.674,

$$C_{kk'}^{(x)} := \int_0^1 ds \int_0^1 dt\; \theta(s-t)\, \big\langle \{\, \mathcal{S}_k^{(x)}(s),\, \mathcal{S}_{k'}^{(x)}(t)\, \}_c \big\rangle_{\mathbf{\Psi}},$$

so the $\mathcal{O}(\epsilon^2)$ contribution to the *imaginary* part of the overlap phase is $-\frac{1}{2}\,\epsilon_k C_{kk'}^{(x)} \epsilon_{k'}$, yielding the stated identity (the $o(\epsilon^2)$ remainder collects higher cumulants).

Symmetry. Since the connected anticommutator is symmetric in $(k,s) \leftrightarrow (k',t)$ and $\theta(s-t) + \theta(t-s) = 1$, we may rewrite

$$C_{kk'}^{(x)} = \frac{1}{2} \int_0^1 ds \int_0^1 dt\; \big\langle \{\, \mathcal{S}_k^{(x)}(s),\, \mathcal{S}_{k'}^{(x)}(t)\, \}_c \big\rangle_{\mathbf{\Psi}} = C_{k'k}^{(x)}.$$

Positive semidefiniteness. For any real vector $v = (v_k)$ define the selfadjoint band–smeared operator $Y_v := \int_0^1 ds\, X_v(s)$ with $X_v(s) := \sum_k v_k\, \mathcal{S}_k^{(x)}(s)$. Using the previous symmetrisation,

$$v_k\, C_{kk'}^{(x)}\, v_{k'} = \frac{1}{2} \int_0^1 ds \int_0^1 dt\; \big\langle \{\, X_v(s), X_v(t)\, \}_c \big\rangle_{\mathbf{\Psi}} = \frac{1}{2} \big\langle \{\, Y_v, Y_v\, \}_c \big\rangle_{\mathbf{\Psi}} = \Big\langle \big(Y_v - \langle Y_v \rangle \big)^2 \Big\rangle_{\mathbf{\Psi}} \;\geq 0,$$

so $C^{(x)}$ is positive semidefinite. The overall minus sign in the lemma then implies $\operatorname{Im} \Lambda_{\text{law}}^{(\text{corr};x)} \leq 0$.

BRST/Nielsen robustness. Because $\mathcal{S}_k^{(x)}$ are BRST-closed channel sources and the readout is taken on $\mathcal{H}_{\text{phys}}$, the above quadratic form and the extracted phase are gauge-parameter independent on certified plateaus by Lemma 7.552 and Proposition 7.556. □

Proposition 7.676 (Localizing explicit breaking in operator space)**.** *Let $\boldsymbol{\epsilon} = (\epsilon_k)$ and consider the directional derivative of the T–even quadrature along the unit vector $\hat{\mathbf{e}}_j$ in spurion space. To leading order,*

$$\frac{\partial}{\partial \epsilon_j} \operatorname{Im} \Lambda_{\text{law}}^{(\text{corr};x)} \;=\; -\sum_k C_{jk}^{(x)}\, \epsilon_k \;+\; o(\epsilon).$$

Thus the vector $\mathbf{g}^{(x)} := -\nabla_\epsilon \operatorname{Im} \Lambda_{\text{law}}^{(\text{corr};x)} = C^{(x)} \boldsymbol{\epsilon} + o(\epsilon)$ identifies the subspace spanned by the active explicit–breaking operators $\{\mathcal{O}_k\}$; a sparse (or dominant–component) pattern in $\mathbf{g}^{(x)}$ localizes the breaking to specific operator directions.

Proof. By Lemma 7.675 and Definition 7.674,

$$\operatorname{Im} \Lambda_{\text{law}}^{(\text{corr};x)} \;=\; -\tfrac{1}{2} \sum_{k,k'} \epsilon_k\, C_{kk'}^{(x)}\, \epsilon_{k'} \;+\; r(\boldsymbol{\epsilon}), \qquad r(\boldsymbol{\epsilon}) = o(\epsilon^2),$$

with $C^{(x)}_{kk'} = C^{(x)}_{k'k}$. Differentiate w.r.t. ϵ_j:

$$\frac{\partial}{\partial \epsilon_j} \operatorname{Im} \Lambda^{(\mathrm{corr};x)}_{\mathrm{law}} = -\tfrac{1}{2} \sum_{k'} \Big(\delta_{jk}\, C^{(x)}_{kk'}\, \epsilon_{k'} + \epsilon_k\, C^{(x)}_{kj'}\, \delta_{j'k'} \Big) \;+\; \partial_{\epsilon_j} r(\boldsymbol{\epsilon}).$$

Using symmetry $C^{(x)}_{kj} = C^{(x)}_{jk}$, the two terms inside the sum coincide, giving

$$\frac{\partial}{\partial \epsilon_j} \operatorname{Im} \Lambda^{(\mathrm{corr};x)}_{\mathrm{law}} = -\sum_{k} C^{(x)}_{jk}\, \epsilon_k \;+\; o(\epsilon),$$

which is the stated component formula. In vector form, $-\nabla_\epsilon \operatorname{Im} \Lambda^{(\mathrm{corr};x)}_{\mathrm{law}} = C^{(x)}\boldsymbol{\epsilon} + o(\epsilon)$. Because $C^{(x)}$ is positive semidefinite (see Lemma 7.675), the quadratic form $-\frac{1}{2}\boldsymbol{\epsilon}^\top C^{(x)}\boldsymbol{\epsilon}$ decreases most steeply along the leading eigenvector(s) of $C^{(x)}$, so the large components of $\mathbf{g}^{(x)}$ select the operator directions that dominantly source the explicit breaking on $\mathcal{H}_{\mathrm{phys}}$. Gauge-parameter independence on certified plateaus follows from the BRST/Nielsen arguments cited in Lemma 7.675. □

Corollary 7.677 (Channel–resolved QIV signature)**.** *On any certified plateau $\mathfrak{P}$:*

Spectral (T–odd) saturation.
$-\operatorname{Re} \Lambda^{(\mathrm{spec};x)}_{\mathrm{law}}$ *saturates the law–deficit lower bound and tracks $|\mathcal{R}^{(x)}_a|$ (Proposition 7.673).*

Correlational (T–even) stiffness.
$\operatorname{Im} \Lambda^{(\mathrm{corr};x)}_{\mathrm{law}}$ *encodes the quadratic stiffness tensor $C^{(x)}$ (Lemma 7.675); its ϵ–gradient (Proposition 7.676) localizes the explicit breaking in operator space.*

Vacuum branch triviality.
$\Lambda^{(\mathrm{vac};x)}_{\mathrm{state}} \to 1$ *uniformly (Theorem 7.589); the vacuum piece does* not *contribute to the law deficit in QIV (Corollary 7.581).*

All statements hold on $\mathcal{H}_{\mathrm{phys}}$ and are Nielsen–stable (Lemma 7.552 and Proposition 7.556).

Proof. (1) *Spectral (T–odd) saturation.* Write the T–odd branch overlap to quadratic order by projecting the Duhamel/BCH series onto commutators:

$$-\operatorname{Re} \Lambda^{(\mathrm{spec};x)}_{\mathrm{law}} = \frac{1}{2} \sum_{k,k'} \epsilon_k \epsilon_{k'} \int_0^1 ds \int_0^1 dt\; \theta(s-t) \left\langle [\, \mathcal{S}^{(x)}_k(s), \mathcal{S}^{(x)}_{k'}(t)\,] \right\rangle_{\boldsymbol{\Psi}} \;+\; o(\epsilon^2).$$

Using the spectral (KL) representation of the commutator and the improved Ward identity for the explicitly broken charge, one obtains a lower bound in terms of the Ward source $\mathcal{R}^{(x)}_a$; on $\mathfrak{P}$, the normalised retarded kernel achieves equality up to $o(\epsilon^2)$ (plateau oscillations), whence the stated *saturation* and the tracking of $|\mathcal{R}^{(x)}_a|$ (Proposition 7.673).

(2) *Correlational (T–even) stiffness.* By Definition 7.674 and Lemma 7.675,

$$\operatorname{Im} \Lambda^{(\mathrm{corr};x)}_{\mathrm{law}} = -\tfrac{1}{2}\, \boldsymbol{\epsilon}^\top C^{(x)} \boldsymbol{\epsilon} \;+\; o(\epsilon^2), \qquad C^{(x)} \succeq 0,\; (C^{(x)})^\top = C^{(x)}.$$

Differentiating gives $-\nabla_\epsilon \operatorname{Im} \Lambda^{(\mathrm{corr};x)}_{\mathrm{law}} = C^{(x)}\boldsymbol{\epsilon} + o(\epsilon)$ (Proposition 7.676). The dominant components of this gradient identify the operator directions that most strongly source the explicit breaking on $\mathcal{H}_{\mathrm{phys}}$.

(3) *Vacuum branch triviality.* In QIV the physical vacuum is unique; by Theorem 7.589 the vacuum overlap obeys $\Lambda_{\text{state}}^{(\text{vac};x)} \to 1$ uniformly on $\mathfrak{P}$. The additive robustness result (Corollary 7.581) then shows that the total law deficit decomposes into spectral and correlational contributions only; the vacuum piece contributes neither at leading nor subleading order on $\mathfrak{P}$.

Finally, all three statements are evaluated in the BRST cohomology $\mathcal{H}_{\text{phys}}$, and invariance under gauge–parameter deformations on certified plateaus follows from the descent/Nielsen arguments in Lemma 7.552 and Proposition 7.556. □

Theorem 7.678 (Channel–resolved holosymmetric diagnostics (completion of Point 9))**.** *Assume Stage–I BRST viability, adjoint–covariant spurions, and a certified plateau $\mathfrak{P}$. Then for every $x \in \mathfrak{P}$ the holosymmetric readout admits the decomposition*

$$\Lambda_{\text{law}}^{(x)} \;=\; \underbrace{\Lambda_{\text{law}}^{(\text{spec};x)}}_{\substack{T\text{–odd, non–conservation}}} \;+\; \underbrace{\Lambda_{\text{law}}^{(\text{corr};x)}}_{T\text{–even, stiffness}} \;+\; \underbrace{\Lambda_{\text{law}}^{(\text{vac};x)}}_{\text{vacuum}},$$

with: (i) the spectral piece controlled from below by the Ward source (Proposition 7.673); (ii) the correlational piece determined to order ϵ^2 by the positive semidefinite stiffness tensor $C^{(x)}$ (Lemma 7.675); (iii) the vacuum piece trivial in QIV (Theorem 7.589). Hence the channel–resolved analysis simultaneously quantifies *persistent non–conservation and* localizes *explicit breaking, and is robust under BRST/Nielsen gates and plateau certification.*

Proof. Step 1: Existence of the channel decomposition. By definition of the holosymmetric readout and its spectral representation (see eqs. (7.706) and (7.744)), the law branch overlap decomposes into a sum of three pieces: (i) the *spectral* (T–odd) contribution $\Lambda_{\text{law}}^{(\text{spec};x)}$ built from the retarded two–point and its spectral density restricted by the cone–preserving taggers; (ii) the *correlational* (T–even) contribution $\Lambda_{\text{law}}^{(\text{corr};x)}$, coming from time–ordered even correlators in the spurion sources; and (iii) the *vacuum* contribution $\Lambda_{\text{law}}^{(\text{vac};x)}$. Time–reversal parity separates (i) and (ii), while linearity of the overlap functional gives the additive splitting, yielding the displayed decomposition. All constructions are on $\mathcal{H}_{\text{phys}}$ and commute with BRST/G (Definition 7.551 and Proposition 7.573).

Step 2: Spectral piece tracks the Ward source. On a certified plateau, Proposition 7.609 gives the tomographic lower bound $1-|\Lambda_{\text{law}}^{(x)}| \geq \kappa_{\text{spec}}(x)\,\mathcal{T}_a^{(x)}[\chi_\tau] - O(\eta_{\mathfrak{P}}) - o_\tau(1)$. The zero–frequency Ward/PCAC matching (Lemma 7.608), with the uniform error control from Lemma 7.637 and Proposition 7.638, implies $\mathcal{T}_a^{(x)}[\chi_\tau] = c_0(x)\,|\mathcal{R}_a^{(x)}| + O(\eta_{\mathfrak{P}})$. Combining and using the modulus–deficit vs. T–odd inequality (Lemma 7.578) yields precisely the bound stated in Proposition 7.673:

$$-\,\text{Re}\,\Lambda_{\text{law}}^{(\text{spec};x)} \;\gtrsim\; \kappa_{\text{spec}}(x)\,c_0(x)\,|\mathcal{R}_a^{(x)}| \;-\; O(\eta_{\mathfrak{P}}),$$

i.e. the spectral (T–odd) channel provides a *linear* low–frequency tracker of explicit non–conservation.

Step 3: Correlational piece encodes the T–even stiffness. Denote by $C^{(x)}$ the T–even stiffness tensor of Definition 7.674. The quadratic expansion proved in Lemma 7.675 gives, to order ϵ^2,

$$\text{Im}\,\Lambda_{\text{law}}^{(\text{corr};x)} \;=\; -\tfrac{1}{2}\sum_{k,k'} \epsilon_k\, C_{kk'}^{(x)}\, \epsilon_{k'} \;+\; o(\epsilon^2),$$

with $C^{(x)}$ symmetric positive semidefinite. Thus the correlational (T–even) piece is *determined* at $\mathcal{O}(\epsilon^2)$ by the static stiffness $C^{(x)}$, and its ϵ–gradient localizes the explicit breaking in operator space (cf. Proposition 7.676). This identifies the role of the T–even channel as a *stiffness tomograph*.

Step 4: Vacuum piece is trivial on QIV plateaus. The state–visibility guardrail Theorem 7.589 (and its operational tests, Corollary 7.590 and Propositions 7.592 and 7.594) implies that, in QIV with a unique vacuum on the band, the vacuum overlap obeys $\Lambda_{\text{state}}^{(\text{vac};x)} \to 1$ uniformly on $\mathfrak{P}$ as the volume window is certified; consequently $\Lambda_{\text{law}}^{(\text{vac};x)}$ does not contribute to the law deficit beyond $O(\eta_{\mathfrak{P}})$ (see also the vacuum triviality component recorded in the channel signature corollary).

Step 5: Robustness under BRST/Nielsen and the plateau gates. BRST-exact variations and total–derivative improvements vanish on $\mathcal{H}_{\text{phys}}$ (Lemma 7.552), and gauge–parameter (Nielsen) independence of poles/residues and of the spectral projectors holds by Proposition 7.644. The taggers commute with BRST/G and preserve cones (Definition 7.551 and Proposition 7.573), ensuring non–signalling and stability of the tomographic constructions (Proposition 7.612 and Theorem 7.614). Plateau certification (Definition 6.300) supplies the oscillation budget $\eta_{\mathfrak{P}}$ and the improving–physicality inequalities, making all statements uniform on $\mathfrak{P}$ (cf. Theorem 7.664).

Conclusion. Steps 2–4 establish items (i)–(iii) for the three channels, while Step 5 provides the robustness claims. Therefore the channel–resolved holosymmetric analysis simultaneously quantifies the persistent non–conservation (T–odd) and localizes explicit breaking via stiffness (T–even), with the vacuum piece trivial on QIV plateaus, completing Point 9. □

7.9.18 Channel–resolved Readout: Operational Note (What Drives What)

Context. By Proposition 7.555, holosymmetric visibilities decompose as:

$$\Lambda_{\bullet}^{(x)} = \sum_{\alpha \in \{\text{spec},\text{corr},\text{vac}\}} \Lambda_{\bullet}^{(\alpha;x)}.$$

In QIV the *T–odd spectral* piece controls the law-deficit, while the *T–even correlational* piece quantifies stiffness/ordering responses to explicit spurions. We formalize the readout and the reporting map.

Definition 7.679 (Channel projectors and readouts)**.** Let $\{\Pi_{\text{spec}}, \Pi_{\text{corr}}, \Pi_{\text{vac}}\}$ be the orthogonal projectors of Proposition 7.555, commuting with the taggers (Definition 7.551). Define

$$\Lambda_{\text{law}}^{(\alpha;x)} := \text{Tr}\Big[\big(\Pi_\alpha U_B^{(x)} \Pi_\alpha\big)^\dagger \big(\Pi_\alpha U_A^{(x)} \Pi_\alpha\big)\, \rho_0^{(x)}\Big], \quad \alpha \in \{\text{spec}, \text{corr}, \text{vac}\}.$$

The *spectral* branch is T–odd and admits the tomography representation of Definition 7.607; the *correlational* branch is T–even and is generated by connected two–point response to spurions.

Proposition 7.680 (Primary driver of the law–deficit)**.** *On a certified plateau $\mathfrak{P}$, the modulus deficit satisfies*

$$1-|\Lambda_{\mathrm{law}}^{(x)}| \;\geq\; -\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \quad \textit{and} \quad -\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} = \int d\omega\, \mathsf{K}_{\mathrm{spec}}(x;\omega)\; \mathsf{S}_a(x;\omega),$$

with S_a the T–odd spectral density (Definition 7.607). Equality holds up to T–even contributions and plateau oscillations. Hence the spectral *piece is the primary quantitative driver for the law deficit.*

Proof. Step 1: Channel decomposition and vacuum triviality. Decompose the law–branch overlap into spectral (T–odd), correlational (T–even), and vacuum pieces,

$$\Lambda_{\mathrm{law}}^{(x)} = \Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} + \Lambda_{\mathrm{law}}^{(\mathrm{corr};x)} + \Lambda_{\mathrm{law}}^{(\mathrm{vac};x)}.$$

On a certified plateau, the vacuum branch is trivial: $\Lambda_{\mathrm{law}}^{(\mathrm{vac};x)} = 1 + O(\eta_{\mathfrak{P}})$ uniformly (Theorem 7.589). Moreover, the correlational branch contributes at order ϵ^2 with *T–even* phase: $\operatorname{Im}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)} = -\frac{1}{2}\,\epsilon^{\top} C^{(x)} \epsilon + o(\epsilon^2)$ and $\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)} = O(\epsilon^3)$ (Lemma 7.675), hence $|\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)}| = O(\epsilon^2)$.

Step 2: Modulus–deficit lower bound by the T–odd real part. Write $A := \Lambda_{\mathrm{law}}^{(\mathrm{vac};x)} + \Lambda_{\mathrm{law}}^{(\mathrm{spec};x)}$ and $B := \Lambda_{\mathrm{law}}^{(\mathrm{corr};x)}$. The triangle inequality gives

$$1-|\Lambda_{\mathrm{law}}^{(x)}| = 1-|A+B| \;\geq\; 1-|A|-|B| \;=\; \big(1-|A|\big) \;-\; O(\epsilon^2),$$

where $O(\epsilon^2)$ is within the plateau budget $O(\eta_{\mathfrak{P}})$ by certification. Now A is real up to $O(\eta_{\mathfrak{P}})$ because the T–odd piece contributes to the *real* part and the vacuum piece is real, whence $|A| = A + O(\eta_{\mathfrak{P}})$. Using $\Lambda_{\mathrm{law}}^{(\mathrm{vac};x)} = 1 + O(\eta_{\mathfrak{P}})$,

$$1-|A| = 1-\Big(1+\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)}\Big) + O(\eta_{\mathfrak{P}}) = -\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;+\; O(\eta_{\mathfrak{P}}).$$

Combining the two displays yields

$$1-|\Lambda_{\mathrm{law}}^{(x)}| \;\geq\; -\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} \;-\; O(\eta_{\mathfrak{P}}),$$

which is the stated bound "up to T–even contributions and plateau oscillations." Dropping the harmless $O(\eta_{\mathfrak{P}})$ remainder gives the first inequality in the proposition.

Step 3: Spectral representation (tomography identity). By the definition of T–odd tomography (Definition 7.607) and the spectral (Källén–Lehmann) representation on $\mathcal{H}_{\mathrm{phys}}$, the T–odd real part equals the positive quadratic form of the spectral density:

$$-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} = \int_{\mathbb{R}} \mathsf{K}_{\mathrm{spec}}(x;\omega)\; \mathsf{S}_a(x;\omega)\, d\omega,$$

with $\mathsf{K}_{\mathrm{spec}}(x;\omega) \geq 0$ continuous on compact ω–windows (cone–preserving taggers) and $\mathsf{S}_a \geq 0$ the T–odd spectral density. This is the second identity in the statement.

Step 4: Primary driver conclusion. The correlational (T–even) piece affects the modulus only at $O(\epsilon^2)$ and enters primarily as a phase (Step 1), while the vacuum piece is unity up

to $O(\eta_{\mathfrak{P}})$. Therefore the spectral integral in Step 3 provides the dominant, quantitatively controlled contribution to the modulus deficit, establishing that the *spectral* channel is the primary driver of the law–deficit on certified plateaus.

This completes the proof. □

Definition 7.681 (Operator–space localization vector)**.** Let $\epsilon = (\epsilon_k)$ be the spurion vector and define the *operator–space localization*

$$\mathbf{g}^{(x)} \in \mathbb{R}^K, \qquad g_k^{(x)} := \frac{\partial}{\partial \log|\epsilon_k|}\Big(-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)}\Big)\Big|_{\epsilon=\epsilon^*},$$

evaluated at the working point ϵ^* inside the GMOR linear window (Definitions 7.634 and 7.654). Normalize $\tilde{\mathbf{g}}^{(x)} = \mathbf{g}^{(x)}/\|\mathbf{g}^{(x)}\|_1$ to report a probability–like attribution over explicit operators.

Lemma 7.682 (Computation via sensitivity WLS)**.** *Vary one spurion at a time $\epsilon_k \mapsto (1+\delta)\epsilon_k$ with $\delta = \pm\delta_0$ (small, inside Definition 7.654), hold all other spurions fixed, and fit the symmetric difference of the correlational channel by WLS. Denoting*

$$f^{(x)}(\epsilon) := -\operatorname{Im}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)}(\epsilon) \qquad (\textit{so that } \nabla_\epsilon f^{(x)} = \mathbf{g}^{(x)} \textit{ with } g_k^{(x)} = (C^{(x)}\epsilon)_k + o(\epsilon)),$$

the weighted least–squares slope from the data

$$Y_j := f^{(x)}\big(\epsilon+\delta_j\epsilon_k\mathbf{e}_k\big) - f^{(x)}\big(\epsilon-\delta_j\epsilon_k\mathbf{e}_k\big), \qquad X_j := 2\,\epsilon_k\,\delta_j, \qquad \delta_j \in \{\pm\delta_0,\ \textit{or a small grid}\},$$

provides an estimator $\widehat{g}_k^{(x)}$ with bias $O(\delta_0^2)$*. The construction is BRST/Nielsen safe on $\mathcal{H}_{\mathrm{phys}}$ by Lemma 7.552 and Proposition 7.556.*

Proof. (a) Second–order accurate symmetric difference. Fix x and the baseline spurion vector ϵ (inside the analytic window of Definition 7.654). By type–(A) analyticity (Proposition 7.642), $f^{(x)}$ admits a multivariate Taylor expansion in a neighbourhood of ϵ. Along the coordinate line in direction $\mathbf{e}_k$,

$$f^{(x)}(\epsilon \pm \delta\,\epsilon_k\mathbf{e}_k) = f^{(x)}(\epsilon) \pm \delta\,\epsilon_k\,\partial_{\epsilon_k}f^{(x)}(\epsilon) + \tfrac{1}{2}(\delta\,\epsilon_k)^2\,\partial_{\epsilon_k}^2 f^{(x)}(\epsilon) \pm \tfrac{1}{6}(\delta\,\epsilon_k)^3\,\partial_{\epsilon_k}^3 f^{(x)}(\epsilon_\pm),$$

for some $\epsilon_\pm$ between ϵ and $\epsilon \pm \delta\,\epsilon_k\mathbf{e}_k$. Subtracting the "±" expansions cancels *all even* derivatives and yields

$$Y(\delta) := f^{(x)}(\epsilon+\delta\,\epsilon_k\mathbf{e}_k) - f^{(x)}(\epsilon-\delta\,\epsilon_k\mathbf{e}_k) = 2\,\delta\,\epsilon_k\,\partial_{\epsilon_k}f^{(x)}(\epsilon) + O\Big((\delta\,\epsilon_k)^3\Big).$$

Divide by $X(\delta) = 2\,\epsilon_k\,\delta$ to get the central–difference estimator

$$\frac{Y(\delta)}{X(\delta)} = \partial_{\epsilon_k}f^{(x)}(\epsilon) + O(\delta^2),$$

i.e. a *bias* of order $O(\delta^2)$ (the constant is controlled by a uniform bound on $\partial_{\epsilon_k}^3 f^{(x)}$ inside the analytic window). Since $g_k^{(x)} = \partial_{\epsilon_k}f^{(x)}(\epsilon)$ by definition (recall $f^{(x)} = -\operatorname{Im}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)}$ and Lemma 7.675), this shows the basic second–order accuracy.

(b) WLS with multiple symmetric pairs. Collect pairs $\{\pm\delta_j\}$ (e.g. $\delta_j \in \{\delta_0, 2\delta_0\}$) and define (Y_j, X_j) as in the statement. Then

$$Y_j \;=\; X_j\, g_k^{(x)} \;+\; b_j, \qquad |b_j| \;\le\; C\,|\epsilon_k|^3\,|\delta_j|^3,$$

for some C uniform on the certified mask (plateau compactness). Weighted least squares with positive weights w_j solves $\widehat{g}_k^{(x)} = (\sum_j w_j X_j^2)^{-1} \sum_j w_j X_j Y_j$ and satisfies

$$\widehat{g}_k^{(x)} - g_k^{(x)} = \frac{\sum_j w_j X_j b_j}{\sum_j w_j X_j^2} = O\Big(\max_j \delta_j^2\Big) =: O(\delta_0^2),$$

because $X_j \propto \delta_j$ while $b_j = O(\delta_j^3)$. Thus the WLS estimator inherits the *second–order* bias of the central difference and can reduce variance in the presence of heteroscedastic readout noise.

(c) BRST/Nielsen safety. The correlational channel is built from band–descended, BRST–commuting taggers (Definition 7.551 and Proposition 7.573); therefore $f^{(x)}$ is computed from physical matrix elements on $\mathcal{H}_{\mathrm{phys}}$. Gauge–parameter variations are BRST–exact (Nielsen identity), so physical matrix elements and spectral data are gauge–independent (Lemma 7.643 and Proposition 7.556). Consequently, both $g_k^{(x)}$ and its estimator $\widehat{g}_k^{(x)}$ are BRST/Nielsen safe; varying α_{gf} changes neither the target derivative nor the regression design, up to the numerical/plateau tolerance.

(d) Consistency with stiffness tomography. From Lemma 7.675 we have $-\operatorname{Im}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)} = \frac{1}{2}\epsilon^\top C^{(x)}\epsilon + o(\epsilon^2)$, hence $g_k^{(x)} = (C^{(x)}\epsilon)_k + o(\epsilon)$. The sensitivity–WLS procedure above therefore provides an operational readout of the k–th component of $C^{(x)}\epsilon$ with $O(\delta_0^2)$ bias, justifying its use for localizing explicit breaking (Proposition 7.676).

This proves the lemma. □

Remark on notation. The T–even correlational piece contributes to the *imaginary* part (cf. Lemma 7.675). If an alternative convention is used in which it contributes to the real part, the proof carries over verbatim with Im replaced by Re throughout.

Remark 7.683 (Spatial localization (optional))**.** If spurions are spatially addressable (e.g. patterned sources), define region weights $\{\omega_m\}$ and repeat the sensitivity protocol with local toggles to obtain a coarse spatial map $G_m^{(x)} := \partial_{\omega_m}(-\operatorname{Re}\Lambda_{\mathrm{law}}^{(\mathrm{corr};x)})$. Cone–preserving kernels (Section 7.9.3) ensure causal interpretability.

Definition 7.684 (Reporting (channel–resolved))**.** Per $x \in \mathfrak{P}$ (or inside $\mathfrak{M}_{\mathrm{mask}}$):

1. **Law deficit:** report $1 - |\Lambda_{\mathrm{law}}^{(x)}|$ and its tomographic lower bound $K_{\mathrm{low}}(x)|\mathcal{R}_a^{(x)}|$ (Corollary 7.605); include $\kappa_{\mathrm{spec}}(x)$ and $\widehat{c}_0(x)$.
2. **Spectral (T–odd):** plot $\mathsf{S}_a(x;\omega)$ over $[-\omega_0(x), \omega_0(x)]$ and the kernel $\mathsf{K}_{\mathrm{spec}}$; give $\int \mathsf{K}_{\mathrm{spec}}\mathsf{S}_a$ with CI.
3. **Correlational (T–even):** list $\tilde{\mathbf{g}}^{(x)}$ with CIs; identify dominant spurions/operators.
4. **Vacuum:** state the (near–)unity Λ_{vac} piece (unique vacuum) with the envelope selected in Section 7.9.6.

All quantities are computed on $\mathcal{H}_{\mathrm{phys}}$ and are gauge–flat within the audited tolerances (Section 7.9.14).

7.9.19 Synthesis of QIV

Quadrant IV (QIV) is the "explicitly broken, asymmetrically prepared" regime in which the BRST-improved adjoint-covariant Ward identity on the physical sector carries a non-vanishing source,

$$\nabla_\mu^{(\mathrm{ad})}\, \bar{J}_{a,\mathrm{imp}}^{(\lambda_{\mathrm{UV}},\ell)\mu} = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,a}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} \quad \text{on } \mathcal{H}_{\mathrm{phys}} \qquad (eq.\ (7.665)).$$

Because the divergence along broken directions does not vanish on certified plateaus (Theorem 7.570), exact conservation fails and Goldstone's theorem does not apply. Consequently there are **no exact NG poles**; instead the would-be NG modes pick up **small but nonzero gaps** fixed by a GMOR-type identity that holds on the plateau:

$$f_{\pi_b}^2\, m_{\pi_b}^2 = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} + \mathcal{O}(\epsilon^2),$$

with b any broken generator, f_{π_b} the decay constant in the $\epsilon \to 0$ limit, and the slope read off from the band-tagged Ward source (see Theorem 7.630 and Corollary 7.631; background [94, 100, 91, 112]). On a certified mask, this produces the characteristic *linear scaling* $m_{\pi_b}^2 \propto \epsilon$ with vanishing intercept within plateau tolerance.

The *pattern of splittings* across the light sector is dictated by representation theory of the spurions. By construction, the explicit couplings $\{\epsilon_k\}$ transform in the dual G-module to the breaking operators $\{\mathcal{O}_k\}$ (Definition 7.559 and Lemma 7.566); the Ward source is adjoint-covariant (Proposition 7.568). Within any would-be multiplet, *degeneracies split at* $O(\epsilon)$ according to how the spurion irrep projects onto the broken directions. The cleanest way to follow this is the *cluster view* developed for near-crossings: isolate a pNG cluster by a Riesz projector, track its analytic subspace, and use Kato parallel transport for eigenframe labeling (Definition 7.618, Lemma 7.619, and Proposition 7.620). In that setting, the *subspace GMOR map* remains linear, while individual level slopes stay analytic away from avoided crossings.

All of this sits on a robust analytic foundation. The band-limited Hessian $\mathbb{H}^{(x)}(\epsilon)$ on $\mathcal{H}_{\mathrm{phys}}$ is a **type-(A) analytic family** in the explicit couplings (Proposition 7.642); hence *mixing angles are analytic and small*, $\theta = O(\epsilon)$, and can be tracked unambiguously along isolated clusters by Kato transport (Proposition 7.620). The **radial/Higgs sector** remains gapped on the mask, and its masses/couplings shift *analytically* in ϵ (linear terms from explicit sources plus quadratic curvature corrections), with no singular behavior permitted inside the certified mask (Proposition 7.663 and Theorem 7.664). Moreover, **poles and residues are gauge-flat** on $\mathcal{H}_{\mathrm{phys}}$: Nielsen independence holds theoretically (Proposition 7.644 and Theorem 7.646) and operationally via the *Nielsen slope test* (Section 7.9.14), where $S_{\mathrm{Nielsen}} \le \epsilon_{\mathrm{Nielsen}}$ certifies that quoted matrix elements such as $f_{\pi_b} = \langle 0|\bar{J}_{b,\mathrm{imp}}|\pi_b\rangle$ are physically meaningful.

On the diagnostics side, QIV's law channel is driven by a *T-odd spectral weight* tied to the non-conservation source. The spectral (T-odd) component of the holosymmetric readout admits a positive tomography representation,

$$-\,\mathrm{Re}\;\Lambda_{\mathrm{law}}^{(\mathrm{spec};x)} = \int d\omega\, \mathsf{K}_{\mathrm{spec}}(x;\omega)\, \mathsf{S}_a(x;\omega),$$

where S_a is the retarded spectral density of $\nabla^{(\mathrm{ad})} \cdot \bar{J}_{a,\mathrm{imp}}$ and $\mathsf{K}_{\mathrm{spec}}$ is a cone-preserving kernel floor (see Definition 7.607, Lemma 7.575, Proposition 7.609, and Corollary 7.610). This same low-ω weight both **sets the law-visibility deficit** and **predicts pNG masses** through the GMOR fit, closing the Ward–mass loop (Theorems 7.580 and 7.630). Complementarily, the **T-even correlational branch** yields an **operator-space localization vector** $\mathbf{g}^{(x)}$ that identifies which explicit operators dominate the observed stiffness and splittings; its computation by small spurion toggles is BRST/Nielsen safe and provides actionable attribution for mass shifts (Section 7.9.18, Definitions 7.681 and 7.684, and Lemma 7.682).

Finally, QIV's **state channel is trivial** in the thermodynamic sense: explicit terms select a **unique vacuum**, so $|\Lambda_{\mathrm{state}}(x;V)| \to 1$ with a certified envelope (exponential if gapped, power-law if critical but non-SSB), ruling out thermodynamic orthogonality and eliminating *topological vacuum relics* such as domain-wall or string zero modes (Definition 7.582 and Theorem 7.589). All "soft" long-distance physics in QIV is thus encoded in **light pseudo-Goldstones**, not in a vacuum manifold.

These conclusions *sharply separate QIV from the other quadrants*. In **QI** (symmetric vacuum, no explicit breaking; Section 7.1) the law channel *conserves on the band* and there is *no pNG sector*—the spectrum is whatever $\mathcal{L}_0$ provides. In **QII** (SSB; Section 7.7) one finds *exact NG modes* and *state decoherence* with volume (orthogonal vacua), while the law channel is effectively conserved up to improvements; **QIV flips both features**: a **unique vacuum** and **no exact NG**, only pNG with $m_\pi^2 \propto \epsilon$. In **QIII** (small explicit breakings but symmetric state; Section 7.8) the non-conservation *heals in the IR* so the law-deficit improves like $\ell^{\Delta-(d+z)}$, and there is *no asymmetric state*—hence *no pNG sector*. **QIV**, by contrast, shows a **scale-independent saturation deficit** on the law channel together with a **light, linearly scaling pNG band**, both certified on $\mathcal{H}_{\mathrm{phys}}$ and robust under BRST/Nielsen gates and plateau audits (Theorem 7.580, Corollary 7.617, and Propositions 7.569 and 7.616).

Within QIV the **spin content is fixed by the symmetric limit and is not altered by the explicit breaking**. What changes are the **masses and mixings**, not the Lorentz (or rotational) representation carried by each mode. Concretely, work on $\mathcal{H}_{\mathrm{phys}}$ with the QIV hypotheses and the scale–tagged Ward identity (eq. (7.665)). In the *internal–symmetry* case (the QII benchmark breaks $G \to H_0$ without touching spacetime symmetries), every would–be NG is a *Lorentz scalar*; in QIV each becomes a **pseudo–NG scalar** with a small gap from the GMOR relation on the plateau,

$$f_{\pi_b}^2\, m_{\pi_b}^2 = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\mathrm{UV}})} \right\rangle_{\mathbf{\Psi}} + \mathcal{O}(\epsilon^2),$$

so their **spin remains** 0 while $m_{\pi_b}^2 = O(\epsilon)$ (Theorem 7.630 and Corollary 7.631). The **radial (Higgs) modes**—amplitude fluctuations of the order parameter—are also **spin–0** and stay gapped; their masses shift *analytically* in ϵ by type–(A) perturbation theory on the band (Proposition 7.642 and Theorem 7.646).

If some broken directions are *gauged*, BRST projection removes the corresponding would–be NGs ("eaten" longitudinal modes), and the physical spectrum contains **massive spin–1 vectors** with the usual three polarizations; this counting is handled on $\mathcal{H}_{\mathrm{phys}}$ by the Stage-I gate and the descent lemmas (Lemma 7.552) and remains *Nielsen–independent* (Proposition 7.644). Again, the explicit breaking shifts masses/mixings *analytically* in ϵ without changing spin.

If *spacetime symmetries* (e.g. translations/rotations) are the ones broken in the $\epsilon \to 0$ benchmark, the QII NG content is phonon/rotational modes with definite *polarizations* under the spatial rotation group (or its lattice point group). In QIV those become *pseudo–NGs with the same polarization content* (same little-group representation), now with a small gap $O(\epsilon)$. Our scale–aware formalism (dynamic exponent z, cone-preserving taggers) and the Ward–mass link apply verbatim; the *polarization labels* are inherited from the symmetric limit and are unaffected by turning on $\{\epsilon_k\}$ (Section 7.9.3, Definition 7.607, and Theorem 7.630).

Mixings respect these spin/polarization labels: the *band Hessian* $\mathbb{H}^{(x)}(\epsilon)$ decomposes into irreps of the little group, so *modes of different spin (or different J^{PC}/point-group irrep)* do **not** mix at quadratic order unless spacetime symmetry is itself explicitly broken by the spurions. Within a fixed spin/irrep block, mixings are *analytic and* $O(\epsilon)$ and are tracked by *Kato transport* on isolated clusters (Definition 7.618 and Proposition 7.620). All pole residues/decay constants used to identify spins are *gauge-flat* by Nielsen independence (Proposition 7.644 and Theorem 7.630).

1. For *internal* symmetry breaking: expect **spin-0** pNGs (one per QII NG), plus **spin-0** radial modes and whatever other gapped content the QI baseline had; explicit breaking only makes the pNGs light but massive and perturbs gaps/mixings analytically.

2. For *spacetime* symmetry breaking: expect the **same polarization content** as in QII (e.g. longitudinal/transverse phonons), now as **gapped pseudo-modes** with $m^2 = O(\epsilon)$.

3. If some broken directions are *gauged*, the physical spectrum shows **massive spin-1** vectors (Higgs mechanism) and *no* corresponding pNGs on $\mathcal{H}_{\text{phys}}$.

In all cases, QIV's explicit breaking **does not change spin**; it controls **masses and mixings**—and we certify both analytically and gauge-independently on the plateau using the mass/mixing ledger, GMOR fits, and Nielsen tests (Sections 7.9.10 and 7.9.14 and Theorem 7.630).

First, we place the two stacks in the canonical roles we established upstream: the **gaiamiti fields** live in the configuration/order-parameter stack $\hat{\mathbf{\Phi}}$, while the **tantrakyma fields** comprise the gauge-and-scaffold stack $\hat{\mathbf{\Theta}}$ (connections A_μ, gauge-fixing auxiliaries, and BRST doublets). The generalized field vector is $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^\top$ and all statements are taken **on the physical sector** $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ after the Stage-I gate (nilpotent ζ, anomaly-free) so that our readouts are **Nielsen-independent** and **BRST-safe** (Lemma 7.552, Proposition 7.556, and Theorem 7.646).

Spins and masses from the gaiamiti sector $\hat{\mathbf{\Phi}}$ In the $\epsilon \to 0$ benchmark (QI/QII reference), let the internal symmetry G act on $\hat{\mathbf{\Phi}}$ with vacuum breaking $G \to H_0$. The **broken generators** then label would-be NG directions in the $\hat{\mathbf{\Phi}}$ manifold; these modes carry the **spin content of the symmetric limit**. For **internal** G, that means **spin-0** scalars. Turning on QIV's explicit spurions $\{\epsilon_k\}$ lifts those flat directions to **light pseudo-NG (pNG) scalars** with masses fixed on the plateau by the GMOR-type Ward–mass relation (eq. (7.665), Theorem 7.630, and Corollary 7.631):

$$f_{\pi_b}^2\, m_{\pi_b}^2 = \sum_k \epsilon_k \left\langle \mathcal{S}_{k,b}^{(\lambda_{\text{UV}})} \right\rangle_{\mathbf{\Psi}} + \mathcal{O}(\epsilon^2), \quad b \in \mathfrak{g}/\mathfrak{h}_0.$$

Thus **spin stays** 0 and **mass is generated linearly in the spurions** across the certified mask. Within any would-be multiplet, pNG **mass splittings** appear at $O(\epsilon)$ according to the **spurion irrep** that pairs with $\{\mathcal{O}_k\}$ (Definition 7.559 and Lemma 7.566); slopes are analytic and tracked reliably away from avoided crossings by the **Riesz/Kato** machinery (Definition 7.618 and Proposition 7.620). The **radial (Higgs) modes** in $\hat{\Phi}$ remain **spin-0 and gapped**; their masses are the positive eigenvalues of the band Hessian in the orthogonal (amplitude) directions and shift **analytically** in ϵ by type-(A) perturbation theory (Proposition 7.642 and Theorem 7.646). No singular behavior is permitted inside the plateau mask (Proposition 7.663 and Theorem 7.664).

If, instead, the reference breaking involves *spacetime symmetries* (e.g. broken translations/rotations carried by tensorial components of the gaiamiti sector), the QII benchmark yields phonon/rotational NGs with definite *polarizations* under the spatial little group. In QIV those become *gapped pseudo-phonons* with *the same polarization content*; spins/polarizations are inherited unchanged, while the small gap obeys the same Ward–mass logic (our cone-preserving taggers and dynamic exponent z keep the causal/tomographic control intact; Section 7.9.3 and Definition 7.607).

In the present terminology, *phonons* are a distinguished subclass of **apeirons**. They arise when the *gaiamiti* background breaks spacetime symmetries—typically spatial translations and/or rotations—so that, in Quadrant II, they appear as Nambu–Goldstone apeirons associated with the broken generators, carrying the familiar longitudinal and transverse polarizations. In Quadrant IV, the same modes persist as **pseudo-phonons**: they remain apeirons with identical polarization content, but acquire small gaps through the explicit spurions, with masses governed on the certified plateau by the Ward–GMOR relation linking the non-conserved spacetime currents to the pseudo-NG mass matrix.

Crucially, phonons are *not kymons*. **Kymons** are the quanta of the *tantrakyma* (gauge/scaffold) sector—typically spin-1 excitations after BRST projection—whereas phonons belong to the gaiamiti sector and are determined by broken *spacetime* rather than internal symmetry. For a stricter house style, the term "phonon" may be replaced by *"translational apeiron (longitudinal/transverse)"*, reserving "kymon" exclusively for tantrakyma quanta. In Quadrant IV the translational apeirons obey the same pseudo-NG mass law as their internal-symmetry counterparts; the only difference is that the Ward source is built from the **spacetime Noether currents (stress–energy/elastic currents)**, rather than from internal currents.

Spins and masses from the tantrakyma sector $\hat{\Theta}$ The tantrakyma stack contains the *gauge scaffold*: gauge fields, gauge-fixing auxiliaries, ghosts and anti-ghosts (the latter forming BRST doublets). On $\mathcal{H}_{\text{phys}}$ only *gauge-invariant, BRST-closed* excitations survive. If some of the broken directions of G are *gauged*, the corresponding would-be NGs from the gaiamiti sector are **removed by BRST projection** (they are "eaten"), and one observes **massive spin-1 vectors** (three polarizations) with masses set primarily by the Higgs mechanism (symmetric-limit decay constants and gauge couplings), now receiving *analytic QIV shifts* in ϵ via mixing terms allowed by gauge invariance. Ghosts and Nakanishi–Lautrup auxiliaries do **not** appear as particle-like poles on $\mathcal{H}_{\text{phys}}$ (they cancel in cohomology). Importantly, QIV's explicit breakings are installed as *spurions* precisely so that the band Ward identity remains adjoint-covariant and gauge-consistent (Definition 7.559 and Proposition 7.568); any

"explicitly gauge-noninvariant" operator is only admitted in a way that is *cohomologically trivial* (improvements/BRST-exact pieces), otherwise the Stage-I gate would fail.

Why spins don't change, but masses/mixings do All quadratic data live in the *band Hessian* $\mathbb{H}^{(x)}(\epsilon)$ restricted to $\mathcal{H}_{\text{phys}}$. Because $\mathbb{H}^{(x)}(\epsilon)$ *commutes with the little group* of the spacetime symmetries preserved by the background, it *block-diagonalizes by spin/irrep*. Hence QIV's explicit spurions cannot mix different spins (or different point-group irreps) at quadratic order unless spacetime symmetry is itself explicitly broken. Within a fixed spin/irrep block, however, the *eigenvalues and eigenvectors vary analytically* in ϵ: pNG–pNG and pNG–radial mixings are $O(\epsilon)$, controlled by Kato transport on isolated clusters and reported with the near-degeneracy protocol (Definition 7.618 and Proposition 7.620). The **masses** follow from these eigenvalues (Hessian) and, for the pNG block, are *locked to the Ward source* by GMOR (Theorem 7.630 and Proposition 7.629). The *residues/decay constants* (used to identify spins and couplings) are *Nielsen-flat* by construction (Proposition 7.644 and Section 7.9.14).

Operational cross-checks specific to QIV

- The **law-channel deficit** is driven by the **T-odd spectral weight** of $\nabla^{(\text{ad})} \cdot \bar{J}_{a,\text{imp}}$ (Definition 7.607 and Proposition 7.609); the same low-ω weight determines the **pNG masses** via GMOR. This ties the observed small scalar gaps in the gaiamiti sector directly to measured non-conservation (Theorem 7.580 and Corollary 7.610).
- The **state channel** confirms a **unique vacuum** (no topological relics); exponential or power-law approach $|\Lambda_{\text{state}}| \to 1$ is guaranteed by a mass gap or critical-but-non-SSB scaling (Definition 7.582 and Theorem 7.589).
- If some directions are gauged, expect **spin-1** vectors with analytic ϵ-dependent masses and **no** physical NGs along those directions (BRST descent; Lemma 7.552). Otherwise, all light modes in QIV are **spin-0 pNGs** (one per QII NG), plus **spin-0 radial** excitations that remain gapped and analytic.

In short: for the **gaiamiti** (order-parameter) fields, **spin is inherited** from the symmetric limit (typically scalars), and **mass emerges** by (i) curvature of the potential for radial modes and (ii) **GMOR-controlled explicit breaking** for pNGs. For the **tantrakyma** (gauge scaffold) fields, physical *spin-1 vectors* appear only when the corresponding broken directions are gauged (Higgs mechanism), while ghosts/auxiliaries never survive to $\mathcal{H}_{\text{phys}}$. Across the board, QIV *modifies masses and mixings analytically*—but **does not change spins**—and every statement is made *on certified plateaus*, BRST/Nielsen safe, with adjoint-covariant Ward control (eq. (7.665) and Propositions 7.568 and 7.569).
Formally, the framework now treats **both** "standard–model–like particles" and traditional **quasiparticles** within a single scale–aware, BRST–cohomological machinery, with contributions organized by the two stacks:

- **Gaiamiti** (chronogeometric) stack $\hat{\mathbf{\Phi}}$ supplies **apeirons**: collective/geometric excitations, including the translational/rotational subclasses ("phonons" $\equiv$ translational apeirons) when spacetime symmetries are broken. In QII these appear as exact NG apeirons; in

QIV they become **pseudo–NG apeirons** with small, spurion–controlled gaps certified on the plateau by the Ward–GMOR link (eq. (7.665), Theorem 7.630, and Corollary 7.631). Their mixing and level splittings are analytic in $\{\epsilon_k\}$ (type–(A) family; Proposition 7.642 and Theorem 7.646) and Nielsen–flat on $\mathcal{H}_{\text{phys}}$ (Proposition 7.644).

- **Tantrakyma** (matter/gauge) stack $\hat{\boldsymbol{\Theta}}$ supplies *kymons*: the particle–like excitations of gauge and matter fields (vectors, scalars, spinors) after BRST projection to $\mathcal{H}_{\text{phys}}$. Broken gauged directions "eat" the corresponding apeirons and yield **massive spin–1** kymons; ungauged directions leave light apeirons in the spectrum. Masses and residues of kymons shift *analytically* with explicit breakers while preserving spin/irrep blocks, and stay *gauge–parameter independent* by Nielsen identities (Propositions 7.569 and 7.644).

Operationally, both classes enter identically as *band–limited poles/residues* on $\mathcal{H}_{\text{phys}}$, extracted from the *Hessian/mass ledger* and certified inside a *plateau mask* (Proposition 7.663 and Theorem 7.664). The *law–channel* T–odd spectral weight of $\nabla^{(\text{ad})} \cdot \bar{J}_{a,\text{imp}}$ fixes the persistent deficit (Theorem 7.580) and simultaneously governs *pNG masses* through GMOR; the *state channel* enforces a *unique vacuum* in QIV (Definition 7.582 and Theorem 7.589). Hence "standard–model particles" (kymons of the tantrakyma sector) and "quasiparticles" (apeirons of the gaiamiti sector) are unified as certified spectral features whose *spins are inherited from the symmetric limit* and whose *masses/mixings* are controlled either by curvature (radial/Higgs) or by *explicit spurions* (pNGs), all within the same BRST/Nielsen–safe, adjoint–covariant Ward framework.

This reframes "fundamental" from a field–content notion to a **spectral–cohomological** notion. In this treatise the objects that qualify as fundamental are those **BRST–closed, gauge–parameter–independent poles on $\mathcal{H}_{\text{phys}}$** that remain **plateau–stable** under UV/IR tagging and mesh refinement. Standard–Model–like excitations then appear as *kymons* (tantrakyma quanta), while familiar quasiparticles appear as *apeirons* (gaiamiti quanta). Both are treated on exactly the same footing: as certified spectral features with spins fixed by the symmetric limit, and with masses and mixings controlled either by *curvature of the band Hessian* (radial/Higgs–type) or by *explicit spurions* via the *Ward–GMOR* link for pseudo–NG sectors (eq. (7.665), Theorem 7.630, and Corollary 7.631). In this view, "fundamental" means **cohomologically physical and instrument–robust**, not "elementary field in the Lagrangian."

Crucially, nothing in this reclassification contradicts established constraints: charges and spins are inherited from the symmetric benchmark; gauged breakings Higgs–eat the relevant apeirons; anomalies are excluded at the Stage–I gate; poles/residues are *Nielsen–flat*; and all quoted spectra live inside a *certified plateau mask* (Propositions 7.644 and 7.663 and Theorem 7.664). What changes is the organizing principle: Standard–Model particles and traditional quasiparticles become two manifestations (kymons vs. apeirons) of the same underlying **scale–aware, BRST–cohomological spectrum**, with **law–channel visibilities** and *T–odd tomography* tying observed gaps directly to controlled non–conservation on $\mathcal{H}_{\text{phys}}$ (Theorem 7.580, Definition 7.607, and Corollary 7.610).

7.10 Consolidation of Law–State Signatures, Ward Sources, and Spectral Content (QI–QIV)

This section consolidates the four laws–states quadrants into a single operational ledger, aligning the interferometric visibilities, the scale-tagged Ward identities, and the certified spectral content into one coherent diagnostic. All statements are made on certified plateaus $\mathfrak{P}$ and, where invoked, within the IR mask $\mathfrak{M}$ fixed by the acceptance gates and slope/curvature/oscillation metrics (eq. (7.28), Proposition 6.288, Definition 7.42, Theorem 6.253, and Sections 7.8.9 and 7.9). UV/IR instrumentation follows the spectral projector $P_x(\lambda_{\mathrm{UV}})$ and the IR window $K^{(\ell)}_{*\mathrm{IR}}$ (Definitions 7.26 and 7.35 and eq. (7.29)), with all readouts living on the BRST cohomology $\mathcal{H}_{*\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$; gauge-parameter independence is ensured by the Nielsen identities and gauge-safe analyticity (Propositions 6.276 and 7.644 and Theorem 7.646). Unless stated otherwise, operators and residues are those induced by the holosymmetric lift on $\mathfrak{P}$ and restricted to $\mathcal{H}_{\mathrm{phys}}$.

The quadrant logic is governed by the visibilities $\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$ and their overlays (Definitions 7.35 and 7.42). For ease of reference, Definition 7.685 specifies the assignment rules on a certified plateau $\mathfrak{P}$, separating the symmetric/symmetric baseline (QI), the symmetric law with state-level SSB (QII), the IR-healing of explicit-looking law deficits (QIII), and the persistent law deficit with a unique state (QIV). This classification is not merely taxonomic: it is the interface through which Ward statements and spectral data are read consistently across scales.

Definition 7.685 (Quadrant decision rule on a certified plateau $\mathfrak{P}$)**.** Write $u = \ln \lambda_{\mathrm{UV}}$, $v = \ln \ell$. On a certified plateau $\mathfrak{P}$ (Section 6.12.4), interpret "≈ 1" as $\big|\,|\cdot| - 1\big| \le \varepsilon_{\mathrm{tol}}$ uniformly on $\mathfrak{P}$. Given the visibilities $(\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}})$ on $\mathfrak{P}$, set

$$\mathrm{Quad}(\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}) = \begin{cases} \textbf{QI}, & |\Lambda_{\mathrm{law}}| \approx 1, \quad |\Lambda_{\mathrm{state}}| \approx 1, \\ \textbf{QII}, & |\Lambda_{\mathrm{law}}| \approx 1, \quad \Lambda_{\mathrm{state}}(V) \to 0 \ (V \to \infty), \\ \textbf{QIII}, & 1 - |\Lambda_{\mathrm{law}}(\ell)| = \mathcal{O}\Big(\ell^{\Delta-(d+z)}\Big), \quad |\Lambda_{\mathrm{state}}| \approx 1, \\ \textbf{QIV}, & \exists\, \delta_\star \in (0,1): \ |\Lambda_{\mathrm{law}}| \le 1 - \delta_\star \text{ uniformly on } \mathfrak{P}, \\ & \qquad\qquad \Lambda_{\mathrm{state}}(V) \to 1 \ (V \to \infty). \end{cases}$$

Remark 7.686 (Intuition & reading guide on a certified plateau $\mathfrak{P}$)**.** *Intuition.*

- **QI** is the fully coherent reference: both visibilities are ≈ 1 on $\mathfrak{P}$ and furnish the calibration baseline.
- **QII** preserves law-level conservation but exhibits state-level decoherence driven by a vacuum manifold; distinct vacua orthogonalize as $V \to \infty$.
- **QIII** shows explicit-looking law asymmetries that *heal* under coarse-graining: $1 - |\Lambda_{\mathrm{law}}(\ell)| = \mathcal{O}\Big(\ell^{\Delta-(d+z)}\Big)$ on $\mathfrak{P}$, reflecting RG irrelevance.
- **QIV** retains a *persistent* law deficit $|\Lambda_{\mathrm{law}}| \le 1 - \delta_\star$ on $\mathfrak{P}$, tied to a non-vanishing Ward source; the state is uniquely prepared (no vacuum cat).

Reading guide. Measure the visibilities on $\mathfrak{P}$ *after* BRST projection (evaluate in $\mathcal{H}_{\mathrm{phys}}$).

1. If the law's deficit scales away as in eq. (7.746), classify as **QIII**.
2. If a *persistent* law gap remains (uniform $\delta_\star > 0$), classify as **QIV** and expect GMOR-type gaps via eq. (7.747).
3. Otherwise (law ≈ 1 on $\mathfrak{P}$), decide between **QI**/**QII** purely by the state channel: $|\Lambda_{\text{state}}(V)| \to 0 \Rightarrow$ **QII**; $|\Lambda_{\text{state}}| \approx 1 \Rightarrow$ **QI**.

All statements are plateau-uniform (tolerance ε_{tol}) and gauge-parameter independent by the Nielsen/cohomological identities.

Theorem 7.687 (Equivalence of signatures, Ward statements, and spectral content)**.** *On a certified plateau $\mathfrak{P}$ (and inside the QIII mask $\mathfrak{M}$ when invoked), the following data are mutually consistent and diagnostically equivalent for quadrant assignment:*

Visibility overlays.
Visibility overlays of $\Lambda_{\text{law}}, \Lambda_{\text{state}}$ (Definition 7.42).

Scale-tagged Ward statements.
Scale-tagged Ward statements for improved currents (Definition 6.272): QI/QII exhibit band conservation up to improvements on $\mathcal{H}_{\text{phys}}$ (Sections 7.1 and 7.7); QIII has adjoint divergence trending to zero with ℓ (Theorem 6.253 and Section 7.8.9); QIV carries a non-vanishing adjoint-covariant source (eq. (7.665) and Theorem 7.570).

Light-sector spectrum and residues.
Light-sector spectrum and residues on $\mathcal{H}_{\text{phys}}$ (Nielsen-flat; Proposition 7.644 and Theorem 7.646): QI has no NG sector; QII supports exact NG poles with standard counting [94, 91]; QIII shows no NG/pNG sector with IR healing; QIV exhibits a pseudo-NG band with GMOR slope on the plateau (Theorem 7.630 and Corollary 7.631; [100, 112]).

Proof of Theorem 7.687. **Standing hypotheses and notation.** Work on the certified plateau $\mathfrak{P}$ (and inside the QIII mask $\mathfrak{M}$ when invoked). All readouts are evaluated on the physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ with BRST–closed scale tags $P_x(\lambda_{\text{UV}})$, $K_{\text{IR}}^{(\ell)}$ commuting with the channel projectors, so Nielsen identities hold (Propositions 6.264 and 6.276). Write $\bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu}$ for the improved current and $\mathcal{S}_{k,a}^{(\lambda_{\text{UV}})}$ for the tagged symmetry–breaking insertions. The scale–tagged Ward statement on $\mathcal{H}_{\text{phys}}$ is (Proposition 6.296)

$$\nabla_\mu^{(\text{ad})} \bar{J}_{a,\text{imp}}^{(\lambda_{\text{UV}},\ell)\mu} = \sum_k \epsilon_k(\ell) \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\Psi}. \tag{7.745}$$

Visibilities $(\Lambda_{\text{law}}, \Lambda_{\text{state}})$ are as in Definitions 6.275 and 7.42, with plateau uniformity as in Remark 6.254. "Nielsen–flat" spectra means gauge–parameter independence on $\mathcal{H}_{\text{phys}}$ (Proposition 7.644 in Chapter 8).

Outline. We prove mutual equivalence by showing the implications

$$\text{(1) overlays} \Rightarrow \text{(2) Ward)} \Rightarrow \text{(3) spectrum} \Rightarrow \text{(1) overlays},$$

and we do so quadrant by quadrant, using plateau uniformity.

(1) ⇒ (2): Visibility overlays determine the Ward pattern.

- *QI/QII (law coherent).* On $\mathfrak{P}$, $|\Lambda_{\text{law}}| \approx 1$ with only IR–irrelevant corrections (Theorems 6.253 and 6.258). The Duhamel/BCH expansion for the two–path operator (cf. proof of Theorem 6.258) bounds the law–deficit by the integrated norm of the tagged breaking insertions. Plateau–smallness of the deficit forces the r.h.s. of (7.745) to vanish on $\mathfrak{P}$ (up to ζ–exact improvements), i.e. adjoint conservation bandwise.
- *QIII (law healing).* The overlay reads $1 - |\Lambda_{\text{law}}(\ell)| = \mathcal{O}(\ell^{\Delta-(d+z)})$ with $\Delta > d + z$ (Theorem 6.253). The same Duhamel estimate gives $\sum_k \epsilon_k(\ell)\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})}\rangle = \mathcal{O}(\ell^{\Delta-(d+z)})$, i.e. the adjoint divergence in (7.745) trends to 0 with the same exponent (uniformly on $\mathfrak{P}$).
- *QIV (persistent law deficit).* A uniform gap $|\Lambda_{\text{law}}| \le 1 - \delta_\star$ on $\mathfrak{P}$ implies a nonzero lower bound on the integrated breaking strength; thus the r.h.s. of (7.745) does not vanish on $\mathfrak{P}$ (Theorem 7.570). Hence a persistent adjoint–covariant source appears.

(2) ⇒ (3): Ward pattern fixes the light–sector spectrum. Consider the spectral representation of current–current correlators on $\mathcal{H}_{\text{phys}}$, with residues in the channel selected by the plateau tags (Källén–Lehmann on $\mathfrak{P}$; gauge–flat by Nielsen identities).

- *QI.* Exact band conservation and a unique symmetric state forbid massless poles in the G–charged two–point functions. The spectral density is regular at $p^2 = 0$; no NG sector.
- *QII.* Exact band conservation but state asymmetry (SSB for global G) implies Ward–Takahashi identities with nontrivial vacuum order parameter. Standard arguments (Goldstone theorem) give exact NG poles with the usual counting ([94, 91]); residues are Nielsen–flat on $\mathcal{H}_{\text{phys}}$ (Theorem 7.646).
- *QIII.* The adjoint divergence in (7.745) tends to zero with ℓ, but is strictly zero only in the IR limit. On a finite plateau, this precludes protected massless poles: any would-be pole would force a non-decaying RHS by LSZ/WT analysis. Thus no NG/pNG sector appears; instead the small explicit insertions dress regular light continua whose strength decays with ℓ (Section 7.8.9).
- *QIV.* A nonvanishing adjoint source implies a PCAC–type relation. In the light sector, this yields pseudo–Nambu–Goldstones with $m_{\text{pNG}}^2 f^2 \propto$ (Ward source) and hence a GMOR slope on the plateau (Theorem 7.630 and Corollary 7.631; see also [100, 112]).

(3) ⇒ (1): Spectrum and residues reproduce the overlays. Write the holosymmetric law–visibility as a controlled overlap of two tagged evolutions (Chapter 7). Low–energy spectral data dominate the overlap decay on $\mathfrak{P}$.

- *QI.* No NG sector and a unique symmetric vacuum ⇒ no infrared orthogonality and no long–time dephasing in the tagged evolutions. Therefore $|\Lambda_{\text{law}}| \approx 1$ and $|\Lambda_{\text{state}}| \approx 1$.
- *QII.* Exact NG poles induce phase–twist stiffness and vacuum–sector orthogonality as $V \to \infty$ (Theorem 6.261); hence $|\Lambda_{\text{law}}| \approx 1$ (law conserved) while $\Lambda_{\text{state}}(V) \to 0$.
- *QIII.* With no NG/pNG sector and only irrelevant breakings, the tagged overlap improves with coarse–graining; RG power counting gives $1 - |\Lambda_{\text{law}}(\ell)| = \mathcal{O}(\ell^{\Delta-(d+z)})$ (the "healing" law; Theorem 6.262), and the symmetric state yields $|\Lambda_{\text{state}}| \approx 1$.

- *QIV.* A pNG band with GMOR slope enforces a finite, scale–stable dephasing in the law–overlap on $\mathfrak{P}$ (its residue cannot be removed by coarse–graining because the Ward source is nonzero); thus $|\Lambda_{\text{law}}| \le 1-\delta_\star$ uniformly. The unique vacuum gives $|\Lambda_{\text{state}}(V)| \to 1$.

Plateau uniformity and gauge independence. All implications are uniform on $\mathfrak{P}$ by Remark 6.254 and inherit Nielsen–flatness by Proposition 6.299. Channel decompositions are preserved by functoriality and cone stability (Propositions 6.257 and 6.281 and Corollary 6.263).

Conclusion. For each quadrant, the three descriptions—(1) visibility overlays, (2) scale–tagged Ward statements, and (3) light–sector spectral content—are equivalent and mutually consistent on a certified plateau $\mathfrak{P}$ (and within $\mathfrak{M}$ for QIII). Any one determines the other two, completing the proof. □

Intuition. The quadrant is not inferred from a single scalar: the interferometric signatures, the scale-tagged Ward identity, and certified poles/residues *cohere*. In QIV, the persistent law deficit $\Longleftrightarrow$ the non-zero Ward source $\Longleftrightarrow$ the pNG band with GMOR scaling; in QIII, the decaying deficit $\Longleftrightarrow$ vanishing adjoint source in the IR $\Longleftrightarrow$ absence of NG/pNG modes.

Key boxed relations

$$\boxed{1-|\Lambda_{\text{law}}(\ell)| = \mathcal{O}\big(\ell^{\Delta-(d+z)}\big) \qquad \text{(QIII on the mask } \mathfrak{M}\text{; Theorem 6.253 and Section 7.8.9).}} \tag{7.746}$$

$$\boxed{\nabla^{(\text{ad})\mu}\bar{J}^{(\lambda_{\text{UV}},\ell)\mu}_{a,\text{imp}} = \sum_k \epsilon_k \big\langle \mathcal{S}^{(\lambda_{\text{UV}})}_{k,a}\big\rangle_{\mathbf{\Psi}} \;\Rightarrow\; f^2_{\pi_b} m^2_{\pi_b} = \sum_k \epsilon_k \big\langle \mathcal{S}^{(\lambda_{\text{UV}})}_{k,b}\big\rangle_{\mathbf{\Psi}} + \mathcal{O}(\epsilon^2)} \tag{7.747}$$

(QIV on $\mathcal{H}_{\text{phys}}$; Ward source $\neq 0$ and GMOR fit on the plateau: eq. (7.665), Theorem 7.630, and Corollary 7.631.)

The two boxed relations are decisive for separating the IR–healing regime (QIII) from the explicitly persistent regime (QIV). In particular, eq. (7.746) asserts that any law-channel deficit decays as a power of the IR dilation scale, while eq. (7.747) identifies a non-vanishing adjoint-covariant source that pins a strictly positive plateau deficit. Together they make the overlay rules in Definition 7.685 operational beyond taxonomy, providing the precise hinge on which the existence of a certified QIII versus a certified QIV plateau turns; this is exactly the content that underwrites the equivalence claims in Theorem 7.687.

These relations also close the three-way correspondence between interferometric visibilities, scale-tagged Ward structure, and spectral content. On the one hand, eq. (7.746) implies the vanishing of the (improved) adjoint divergence on the IR mask, hence no protected discontinuity remains to be saturated and no NG/pNG sector can persist (Theorem 6.253 and Section 7.8.9). On the other hand, eq. (7.747) ties a non-zero adjoint source directly to the pseudo-Goldstone band and fixes its leading scaling on the plateau via the GMOR fit (Theorem 7.630 and Corollary 7.631). This implements, in both directions, the diagnostic equivalences summarized in Theorem 7.687 using only the visibility overlays from Definitions 7.35 and 7.42 and the scale-tagged equations of motion.

Moreover, the pair furnishes a quantitative and falsifiable calculus. The decay rate in eq. (7.746), controlled by $\Delta - (d + z)$, makes the QIII assignment testable by slope/curvature metrics on certified plateaus and masks, while the source–mass bridge in eq. (7.747) enables an inversion-ready QIV analysis: measured residues $f_{\pi_b}^2$ and masses $m_{\pi_b}^2$ determine (or are predicted from) the explicit breaking coefficients $\{\epsilon_k\}$. Both operations are defined with the UV projector and IR window instrumentation $P_x(\lambda_{\mathrm{UV}})$, $K_{\mathrm{IR}}^{(\ell)}$ (Definition 7.26 and eq. (7.29)) and the readout protocol of Definition 7.35, thereby rendering the classification reproducible with fixed scale tags.

Crucially, the statements are regulator- and gauge-parameter independent on the physical Hilbert space. All currents are improved and all correlators are restricted to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, so BRST/Nielsen identities and gauge-safe analyticity ensure that neither the decay law in eq. (7.746) nor the GMOR slope in eq. (7.747) can be artefacts of gauge choice or regulator details (Propositions 6.276 and 7.644 and Theorem 7.646). This is the sense in which the ledger's decisions are stable under admissible changes of presentation.

The spectral implications follow without additional assumptions. In QIII, IR healing of the law channel as in eq. (7.746) excludes NG and pNG light sectors and enforces multiplet reconvergence under coarse-graining (Theorem 6.253 and Section 7.8.9), in agreement with the synopsis of Section 7.10.1. In QIV, the non-zero source in eq. (7.747) both necessitates a pNG band and fixes its leading scaling (GMOR on the plateau), while radial modes remain analytic and gapped—again matching the entries in Section 7.10.1.

Finally, these two relations can be viewed as the minimal scale-sensitive normal forms of the ledger. The conserved-law corner (QI/QII) in Definition 7.685 leaves them inert, with QII's state-channel decoherence orthogonal to the law channel. Consequently, all nontrivial flows pertinent to quadrant assignment reduce to verifying the decay prescribed by eq. (7.746) or the source–slope linkage in eq. (7.747). Practically, the pipeline—choose scale tags, certify $\mathfrak{P}$ (and $\mathfrak{M}$ when invoked), read visibilities, evaluate the adjoint divergence, and fit poles/residues—culminates in a cross-check against these two boxed relations, after which Definition 7.685 and Theorem 7.687 yield a regulator-robust decision.

7.10.1 Comparative Table

Table 7.4: Quadrant synopsis on a certified plateau $\mathfrak{P}$.

Quadrant	**Law channel**	**State channel**	**Low-energy sector (IR window on $\mathcal{H}_{\text{phys}}$)**
QI	Conserved on band (improved)	Unique/coherent	No NG; baseline gapped content; Nielsen-flat residues
QII	Conserved on band	Orthogonality: $\Lambda_{\text{state}}(V) \to 0$	Exact NGs (Goldstone); gauged directions eaten
QIII	Deficit heals: $\mathcal{O}(\ell^{\Delta-(d+z)})$	Unique/coherent	No NG/pNG; multiplet reconvergence; improved physicality
QIV	Persistent deficit $\leq 1-\delta_\star$	Unique/coherent	pNGs with GMOR slope; radial analytic and gapped; gauge-flat poles

Narrative synthesis and operational reading. On QI plateaus, both visibilities saturate (Definition 7.685), the improved current is conserved on band (Section 7.1), and the light spectrum matches the symmetric law without NG content, with residues flat under gauge-parameter variations (Proposition 7.644 and Theorem 7.646). QII inherits the same law conservation but Λ_{state} decoheres with volume, resolving a vacuum manifold; the Goldstone sector appears as exact poles with standard counting and, under gauging, is re-packaged into massive vector modes (Section 7.7, [94, 91]). QIII exhibits a non-saturating law channel at finite scale that *heals* under IR dilation as in eq. (7.746); the associated Ward divergence tends to zero on $\mathfrak{M}$ and no NG/pNG modes are present (Theorem 6.253 and Section 7.8.9). QIV is singled out by a uniform, scale-stable deficit in the law visibility on $\mathfrak{P}$, a non-vanishing adjoint-covariant source, and a pNG band obeying the GMOR fit on the plateau (eqs. (7.665) and (7.747), Theorem 7.630, and Corollary 7.631); the state channel is unique, and radial fluctuations remain analytic and gapped.

Finally, because all objects are computed within $\mathcal{H}_{\text{phys}}$ and certified by the plateau gates, the ledger is regulator-robust and gauge-safe (Propositions 6.276 and 7.644 and Theorem 7.646). In practice: (i) choose scale tags $(\lambda_{\text{UV}}, \ell)$ and the channel decomposition; (ii) certify $\mathfrak{P}$ and, where needed, $\mathfrak{M}$; (iii) read $\Lambda_{\text{law}}, \Lambda_{\text{state}}$, the scale-tagged Ward divergence, and the light-sector residues; (iv) assign the quadrant via Definition 7.685 and validate by Theorem 7.687. This completes the consolidated, cross-validated map from interferometric signatures to Ward sources to spectral content across the four quadrants.

Table 7.5: Spins and modes across quadrants on a certified plateau $\mathfrak{P}$ (and, where invoked, within the IR mask $\mathfrak{M}$). Entries are stated on $\mathcal{H}_{\text{phys}}$ and are gauge-parameter independent by BRST/Nielsen safety (Propositions 6.276 and 7.644 and Theorem 7.646). Quadrant assignment follows Definition 7.685; IR healing and explicit persistence follow eqs. (7.746) and (7.747). Here G_{IR} denotes the IR-recovered unbroken gauge group after band/BRST cleaning.

Species / Mode	**QI** (law $\simeq$ 1, state $\simeq$ 1)	**QII** (law $\simeq$ 1, state decoheres)	**QIII** (law heals, state $\simeq$ 1)	**QIV** (law deficit persists, state $\to$ 1)
Spin-2, massless (helicity ± 2)	Present as in symmetric law	Present as in symmetric law	Present; IR re-converges to QI	Present iff space-time symmetry unbroken
Spin-1, massless (unbroken gauge)	Present for each unbroken generator	Present for each unbroken generator	Present for each generator of G_{IR}; reconverges to QI	Present for each unbroken generator
Spin-1, massive (gauged broken)	Absent (no breaking)	Present (BEH: would-be NG eaten)	Absent in strict IR (no SSB); any finite-ℓ emergent masses vanish as $\ell \to \infty$ by eq. (7.746)	Present when broken directions are gauged (BEH), with analytic mass/mixing shifts
Spin-0, NG (global broken)	Absent	Present: one per broken global generator	Absent in strict IR (healing as eq. (7.746))	Absent (replaced by pNG)
Spin-0, pNG (GMOR)	Absent	Absent	Absent in strict IR; finite-ℓ transients must vanish with ℓ	Present with $m^2_{\pi_b} = \mathcal{O}(\epsilon)$ and slope fixed by eq. (7.747)
Spin-0, radial (Higgs-like)	Present, gapped, analytic	Present, gapped, analytic	Present, gapped; reconverges to QI	Present, gapped, analytic; spin unchanged under explicit breaking
Spacetime NG (phonons/rotations)	Absent	Present if space-time symmetry is spontaneously broken (longitudinal/transverse polarizations)	Absent in strict IR (no SSB)	Absent as exact NG; replaced by pseudo-phonons if explicit space-time breaking

Table 7.5: – *Continued from previous page*

Species / Mode	**QI** (law $\simeq$ 1, state $\simeq$ 1)	**QII** (law $\simeq$ 1, state decoheres)	**QIII** (law heals, state $\simeq$ 1)	**QIV** (law deficit persists, state $\to$ 1)
Spacetime pseudo-phonons	Absent	Absent	Absent in strict IR	Present with same polarization content as QII, now gapped $\mathcal{O}(\epsilon)$
Ghosts / auxiliaries	Unphysical; projected out by $\mathsf{P}_{\mathrm{phys}}$	Unphysical; projected out	Unphysical; projected out	Unphysical; projected out

Notes. (i) "Reconverges to QI" indicates channel-wise approach of spectra/residues under IR dilation consistent with eq. (7.746). (ii) In QIV, spins are inherited from the symmetric limit; explicit breaking shifts masses/mixings analytically without changing spin, and the pNG sector obeys the plateau GMOR fit (eq. (7.747), Theorem 7.630, and Corollary 7.631). (iii) All entries are to be read within the certified plateau $\mathfrak{P}$ (and mask $\mathfrak{M}$ when invoked) and under the holosymmetric instrumentation of Definitions 7.26 and 7.35 and eq. (7.29).

The spin assignments that accompany tables 7.5 and 7.6 are fixed by a single chain of band–/BRST–reduced constructions and identities, all evaluated on the physical Hilbert space $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ and within certified plateaus $\mathfrak{P}$.

First, the *physical-sector pole analysis* determines spins and helicities kinematically and reads them dynamically. From the reduced quadratic kernel on $\mathcal{H}_{\mathrm{phys}}$ (constructed after the decoupling of Kugo–Ojima quartets), the *physical mass operator* $\mathbb{M}^2_{\mathrm{phys}}$ is defined blockwise and its poles m_X^2 and residue matrices Z_X are extracted in the polarization blocks $X \in \{A^T,\ h_{\mathrm{TT}},\ \pi\}$; these identify, respectively, massless/massive vectors ($s = 1$), transverse–traceless tensors ($s = 2$), and scalars ($s = 0$) (cf. eqs. (7.485) and (7.486)). The same construction enforces non-negativity of $\mathbb{M}^2_{\mathrm{phys}}$ and a Källén–Lehmann form with positive spectral density on $\mathcal{H}_{\mathrm{phys}}$, making the pole/residue identification intrinsic (i.e. not gauge artifacts). Gauge-parameter independence of pole positions and residues follows from the Nielsen/Slavnov–Taylor identities proved on the band, again after projection to $\mathcal{H}_{\mathrm{phys}}$ (see Proposition 7.644 and Theorem 7.646). [91, 82, 117, 243]

Second, the *Ward/Noether ledger* ties the scalar versus vector content to the presence of symmetry breaking in QuadrantĨI. With *symmetric law* and *broken global symmetry*, the Ward identities and the spectral representation force *Nambu–Goldstone* poles in the correlational channel, hence *spin–0* excitations. When the broken directions are *unbroken gauged*, the would-be Goldstones are ζ-exact and are eaten by the Brout–Englert–Higgs mechanism, producing *massive spin–1* vectors with the longitudinal polarization restored; the ST/Nielsen identities ensure that these physical poles are gauge independent on $\mathcal{H}_{\mathrm{phys}}$ (cf. Section 7.5.8 and Proposition 7.644). [91, 117]

Third, *spacetime symmetry breaking* produces phononic/rotational NG modes with definite longitudinal/transverse polarizations, entered as *spin–0* excitations in QuadrantĨI and

continued into QuadrantÎV as *pseudo-phonons*. In QuadrantÎV the Ward–source bridge fixes the gap scale $m_{\mathrm{ph}}^2 = \mathcal{O}(\epsilon)$ in precise analogy with the internal pseudo–NG sector, and the polarization content is inherited unchanged (cf. eq. (7.747) and Section 7.10.1). [91]

Fourth, *QuadrantÎII healing* excludes persistent NG/pNG bands and reconverges the spin census to the QuadrantÎ baseline. The adjoint-covariant source decays under IR dilation on the mask $\mathfrak{M}$, so no NG/pNG sector survives asymptotically; the only particle-like content that remains is the symmetric one: massless $s = 2$ (when the relevant spacetime symmetry is unbroken), massless $s = 1$ for the IR–recovered unbroken subgroup, and gapped scalar radials (cf. eq. (7.746)).

Fifth, in *QuadrantÎV* the *PCAC/GMOR* relation on a plateau yields a *pseudo–NG* band with $m_{\pi_b}^2 f_{\pi_b}^2$ proportional to the explicit source; the *spin remains* 0. More generally, pole positions and residues within any isolated spectral subspace move *analytically* under small explicit deformations, while the spin/helicity labels are invariant (helicity stability). This is encoded by the analytic Riesz–projector calculus and the gauge-independence theorem for spectral data on $\mathcal{H}_{\mathrm{phys}}$ (cf. Propositions 7.644 and 7.645). [115, 120, 121, 108, 117]

Sixth, the *mode–helicity catalog* (table 7.6) consolidates the outcome: a massless TT tensor ($s = 2, \lambda = \pm 2$) whenever the relevant spacetime symmetry is unbroken (QI, QII, and the QIII limit; also in QIV for the unbroken spacetime sector); a massless transverse vector ($s = 1, \lambda = \pm 1$) for each unbroken gauge generator; a massive vector ($s = 1, \{+1, 0, -1\}$) when broken directions are gauged (QII/QIV); a gapped scalar radial in all quadrants; and the NG/pNG entries just discussed (NG only in QII; GMOR-controlled pNG in QIV). These are the species-level restatements of the blockwise pole/residue analysis above and of the Ward/SSB/BEH logic (cf. Proposition 6.276 and Theorem 7.646). [91, 117]

Finally, the *quadrant overlay by spin* formalizes how the law–/state–visibilities behave per spin across QI–QIV. Combining the tolerance semantics on $\mathfrak{P}$ with helicity stability and analytic transport of Riesz projectors ensures that, on the band, $|\Lambda^{[s]}_{\mathrm{law/state}}|$ satisfies the same QI–QIV inequalities for each spin sector, with QIII power-law healing and a QIV uniform deficit where appropriate (cf. Definition 7.685 and eqs. (7.746) and (7.747)). The upshot is that the *identification* of spins comes from polarization-resolved poles of $\mathcal{D}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$ (via $\mathbb{H}_{\mathrm{phys}}$, Källén–Lehmann, and TT/transverse/scalar projectors), while the *justification* of which spinful modes actually occur in each quadrant is supplied by the Ward/SSB/BEH analysis (QII), IR healing (QIII), and PCAC/GMOR plus helicity stability (QIV), all **BRST/Nielsen-safe** on certified plateaus. [241, 442, 117, 91]

Consolidation of Particle-like Sector

All statements below are made on certified plateaus $\mathfrak{P}$ and, where invoked, within the IR mask $\mathfrak{M}$, with UV/IR instrumentation $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ and holosymmetric readouts on $\mathcal{H}_{\mathrm{phys}}$ (Definitions 7.26 and 7.35 and eq. (7.29)). Gauge-parameter independence and analytic transport of poles/residues are ensured by BRST/Nielsen safety (Propositions 6.276 and 7.644 and Theorem 7.646). Quadrant assignment follows Definition 7.685, and the equivalences between signatures, Ward structure, and spectrum are as in Theorem 7.687. For a quadrant-by-quadrant inventory see also table 7.5.

Massless carriers (reference census). (i) A massless spin-2 sector (helicity ± 2) persists whenever the spacetime symmetry relevant to the low-energy little group is unbroken; this provides the universal reference for spectral health in QI, QII, and the QIII limit, and remains present in QIV for the unbroken spacetime sector. (ii) For each unbroken gauge generator, there is a massless spin-1 vector. These entries are the baseline "conserved-law" content leveraged across quadrants (Definition 7.685 and Section 7.10.1).

Goldstone ladders and their QIV continuations. In QII (symmetric law, state SSB), each broken *global* generator yields an exact NG scalar (spin-0), while broken *gauged* directions yield massive spin-1 vectors via the Brout–Englert–Higgs mechanism (Section 7.7). In QIV (persistent explicit law asymmetry; unique state), the QII NG sector is replaced by a pseudo-NG band with GMOR scaling on the plateau, with masses $m_{\pi_b}^2 = \mathcal{O}(\epsilon)$ and slope fixed by the source–mass bridge (eq. (7.747), Theorem 7.630, and Corollary 7.631). The polarization/spin content of the QIV pseudo-modes is inherited from the corresponding QII NG sector (spins do not change under explicit breaking).

Spacetime NG modes and pseudo-phonons. If spacetime symmetry is spontaneously broken (QII), the spectrum contains phononic/rotational NG modes with definite longitudinal/transverse polarizations under the spatial little group. In QIV, explicit spacetime breaking replaces these by pseudo-phonons with the same polarization content but gapped at $\mathcal{O}(\epsilon)$, governed by the same Ward–source logic as the internal pseudo-NG sector (eq. (7.747) and Section 7.10.1).

Massive vectors from gauged breaking (QII and QIV). Whenever the broken directions are gauged, the would-be NGs are eaten and one observes massive spin-1 vectors with three physical polarizations on $\mathcal{H}_{\text{phys}}$. In QIV, their masses and possible mixings shift analytically with the explicit spurions, but spin/polarization content remains that of spin-1; residues stay Nielsen-flat (Proposition 7.644, Theorem 7.646, and Section 7.10.1).

Radial (Higgs-like) scalars. Across all quadrants, radial/moduli excitations appear as spin-0 gapped modes. They remain analytic on $\mathfrak{P}$; explicit breaking in QIV does not change their spin, only their masses/mixings within the same scalar block. These provide stable anchors for plateau diagnostics and for the GMOR fits that isolate the pseudo-NG sector in QIV (eq. (7.747) and Corollary 7.631).

QIII reconvergence and the absence of NG/pNG in the strict IR. QIII exhibits finite-scale law deficits that *heal* under IR dilation according to the power law in eq. (7.746). On the IR mask $\mathfrak{M}$, the adjoint-covariant source vanishes and no NG/pNG sector persists asymptotically; multiplets reconverge to the QI census (massless spin-2, massless spin-1 for unbroken G_{IR}, and gapped scalar radials). Any finite-ℓ pNG-like transient must decay in accordance with eq. (7.746) (Sections 7.8.9 and 7.10.1).

Spin assignment and analytic transport. Explicit law asymmetry (notably in QIV) does not alter spin assignments: spins are inherited from the symmetric limit, while masses and intra-block mixings shift analytically with spurions and scale tags. Pole residues used for

species identification are gauge-parameter independent on $\mathcal{H}_{\text{phys}}$ (Nielsen-flat), ensuring regulator-robust spectroscopy on $\mathfrak{P}$ (Proposition 7.644 and Theorem 7.646).

Ghosts and auxiliaries. BRST cohomology projects out Faddeev–Popov ghosts and auxiliary fields; they do not appear as particle-like excitations in the physical spectrum. All "particle-like" statements above are therefore to be read within $\mathcal{H}_{\text{phys}}$ (Proposition 6.276).

Operational summary (species-by-quadrant). QI: massless spin-2; massless spin-1 for unbroken gauge; gapped scalar radials; no NG/pNG. QII: add exact NG scalars (global broken) or, if gauged, massive spin-1 vectors; spacetime NGs as phonons/rotations when applicable. QIII: strict-IR reconvergence to QI (no NG/pNG), with finite-ℓ transients suppressed per eq. (7.746). QIV: pseudo-NG scalars (GMOR) and pseudo-phonons (if spacetime explicitly broken); massive spin-1 for gauged broken directions; radial scalars remain gapped/analytic; spins unchanged (see table 7.5).

Terminology (particles vs. quasiparticles). In this chapter, "*particle-like*" denotes any isolated, positive-residue pole on $\mathcal{H}_{\text{phys}}$ certified on $\mathfrak{P}$ (and $\mathfrak{M}$ when invoked), irrespective of UV provenance. It therefore includes both *particles* (kymon sector: massless/massive spin-1 gauge quanta; gapped spin-0 radials; any additional symmetric-law quanta) and *quasiparticles* (apeiron sector: spacetime NG phonons/rotations and their QIV pseudo-phonons; internal NG/pNG scalars in QII/QIV). The species inventory and quadrant placement are summarized in table 7.5; the consolidated logic linking visibilities, Ward sources, and spectra is in Section 7.10.

Polarizations, Helicities, and Mode Catalog

All entries are certified on $\mathcal{H}_{\text{phys}}$ and read on plateaus $\mathfrak{P}$ (and masks $\mathfrak{M}$ when invoked), with gauge/Nielsen safety as in Propositions 6.276 and 7.644 and Theorem 7.646. Quadrant occurrence matches Definition 7.685 and table 7.5, and QIII/QIV scaling follows eqs. (7.746) and (7.747).

Helicity conventions (3+1 reference; general d given below). Massless spin-1: two transverse helicities $\lambda = \pm 1$; *no longitudinal mode*. Massive spin-1: three physical polarizations $\{\lambda = +1, 0, -1\}$. Massless spin-2: two helicities $\lambda = \pm 2$ (transverse traceless). Scalars are spin-0 (no polarization). Spacetime NGs (phonons/rotations) are labeled by longitudinal/transverse content under the spatial little group; QIV pseudo-phonons inherit the same polarization pattern and acquire a gap set by eq. (7.747).

Projectors (for diagnostics, no new labels). Transverse projector for vectors: $P_T^{ij}(\hat{\mathbf{k}}) = \delta^{ij} - \hat{k}^i \hat{k}^j$ (massless spin-1 lives in $\operatorname{Im} P_T$). Transverse-traceless projector for tensors: $\Pi_{\text{TT}}^{ij,kl}(\hat{\mathbf{k}}) = \frac{1}{2}(P_T^{ik}P_T^{jl} + P_T^{il}P_T^{jk}) - \frac{1}{d-1}P_T^{ij}P_T^{kl}$ (massless spin-2 lives in $\operatorname{Im} \Pi_{\text{TT}}$). These are the canonical filters for channel-resolved fits used alongside Definition 7.35 and Section 7.10.1.

Table 7.6: Mode–helicity catalog (species, physical polarizations, quadrant occurrence). "Dispersion" shows plateau prototypes; v_* are channel-dependent cone speeds fixed by the chronogeometric operator used in the holosymmetric lift.

Species	**Spin**	**Pol./Helicity**	**Dispersion (plateau prototype)**	**Quadrants (cf. table 7.5)**
Massless vector (unbroken)	1	$\lambda = \pm 1$	$\omega^2 \simeq v_1^2\,\mathbf{k}^2$	QI, QII, QIII (IR), QIV (unbroken)
Massive vector (gauged broken)	1	$\{+1, 0, -1\}$	$\omega^2 \simeq v_1^2\,\mathbf{k}^2 + m_V^2$	QII, QIV
Massless tensor (TT)	2	$\lambda = \pm 2$	$\omega^2 \simeq v_2^2\,\mathbf{k}^2$	QI, QII, QIII (IR), QIV (unbroken spacetime)
Radial/Higgs-like scalar	0	—	$\omega^2 \simeq v_0^2\,\mathbf{k}^2 + m_H^2$	All quadrants
Internal NG scalar	0	—	$\omega^2 \simeq v_\pi^2\,\mathbf{k}^2$	QII only (global broken)
Internal pNG scalar	0	—	$\omega^2 \simeq v_\pi^2\,\mathbf{k}^2 + m_\pi^2$, $m_\pi^2 \sim \mathcal{O}(\epsilon)$	QIV (GMOR via eq. (7.747))
Spacetime NG (phonon/rotation)	0	L/T	$\omega^2 \simeq c_L^2 k_L^2 + c_T^2 k_T^2$	QII (if spacetime SSB)
Spacetime pseudo-phonon	0	L/T	$\omega^2 \simeq c_{L,T}^2 k^2 + m_{\rm ph}^2$, $m_{\rm ph}^2 \sim \mathcal{O}(\epsilon)$	QIV (explicit spacetime breaking)

Note. "Low-energy/Light sector" refers to physically propagating modes *within the certified IR window* $K_{\rm IR}^{(\ell)}$ (with UV content controlled by $P_x(\lambda_{\rm UV})$) after BRST projection onto $\mathcal{H}_{\rm phys}$. It includes massless carriers for unbroken gauge factors (not necessarily photons), NG/pNG modes (QIV obeys the GMOR slope), and radials below the window; excludes heavy states/continua and ghosts.

Kinematics (plateau prototypes). For massless carriers, group velocities $v_{1,2}$ coincide with the causal cone speeds set by the chronogeometric sector of the holosymmetric lift; for scalars v_0 is channel dependent. In QIV, pNG and pseudo-phonon gaps satisfy the source–mass bridge of eq. (7.747); in QIII, any finite-ℓ pNG-like transient must decay with ℓ according to eq. (7.746).

Degrees of Freedom (DoF) Counts and Conventions

Let $D = d + 1$ be spacetime dimension. Physical DoF per species on $\mathcal{H}_{\text{phys}}$:

$$\begin{aligned} \text{scalar:}\ & 1, \\ \text{massless spin-1:}\ & D-2 = d-1, \\ \text{massive spin-1:}\ & D-1 = d, \\ \text{massless spin-2:}\ & \tfrac{1}{2}D(D-3) = \tfrac{1}{2}(d+1)(d-2). \end{aligned}$$

These counts underwrite the rows of table 7.5 and guide residue normalizations in spectral fits (Nielsen-flat per Proposition 7.644).

Channel ↔ Mode Map

The triadic split used operationally (correlation/vacuum/spectral) decomposes readouts without altering polarization content. A convenient mnemonic (no new labels):

- *Spectral channel:* isolates pole locations and residues for all particle-like species (vectors/tensors/scalars), used for GMOR fits in QIV via eq. (7.747).
- *Vacuum channel:* carries order-parameter plateaus (e.g., QII manifold structure) and the orthogonality trend $\Lambda_{\text{state}}(V) \to 0$ relevant to Definition 7.685.
- *Correlation channel:* sensitive to mixing angles within a fixed spin block; in QIV these vary analytically with explicit spurions, leaving spin assignments unchanged (cf. notes under table 7.5).

Residue Normalization and GMOR Readout (QIV)

For the pNG band, define decay constants f_{π_b} by the usual one-pole saturation of the improved current two-point function on $\mathcal{H}_{\text{phys}}$ (no new label). On plateaus, the source–mass relation in eq. (7.747) fixes the leading slope of $m^2_{\pi_b}$ in the explicit couplings $\{\epsilon_k\}$; radial modes remain gapped/analytic and serve as internal consistency checks for fits.

IR Healing and Multiplet Reconvergence (QIII)

Under IR dilation within $\mathfrak{M}$, eq. (7.746) enforces the decay of the law-channel deficit and rules out a persistent NG/pNG sector. Spectrally, spin blocks reconverge to the QI census with improving positivity/hyperbolicity margins (as summarized in table 7.5); any finite-ℓ anomalies must track the power law in eq. (7.746).

Chapter 8

Parasymmetric Witnesses and Diagnostics

8.1 Sector-Conditioned Witnesses and Quadrant Rules

Chs. 6–7 establish a symmetry-centric, gauge-safe classification based on two predicates—the *law* and the *state* visibilities—read on a certified plateau and mapped to the four quadrants by the decision rule of Definition 7.685. The present section extends that same machinery to further physical sectors without altering the framework.

What stays fixed. The *grid does not change*: we retain the two fundamental visibilities $(\Lambda_{\text{law}}, \Lambda_{\text{state}})$ of Definition 7.35, evaluated after projection to the BRST-physical sector, and we use the same quadrant map. No new cells are introduced.

What changes. Only the *witnesses* and, where needed, the *arena* change. For each admissible sector $\mathscr{S}$ we instantiate the sector-conditioned pair

$$\left(\Lambda_{\text{law}}^{[\mathscr{S}]},\ \Lambda_{\text{state}}^{[\mathscr{S}]}\right)$$

as in Definition 8.9, using the appropriate Ward data/correlators on the relevant arena $\mathcal{A} \in \{\mathfrak{P},\ \mathfrak{P}_\partial\}$ with an IR window $K_{\text{IR}}^{(\ell)}$ (isotropic) or $K_{\text{IR}}^{(\vec{\ell})}$ (anisotropic). Subscripts remain reserved for Λ_{law} and Λ_{state}; sector tags appear only as superscripts.

Scope of this section. We provide witnesses and quadrant assignments for: fermions, SUSY (global/local), p-forms in 3+1D (via BRST-compatible duality), higher-spin $s{>}2$, hydrodynamics, boundary soft/edge modes, anyons/CS (for a chosen symmetry X), fractons/subsystem-symmetric phases, and higher-form/non-invertible symmetries. Each sector is labeled

$$\text{Quad}^{[\mathscr{S}]} = \text{Quad}\left(\Lambda_{\text{law}}^{[\mathscr{S}]}, \Lambda_{\text{state}}^{[\mathscr{S}]}\right).$$

Orthogonality and consistency. Topological order and related modular data are orthogonal to the law/state predicates and are tracked separately when relevant; they do not modify quadrant assignment. BRST/Nielsen safety ensures gauge-parameter independence of all witnesses, and large-window limits distinguish QIII (healing) from QIV (persistence) in the sense of eq. (7.746). Non-equilibrium carriers of the law (Floquet/Lindblad) fit by swapping the dynamical map while keeping the same predicates and decision rule.

How to read the remainder. For each sector block below we (i) specify the witnesses $\big(\Lambda_{\mathrm{law}}^{[\mathscr{S}]}, \Lambda_{\mathrm{state}}^{[\mathscr{S}]}\big)$ on the appropriate arena and window, and (ii) state the resulting QI–QIV assignment, with QIII/QIV decided by the large-window limit in that arena. This yields a uniform, symmetry-agnostic classification across all additional sectors.

Theorem 8.1 (Law–state exhaustion)**.** *On the certified plateau $\mathfrak{P}$, after projection to $\mathcal{H}_{\mathrm{phys}}$, the (binary) visibility predicates associated with the holosymmetric visibilities*

$$\chi_{\mathrm{law}} := \mathbf{1}\{\,|\Lambda_{\mathrm{law}}| \geq 1 - \varepsilon_{\mathrm{tol}}\,\}\,, \qquad \chi_{\mathrm{state}} := \mathbf{1}\{\,|\Lambda_{\mathrm{state}}| \geq 1 - \varepsilon_{\mathrm{tol}}\,\}$$

(Definition 7.35, with the tolerance from the plateau certification Section 6.12.4), together with the decision rule of Definition 7.685, partition the admissible configurations into exactly four disjoint classes **QI–QIV***. The partition is (i)* exclusive *(no configuration belongs to two classes) and (ii)* exhaustive up to threshold sets *on $\mathfrak{P}$. Moreover, the assignment is gauge–parameter independent (BRST/Nielsen safe).*

Proof. **Set–up and notation.** All quantities are evaluated on $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ with BRST–closed scale tags commuting with the channel projectors (Propositions 6.264 and 6.276). Plateau uniformity and derivative bounds are as in Section 6.12.4 and Remark 6.254; in particular, "≈ 1'' means $\big|\,|\cdot| - 1\big| \leq \varepsilon_{\mathrm{tol}}$ uniformly on $\mathfrak{P}$. When $\chi_{\mathrm{law}} = 0$, we refine by the law–deficit dichotomy on $\mathfrak{P}$:

$$\begin{aligned} &\text{either} \quad 1 - |\Lambda_{\mathrm{law}}(\ell)| = \mathcal{O}\big(\ell^{\,\Delta-(d+z)}\big) \quad (\text{QIII mask } \mathfrak{M}), \\ &\text{or} \quad \exists\, \delta_\star \in (0,1) : \ |\Lambda_{\mathrm{law}}| \leq 1 - \delta_\star \text{ uniformly on } \mathfrak{P}, \end{aligned} \tag{$\star$}$$

as established by Proposition 6.277 and equivalently by the Ward/spectral criteria (Theorem 7.687). The state channel is decided by the thermodynamic limit (Theorem 6.258): either $\Lambda_{\mathrm{state}}(V) \to 0$ (SSB) or $|\Lambda_{\mathrm{state}}| \approx 1$ (unique/symmetric vacuum).

(A) Exclusivity. We show the four labels are pairwise disjoint.

QI vs QII. Both require $\chi_{\mathrm{law}} = 1$, but QI imposes $|\Lambda_{\mathrm{state}}| \approx 1$ while QII imposes $\Lambda_{\mathrm{state}}(V) \to 0$. These are mutually exclusive by the thermodynamic orthogonality of distinct vacua in SSB (Theorem 6.261) together with plateau uniformity.

QIII vs QIV. Both have $\chi_{\mathrm{law}} = 0$, but the law–deficit alternatives in ($\star$) are exclusive: if $1 - |\Lambda_{\mathrm{law}}| \to 0$ with a positive power, it cannot be bounded below by any $\delta_\star > 0$, and conversely a uniform gap precludes any power–law decay to zero. This is exactly the "healing'' vs "persistent'' dichotomy proven via the scale–tagged Ward identity (Proposition 6.296) and the overlay bounds (Proposition 6.277).

Cross pairs. QI/QII have $\chi_{\mathrm{law}} = 1$ while QIII/QIV have $\chi_{\mathrm{law}} = 0$, hence disjoint.

(B) Exhaustiveness up to threshold sets. Let a configuration on $\mathfrak{P}$ be given.

If $\chi_{\mathrm{law}} = 1$, then either $\Lambda_{\mathrm{state}}(V) \to 0$ (SSB) or not. In the former case, Theorem 6.261 tags QII; in the latter, $|\Lambda_{\mathrm{state}}| \approx 1$ and we tag QI. If $\chi_{\mathrm{law}} = 0$, apply ($\star$): either the deficit heals with ℓ (QIII, inside $\mathfrak{s}$) or a plateau–uniform gap remains (QIV). Thus every configuration is assigned.

Ambiguities can arise only on *threshold sets*, namely: (i) the $\varepsilon_{\mathrm{tol}}$–boundaries where $\big||\Lambda_{\mathrm{law}}| - 1\big| = \varepsilon_{\mathrm{tol}}$ or $\big||\Lambda_{\mathrm{state}}| - 1\big| = \varepsilon_{\mathrm{tol}}$; (ii) the borderline where the law deficit neither

admits a uniform power–law decay nor a uniform positive gap (e.g. precisely marginal cases tuned to zero amplitude). These sets are of codimension ≥ 1 in control space and of zero measure under generic parameterizations; by definition of "certified plateau'' they are either excluded or flagged (cf. the plateau certification protocol of Section 6.12.4 and the QIII mask construction).

(C) Gauge–parameter independence (Nielsen safety). By Propositions 6.264 and 6.299, $\mathcal{O} \mapsto \mathcal{O}_\xi$ is ξ–independent on $\mathfrak{P}$ for $\mathcal{O} \in \{\, \Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}, D_\lambda \mathcal{O}, D_\ell \mathcal{O} \,\}$, hence both the predicates $\chi_{\mathrm{law}}, \chi_{\mathrm{state}}$ and the alternatives in $(\star)$ are gauge–parameter independent. Therefore the quadrant assignment is BRST/Nielsen safe.

Conclusion. The decision rule of Definition 7.685 induces a partition of the admissible configurations on $\mathfrak{P}$ into four classes that are pairwise disjoint (exclusivity) and cover all cases except for codimension–one threshold sets (exhaustiveness up to thresholds). The entire construction is cohomologically well–defined and gauge–parameter independent. □

Remark 8.2 (Reader intuition and operational recipe for law–state exhaustion)**.** *Big picture.* On a certified plateau $\mathfrak{P}$ (scale–stable readouts), the BRST–safe visibilities $(\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}})$—evaluated in the physical sector $\mathcal{H}_{\mathrm{phys}}$—are sufficient to classify any admissible configuration into exactly one of the four quadrants (QI–QIV) via the decision rule of Definition 7.685. The classification is *exclusive* (no overlap between labels) and *exhaustive up to thresholds* (the only undecidable cases are measure–zero boundaries where "≈ 1'' is saturated or the knife–edge between QIII healing and QIV persistence). Because Nielsen/cohomological identities hold on $\mathfrak{P}$, the assignment is *gauge–parameter independent*. Equivalently, the overlays, the scale–tagged Ward statements, and the light–sector spectrum cohere (Theorem 7.687).

Operational recipe. Measure the two visibilities on $\mathfrak{P}$ after BRST projection.

- If $|\Lambda_{\mathrm{law}}| \approx 1$ on $\mathfrak{P}$, then we are in **QI** or **QII**; the *state* channel decides: if $|\Lambda_{\mathrm{state}}(V)| \to 0$ as $V \to \infty$, assign **QII**; otherwise $|\Lambda_{\mathrm{state}}| \approx 1$ and assign **QI**.
- If $|\Lambda_{\mathrm{law}}| < 1$ on $\mathfrak{P}$, the *law* channel splits **QIII** vs **QIV**: if the deficit heals with coarse–graining,
$$1 - |\Lambda_{\mathrm{law}}(\ell)| = \mathcal{O}\Big(\ell^{\Delta-(d+z)}\Big) \qquad (\ell \downarrow 0),$$
assign **QIII**; if there is a plateau–uniform gap $\exists\, \delta_\star \in (0,1)$ with $|\Lambda_{\mathrm{law}}| \leq 1 - \delta_\star$, assign **QIV**.

Why there are only four. Under the Chapter 7/8 standing assumptions (certified plateau, evaluation in $\mathcal{H}_{\mathrm{phys}}$, BRST/Nielsen invariance), the only binary predicates are:

$$\text{Law: } |\Lambda_{\mathrm{law}}| \approx 1 \text{ vs deficit}, \qquad \text{State: } |\Lambda_{\mathrm{state}}| \approx 1 \text{ vs thermodynamic orthogonality}.$$

Their Cartesian product yields exactly the four classes QI–QIV; no fifth "type'' exists. Variants such as discrete SSB, topological order, anisotropic scaling, or competing irrelevancies are already subsumed once one uses BRST–closed, gauge–invariant probes and reads the visibilities on $\mathfrak{P}$; any non-generic in–between situations are precisely the *threshold sets* flagged by the plateau certification and do not constitute new quadrants.

Remark 8.3 (On apparent "simultaneity'' outside the formal framework)**. Thesis.** Even "in the wild,'' for a fixed symmetry G, at a fixed observational scale/window, and under a fixed measurement protocol, a single physical system cannot have a *law* that is both symmetric and explicitly asymmetric, nor a *state* that is both symmetric and symmetry–broken, at the same time. Apparent counterexamples arise from mixing contexts—scale, space, ensemble, or sector—and dissolve once those are fixed [91, 230, 101, 102, 82].

Ensemble vs single sample. Below T_c, the *ensemble* density matrix of an Ising ferromagnet can remain symmetric with $\langle M\rangle = 0$, while any *single crystal* in zero field selects $+m$ or $-m$. Symmetric in the ensemble, broken in each pure phase—never both for the same object under the same notion of "state.'' In algebraic language: distinct broken phases correspond to disjoint GNS representations (superselection sectors) and become orthogonal in the thermodynamic limit [230, 91].

Finite size and cat states. With exact symmetry and finite volume, the unique ground state may be a Schrödinger–cat superposition of symmetry–broken sectors. Infinitesimal symmetry–breaking fields or the order of limits (take $V\to\infty$ before $h\to 0$) select a definite sector. Thus the state is formally symmetric at finite V but operationally broken once limits/perturbations are specified [91, 230].

Domain/phase coexistence. Near first–order transitions or with quenched disorder, different spatial regions may choose different orientations. Locally broken, globally (after coarse–graining) possibly symmetric—this is spatial mixing, not simultaneity for a single homogeneous state [101].

Scale separation (UV vs IR). Microscopic anisotropies can be visible at short scales and wash out under coarse–graining: the *law* appears asymmetric in the UV but flows to an IR–symmetric fixed point (emergent symmetry). This is scale dependence, not "both at once'' at a fixed scale [102, 82].

Partial or sectoral symmetries. A symmetry group may be only partially broken (e.g. nematic order breaks rotations but not translations) or broken in one sector of the full theory but exact in another (parity violation in weak interactions vs parity conservation in QCD). For any given generator, the verdict is binary once the sector is fixed [91, 101].

Anomalies. Classically symmetric, quantum mechanically not (e.g. $U(1)_A$ in QCD): the correct quantum *law* is asymmetric; calling it "both'' mixes levels of description. This is the textbook chiral–anomaly resolution [82, 91].

Non–equilibrium / time–crystalline behavior. A Hamiltonian (or Floquet operator) can be symmetric while the *state* breaks time–translation symmetry (e.g. period–doubling). That is the canonical "law symmetric, state asymmetric'' case—not simultaneity of symmetric and explicitly asymmetric *law*. See, e.g., discrete time–crystal constructions in periodically driven many–body systems [396, 448, 449].

Topological order. In topologically ordered phases, local order parameters may vanish although the system exhibits long–range entanglement and topological degeneracy. The *state* can be symmetric under G while displaying nonlocal order; this is neither "both symmetric and broken'' nor an extra quadrant—it is a different organizing principle for order [102].

Rule of thumb. To avoid false "both'' verdicts, fix: (i) the symmetry G and generator, (ii) the observation scale/window, (iii) whether we mean a pure sector or an ensemble/disorder average, (iv) the order of thermodynamic/time limits, and (v) gauge–invariant/BRST–closed probes where applicable. Once these are fixed, the law/state verdict is definite and mutually exclusive—matching the formal classification proven in Chapters 7–8 [117, 91, 230].

Definition 8.4 (Witness = sector–conditioned visibility recipe)**.** Fix an admissible sector $\mathscr{S}$ (bulk or boundary, possibly anisotropic) realised on a certified plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$), with BRST–closed scale tags $P_x(\lambda_{\mathrm{UV}})$ and K_{IR} and channel projectors $\{\Pi_\alpha\}$ (ghost number 0). A *witness* for $\mathscr{S}$ is a map that assigns to the tagged data a number in $[0,1]$:

$$\mathbf{W}^{[\mathscr{S}]}:\ \Big(\text{tagged operators, currents, states on } \mathfrak{P}\Big)\ \longrightarrow\ [0,1],$$

constructed from BRST–closed ingredients and evaluated in the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, and satisfying the axioms below. We call the output $\Lambda^{[\mathscr{S}]} := \mathbf{W}^{[\mathscr{S}]}$ a *visibility*.

Definition 8.5 (Law vs. State witnesses)**.** A *law witness* $\Lambda^{[\mathscr{S}]}_{\mathrm{law}}$ diagnoses explicit symmetry breaking in the *dynamics* (e.g. normalized Ward sources, adjoint divergences, control–unitary overlaps). A *state witness* $\Lambda^{[\mathscr{S}]}_{\mathrm{state}}$ diagnoses spontaneous breaking in the *state* (e.g. symmetry–related overlaps/cluster ratios, certified order parameters, pole diagnostics). The *witness pair* for $\mathscr{S}$ is $\big(\Lambda^{[\mathscr{S}]}_{\mathrm{law}},\ \Lambda^{[\mathscr{S}]}_{\mathrm{state}}\big)$.

Definition 8.6 (Certified witness pair and predicates)**.** Fix plateau tolerances $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ (cf. Section 6.12.4). Define binary predicates

$$\chi^{[\mathscr{S}]}_{\mathrm{law}} := \mathbf{1}\Big[\,|\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| \geq 1-\varepsilon_{\mathrm{law}}\,\Big], \qquad \chi^{[\mathscr{S}]}_{\mathrm{state}} := \mathbf{1}\Big[\,|\Lambda^{[\mathscr{S}]}_{\mathrm{state}}| \geq 1-\varepsilon_{\mathrm{state}}\,\Big],$$

and the *law deficit* $d^{[\mathscr{S}]}_{\mathrm{law}} := 1 - |\Lambda^{[\mathscr{S}]}_{\mathrm{law}}|$. The quadrant $\mathrm{Quad}^{[\mathscr{S}]}$ is determined by the canonical decision rule (Definition 7.685), with QIII vs. QIV fixed by the large–window test in the sector arena.

Axioms for a witness (uniform on the certified plateau). Let $\mathbf{W}^{[\mathscr{S}]}$ be built from BRST–closed operators (ghost number 0), with BRST–safe norms. Then on the certified band $B \subset (\lambda_{\mathrm{UV}}, \ell)$ (or its boundary/anisotropic analogue):

(W1) BRST/Nielsen invariance. $\partial_\xi \mathbf{W}^{[\mathscr{S}]} = 0$ and $\mathbf{W}^{[\mathscr{S}]}[\Psi] = \mathbf{W}^{[\mathscr{S}]}[\Psi + \{\hat{Q}_{\mathrm{BRST}}, B\}]$ (Propositions 6.264 and 6.276).

(W2) Cone preservation and functoriality. Holosymmetric lifts, p–form dualities, and triadic projections commute with evaluation and do not alter cones nor mix channels (Propositions 6.257 and 8.16 and Corollary 6.259).

(W3) Normalization and boundedness. $0 \leq \mathbf{W}^{[\mathscr{S}]} \leq 1$. On a sectoral *reference* symmetric instance, $\mathbf{W}^{[\mathscr{S}]} = 1$; explicit breakings reduce it monotonically (up to $o_B(1)$ renormalizations; Remark 6.254).

(W4) Plateau stability (tolerance semantics). $D_\lambda \mathbf{W}^{[\mathscr{S}]}$ and $D_\ell \mathbf{W}^{[\mathscr{S}]}$ are uniformly bounded on B (Proposition 6.298); equalities are interpreted as "≈ 1'' within $(\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}})$.

(W5) Large–window criterion (QIII/QIV). There exists a sector dilation parameter r (bulk ℓ, boundary L, anisotropic $\min(\vec{\ell})$, or non–eq. coarse–graining) such that:

$$\begin{aligned} \text{QIII} &\iff \exists\, \beta > 0,\, C < \infty :\ d_{\text{law}}^{[\mathscr{S}]}(r) \le C\, r^{-\beta}; \\ \text{QIV} &\iff \exists\, \delta_\star \in (\varepsilon_{\text{law}}, 1) :\ d_{\text{law}}^{[\mathscr{S}]}(r) \ge \delta_\star. \end{aligned}$$

(See sector blocks and Theorem 7.687.)

Remark 8.7 (Relationship to earlier notions)**.** The *visibility* $\Lambda_\bullet$ used throughout Chapters 7–8 is the *value* returned by a witness. Sector blocks (fermions, SUSY, hydrodynamics, boundary, subsystem/fracton, higher–spin, p–forms, non–equilibrium) instantiate $\mathbf{W}^{[\mathscr{S}]}$ concretely (e.g. normalized Ward–source quotients, overlap diagnostics), all conforming to **(W1)**–**(W5)**.

Remark 8.8 (Examples (pointers))**.** Hydrodynamic witnesses: Definition 8.21; boundary: Definition 8.31; subsystem/fracton: Definition 8.36; fermionic/SUSY/ p–form/HS blocks: Definitions 8.10, 8.12, 8.15 and 8.18; non–equilibrium (Floquet/Lindblad): Definition 8.43. Their quadrant rules follow from Propositions 8.23, 8.32 and 8.38 and the universal cartography theorems.

Definition 8.9 (Sector-conditioned visibilities and arenas)**.** Let $\mathscr{S}$ be any admissible sector, realised on an arena $\mathcal{A} \in \{\mathfrak{P},\ \mathfrak{P}_\partial\}$. With the UV projector $P_x(\lambda_{\text{UV}})$ and an (optionally anisotropic) IR window $K_{\text{IR}}^{(\vec{\ell})}$ on $\mathcal{A}$, define the BRST-safe pair

$$\left(\Lambda_{\text{law}}^{[\mathscr{S}]},\ \Lambda_{\text{state}}^{[\mathscr{S}]}\right)$$

by instantiating the witnesses of Definition 7.35 using sector-specific Ward sources and correlators (after projection to $\mathcal{H}_{\text{phys}}$ and band-limiting by $P_x(\lambda_{\text{UV}}) \circ K_{\text{IR}}^{(\vec{\ell})}$). The quadrant label is

$$\text{Quad}^{[\mathscr{S}]} := \text{Quad}\left(\Lambda_{\text{law}}^{[\mathscr{S}]}, \Lambda_{\text{state}}^{[\mathscr{S}]}\right),$$

with Quad given in Definition 7.685. *Pointers:* for concrete witnesses see Definitions 8.21, 8.31, 8.33 and 8.36.

8.1.1 Fermionic Witnesses

Definition 8.10 (Fermionic witnesses, tags, and normalization)**.** Work on the certified bulk plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$. Let $S^R(\omega, \mathbf{k})$ be the *retarded* fermion propagator with IR/UV tags $K_{\text{IR}}^{(\ell)}$, $P_x(\lambda_{\text{UV}})$ acting on the fermionic block, and let $\mathcal{D}^{(\ell)}$ denote the tagged wave operator with tagged mass matrix $M^{(\ell)}$. Define the *fermionic law visibility* by the (dimensionless) ratio

$$\Lambda_{\text{law}}^{[\text{ferm}]} := 1 - \frac{\left\|\text{Src}^{(\text{ferm})}\right\|_{\mathfrak{P}}}{\left\|\text{Ref}^{(\text{ferm})}\right\|_{\mathfrak{P}}}, \qquad \text{Src}^{(\text{ferm})} := \sum_k \epsilon_k(\ell) \left\langle \mathcal{S}_{k,a}^{(\lambda_{\text{UV}})} \right\rangle_{\Psi}\Big|_{\text{ferm. block}},$$

where $\|\cdot\|_{\mathfrak{P}}$ is any plateau–uniform, BRST–safe operator norm or spectral (Källén–Lehmann) seminorm compatible with the tags, and the reference $\text{Ref}^{(\text{ferm})}$ is a fixed nonzero, conserved

benchmark (e.g. the tagged, improved Noether density or the S^R residue sum on $\mathfrak{P}$), chosen once and for all so that $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} \in [0,1]$. Define the *fermionic state visibility* by the presence/absence of spontaneous breaking in the fermionic channel (e.g. chiral or flavor order):

$$\Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} := \begin{cases} 1, & \text{symmetric state on } \mathfrak{P} \ \text{ (no fermionic order parameter)}, \\ 0, & \text{SSB in a fermionic channel on } \mathfrak{P} \ \text{ (nonzero order parameter / NG partner)}. \end{cases}$$

All insertions are evaluated as $P_x(\lambda_{\mathrm{UV}})\, K^{(\ell)}_{\mathrm{IR}}\,(\cdot)\, K^{(\ell)}_{\mathrm{IR}}\, P_x(\lambda_{\mathrm{UV}})$ and are BRST–closed, ghost number 0.

Intuition. The law visibility measures explicit symmetry breaking *restricted to the fermion sector*, via the scale–tagged Ward sources on the fermionic block; the normalization makes it dimensionless and plateau–uniform. The state visibility detects whether the *state* itself breaks the same fermionic symmetry (e.g. chiral SSB), and by BRST/Nielsen invariance it is gauge–parameter independent (Propositions 6.276 and 7.644).

Proposition 8.11 (Fermionic quadrant assignment)**.** *On the certified plateau* $\mathfrak{P}$*,*

QI : $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} = 1, \quad \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 1;$

QII : $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} = 1, \quad \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 0, \quad$ *(law conserved; fermionic SSB, NG partners present)*;

QIII : $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}}(\ell) \xrightarrow[\ell\downarrow 0]{} 1, \quad \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 1, \quad$ *(IR healing of irrelevant explicit deformations)*;

QIV : $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} \le 1 - \delta_\star$ *uniformly on* $\mathfrak{P}$, $\quad \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 1,$
(persistent explicit breaking; analytic mass/mixing shifts).

Proof (fermionic specialization of Chapter 7/8 results). Standing hypotheses. Work in $\mathcal{H}_{\mathrm{phys}}$ with BRST–closed tags and channel projectors, so Nielsen identities hold (Propositions 6.264 and 6.276). Let $\bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}}$ be the improved current restricted to the fermionic block; the scale–tagged fermionic Ward statement is the fermionic restriction of Proposition 6.296:

$$\nabla^{(\mathrm{ad})}_\mu \bar{J}^{(\lambda_{\mathrm{UV}},\ell)\mu}_{a,\mathrm{imp}}\Big|_{\mathrm{ferm}} = \sum_k \epsilon_k(\ell) \left\langle \mathcal{S}^{(\lambda_{\mathrm{UV}})}_{k,a} \right\rangle_{\Psi}\Big|_{\mathrm{ferm}}. \tag{8.1}$$

QI. Exact symmetry on the law side implies the r.h.s. of (8.1) vanishes; with the chosen normalization, $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} = 1$. A unique symmetric state on $\mathfrak{P}$ implies $\Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 1$ (no fermionic order parameter; cluster decomposition) [91, 230].

QII. Law symmetry persists $\Rightarrow$ same law verdict as QI. If the state spontaneously breaks a fermionic symmetry (e.g. chiral), the thermodynamic orthogonality of distinct vacua and the Goldstone theorem yield $\Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 0$ with exact NG partners in the spectral function [94, 91].

QIII. Let the fermionic explicit breakings be RG–irrelevant ($\Delta_k > d + z$). Then $\epsilon_k(\ell) = \mathcal{O}(\ell^{\Delta_k - (d+z)})$ and the r.h.s. of (8.1) decays with the same power. Hence $\|\mathrm{Src}^{(\mathrm{ferm})}\|_{\mathfrak{P}}$ is $o(1)$ compared to the fixed reference, so $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}}(\ell) \to 1$; the state remains symmetric, giving $\Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 1$ [102, 82].

QIV. With a relevant/marginal explicit fermionic breaking surviving on $\mathfrak{P}$, $\|\mathrm{Src}^{(\mathrm{ferm})}\|_{\mathfrak{P}}$ is bounded below, so $\Lambda_{\mathrm{law}}^{[\mathrm{ferm}]} \le 1-\delta_\star$. The state is uniquely prepared (no SSB in the fermionic channel on $\mathfrak{P}$), hence $\Lambda_{\mathrm{state}}^{[\mathrm{ferm}]} = 1$. By gauge–safe analyticity of tagged two–point functions on $\mathcal{H}_{\mathrm{phys}}$ (Theorem 7.646), mass/mixing shifts are analytic in the explicit couplings and do not change spin 1/2 assignments.

All steps are plateau–uniform and BRST/Nielsen–safe by construction. □

Consistency checks and edge cases (fermionic).

- *Anomalies.* Axial or gauge anomalies (e.g. $U(1)_A$ in QCD) render the quantum law asymmetric; these are excluded by the anomaly–free BRST standing assumption (Remark 6.266) [82, 91].
- *Discrete chiral SSB.* No NG fermions; domain–wall excitations appear instead. The state predicate still drops to 0 in the thermodynamic limit (orthogonality), matching QII.
- *Topological and symmetry–class structure.* Fermionic protected edge modes (e.g. in topological insulators) do not alter the spin content but may constrain allowed mass deformations; use BRST–closed, gauge–invariant probes and the verdict still lands in QI–QIV [102].
- *Majorana vs Dirac and mixings.* The tags and norms are representation–agnostic; explicit deformations move poles/residues *analytically* without changing spin, consistent with Theorem 7.646.

8.1.2 SUSY Witnesses

Definition 8.12 (SUSY witnesses (tolerance form))**.** Work on a certified plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$. Let S^μ_α be the (band-limited/improved) supercurrent. After projection to $\mathcal{H}_{\mathrm{phys}}$, the tagged SUSY Ward identity reads $\partial_\mu S^\mu_\alpha = \sum_j \epsilon_j(\ell)\, Y_{j,\alpha}$ (modulo BRST-exact improvements). Define the SUSY *law* visibility by

$$\Lambda_{\mathrm{law}}^{[\mathrm{SUSY}]} := 1 - \frac{\left\| \sum_j \epsilon_j \langle Y_j \rangle \right\|_{\mathfrak{P}}}{\| \partial_\mu S^\mu \|_{\mathrm{ref},\mathfrak{P}}} \in [0,1],$$

where the norms are BRST-safe and uniform on $\mathfrak{P}$. Let $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ be the certified tolerances (cf. the plateau criterion). For the *state* witness we adopt plateau–tolerance semantics:

$$\text{Global SUSY:} \quad \begin{cases} \text{unbroken on } \mathfrak{P} \iff |\Lambda_{\mathrm{state}}^{[\mathrm{SUSY}]}| \ge 1-\varepsilon_{\mathrm{state}} \ \ (\text{equivalently } Q_\alpha|\Omega\rangle \approx 0), \\ \text{SSB on } \mathfrak{P} \iff |\Lambda_{\mathrm{state}}^{[\mathrm{SUSY}]}| \le \varepsilon_{\mathrm{state}} \ \ (\text{equivalently } Q_\alpha|\Omega\rangle \not\approx 0). \end{cases}$$

Local SUSY (supergravity):

$$\begin{cases} \text{unbroken on } \mathfrak{P} \iff |\Lambda_{\text{state}}^{[\text{SUSY}]}| \geq 1 - \varepsilon_{\text{state}} \\ \qquad\qquad \text{(vanishing SUSY order parameters,)} \\ \qquad\qquad \text{(background admitting Killing spinor),} \\ \text{broken on } \mathfrak{P} \iff |\Lambda_{\text{state}}^{[\text{SUSY}]}| \leq \varepsilon_{\text{state}} \\ \qquad\qquad \text{(super-Higgs regime).} \end{cases}$$

All insertions are evaluated as $P_x(\lambda_{\text{UV}})\, K_{\text{IR}}^{(\ell)}(\cdot)\, K_{\text{IR}}^{(\ell)}\, P_x(\lambda_{\text{UV}})$ with BRST-closed tags.

Intuition. $\Lambda_{\text{law}}^{[\text{SUSY}]} \approx 1$ (within ε_{law}) iff explicit SUSY-breaking sources are negligible on $\mathfrak{P}$ [52]. The state witness distinguishes spontaneous SUSY breaking: global $\Rightarrow$ goldstino; local $\Rightarrow$ super-Higgs [52].

Lemma 8.13 (Goldstino vs super-Higgs (tolerance form))**.** *Assume on* $\mathfrak{P}$ *that*

$$|\Lambda_{\text{law}}^{[\text{SUSY}]}| \;\geq\; 1 - \varepsilon_{\text{law}}, \qquad |\Lambda_{\text{state}}^{[\text{SUSY}]}| \;\leq\; \varepsilon_{\text{state}}.$$

Then:

Global SUSY.
A massless goldstino appears as the NG mode of SUSY.

Local SUSY.
The goldstino is eaten (super-Higgs) and the gravitino becomes massive; no physical massless goldstino remains.

Proposition 8.14 (SUSY quadrant assignment (tolerance form))**.** *On* $\mathfrak{P}$,

$$\textbf{QI}: \quad \begin{aligned} |\Lambda_{\text{law}}^{[\text{SUSY}]}| &\;\geq\; 1 - \varepsilon_{\text{law}}, \\ |\Lambda_{\text{state}}^{[\text{SUSY}]}| &\;\geq\; 1 - \varepsilon_{\text{state}}, \end{aligned}$$

$$\textbf{QII}: \quad \begin{aligned} |\Lambda_{\text{law}}^{[\text{SUSY}]}| &\;\geq\; 1 - \varepsilon_{\text{law}}, \\ |\Lambda_{\text{state}}^{[\text{SUSY}]}| &\;\leq\; \varepsilon_{\text{state}} \\ &\Big(\textit{global: goldstino; local: super-Higgs to massive } \tfrac{3}{2}\Big), \end{aligned}$$

$$\textbf{QIII}: \quad \begin{aligned} 1 - |\Lambda_{\text{law}}^{[\text{SUSY}]}(\ell)| &\;\leq\; C\, \ell^{\,\Delta-(d+z)} \quad (\ell \downarrow 0), \\ |\Lambda_{\text{state}}^{[\text{SUSY}]}| &\;\geq\; 1 - \varepsilon_{\text{state}}, \end{aligned}$$

$$\textbf{QIV}: \quad \begin{aligned} &\exists\, \delta_\star \in (\varepsilon_{\text{law}}, 1): \; |\Lambda_{\text{law}}^{[\text{SUSY}]}| \;\leq\; 1 - \delta_\star \;\; \textit{uniformly on } \mathfrak{P}, \\ &|\Lambda_{\text{state}}^{[\text{SUSY}]}| \;\geq\; 1 - \varepsilon_{\text{state}}. \end{aligned}$$

Intuition. QII captures spontaneous SUSY breaking (goldstino or super-Higgs) [52, 91]. QIII vs QIV is decided by *decay vs persistent gap* in the SUSY Ward source on $\mathfrak{P}$, in full analogy with the bosonic and fermionic sectors [82, 112]; Nielsen/BRST safety ensures gauge-parameter independence of all witnesses and assignments [82, 91].

8.1.3 p-Forms Witnesses

Definition 8.15 (p-form reduction map in 3+1 (tolerance-consistent))**.** Work on a certified plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ with BRST–closed scale tags $P_x(\lambda_{\rm UV})$, $K_{\rm IR}^{(\ell)}$. Let $\mathscr{P}_p$ be an abelian p-form gauge sector in 3+1 with potential A_p and field strength $F_{p+1} = \mathrm{d}A_p$. Define the BRST–compatible Hodge–duality functor $\mathcal{D} : \mathscr{P}_p \to \mathscr{S}_{\rm spin}$ by the on–shell relations

$$F_{p+1} \;=\; *\tilde{F}_{3-p}, \qquad \tilde{F}_{3-p} = \mathrm{d}\tilde{A}_{2-p},$$

so that, in 3+1,

$$\begin{cases} p=1: & \mathscr{P}_1 \xrightarrow{\mathcal{D}} \text{spin-1 sector } (\tilde{A}_1), \\ p=2: & \mathscr{P}_2 \xrightarrow{\mathcal{D}} \text{spin-0 sector } (\tilde{A}_0 \equiv \varphi). \end{cases}$$

After band–limiting and projection to $\mathcal{H}_{\rm phys}$, define the sector–conditioned visibilities *by transport through* $\mathcal{D}$ and interpret "≈ 1'' with certified plateau tolerances (cf. Section 6.12.4):

$$\Lambda_{\rm law}^{[\mathscr{P}_p]} := \Lambda_{\rm law}^{[\mathcal{D}(\mathscr{P}_p)]}, \qquad \Lambda_{\rm state}^{[\mathscr{P}_p]} := \Lambda_{\rm state}^{[\mathcal{D}(\mathscr{P}_p)]}.$$

All statements are understood modulo BRST–exact improvements and with tolerance semantics ($|\Lambda| \geq 1-\varepsilon$ on $\mathfrak{P}$).

Intuition. In 3+1D, a 1–form gauge field is dual to another 1–form, and a 2–form is dual to a scalar [102, 112]. BRST/Hodge duality preserves the Ward data and two–point structures entering the visibilities, so the p–form sector inherits the scalar/vector rows of the spins table (table 7.6—no new quadrant behavior appears [82, 91, 102].

Proposition 8.16 (Quadrant equivalence for p–forms in 3+1)**.** *For $p \in \{1,2\}$ in 3+1D and on a certified plateau $\mathfrak{P}$ (with tolerance semantics),*

$$\mathrm{Quad}^{[\mathscr{P}_p]} \;=\; \mathrm{Quad}^{[\mathcal{D}(\mathscr{P}_p)]}.$$

Proof sketch. Hodge duality $*$ is an isometry on forms (up to signature–dependent signs) and intertwines conserved currents and Ward sources in abelian p–form theories [102, 82]. With BRST–closed tags and evaluation on $\mathcal{H}_{\rm phys}$, $\mathcal{D}$ preserves: (i) the scale–tagged Ward identity (hence the law–channel deficit, within plateau tolerances), and (ii) the light–sector two–point/spectral data (hence the state–channel verdict) [82, 91]. Functoriality and cone preservation ensure no spurious channel mixing. Therefore the visibility predicates—and thus the quadrant label—are invariant under $\mathcal{D}$ on $\mathfrak{P}$. □

Remark 8.17 (Endpoints and couplings)**.** (i) $p = 0$ is already spin–0. For $p = 3$ in 3+1, F_4 is topological and carries no local propagating DOF; when present it maps to a constant/axion–like background, so its quadrant reduces to the scalar entry of $\mathcal{D}(\mathscr{P}_3)$ on $\mathfrak{P}$ (tolerance semantics understood) [112, 102]. (ii) BF/Stückelberg or θ–type couplings induce mixings but, after band–limited diagonalization in the BRST–closed setting, do not affect Proposition 8.16; the visibilities remain Nielsen/BRST–safe and the quadrant assignment is unchanged on $\mathfrak{P}$ [109, 113, 112].

8.1.4 Higher Spins Witnesses

Definition 8.18 (Higher-spin (HS) witnesses (tolerance form))**.** Work on a certified plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ with BRST–closed scale tags $P_x(\lambda_{\text{UV}})$, $K_{\text{IR}}^{(\ell)}$ [82, 91]. Let $\mathscr{H}_s$ be a consistent higher–spin ($s > 2$) gauge sector with gauge parameter $\xi_{(s-1)}$ and improved (band–limited) conserved current $J^{(s)}$ [102, 112]. After band/BRST cleaning, the tagged HS Ward identity reads $\nabla \cdot J^{(s)} =$ HS Ward sources (modulo BRST–exact improvements) [82, 91]. Define the HS *law* visibility by

$$\Lambda_{\text{law}}^{[s]} := 1 - \frac{\big\|\text{HS Ward sources}\big\|_{\mathfrak{P}}}{\big\|\nabla \cdot J^{(s)}\big\|_{\text{ref},\mathfrak{P}}} \in [0,1],$$

with plateau–uniform BRST–safe norms [82, 112]. Let $\varepsilon_{\text{law}}, \varepsilon_{\text{state}} \in (0,1)$ be the certified tolerances (cf. the plateau criterion). For the *state* witness we use plateau–tolerance semantics:

$$\text{unbroken on } \mathfrak{P} \iff |\Lambda_{\text{state}}^{[s]}| \geq 1 - \varepsilon_{\text{state}}, \qquad \text{SSB on } \mathfrak{P} \iff |\Lambda_{\text{state}}^{[s]}| \leq \varepsilon_{\text{state}},$$

equivalently detected by a HS order parameter / would–be HS NG sector (for global) or by a BEH–like eating if gauged [94, 91, 112, 113]. All insertions are evaluated as $P_x(\lambda_{\text{UV}})\, K_{\text{IR}}^{(\ell)}(\cdot)\, K_{\text{IR}}^{(\ell)}\, P_x(\lambda_{\text{UV}})$.

Intuition. Breaking in the *state* channel produces a would–be HS NG sector; if the symmetry is gauged, a BEH–like mechanism can occur [94, 91, 112, 113]. Explicit breaking in the *law* channel yields persistent masses/mixings; within a certified plateau we read these via the HS Ward sources [82, 102, 112].

Lemma 8.19 (Helicity stability under explicit deformations)**.** *Within the admissible band on $\mathfrak{P}$ and for small explicit breakings, the helicity content of $\mathscr{H}_s$ is invariant: pole locations and residues shift* analytically *while spin labels are unchanged.*

Proposition 8.20 (Higher–spin quadrant assignment (tolerance form))**.** *On $\mathfrak{P}$,*

$$\textit{QI:}\quad |\Lambda_{\text{law}}^{[s]}| \geq 1 - \varepsilon_{\text{law}}, \qquad |\Lambda_{\text{state}}^{[s]}| \geq 1 - \varepsilon_{\text{state}}, \tag{8.2}$$

$$\textit{QII:}\quad |\Lambda_{\text{law}}^{[s]}| \geq 1 - \varepsilon_{\text{law}}, \qquad |\Lambda_{\text{state}}^{[s]}| \leq \varepsilon_{\text{state}} \ \textit{(SSB; if gauged, HS BEH may operate)}, \tag{8.3}$$

$$\textit{QIII:}\quad 1 - |\Lambda_{\text{law}}^{[s]}(\ell)| \leq C\,\ell^{\,\Delta-(d+z)} \ (\ell \downarrow 0), \qquad |\Lambda_{\text{state}}^{[s]}| \geq 1 - \varepsilon_{\text{state}}, \tag{8.4}$$

$$\textit{QIV:}\quad \exists\, \delta_\star \in (\varepsilon_{\text{law}}, 1) : \ |\Lambda_{\text{law}}^{[s]}| \leq 1 - \delta_\star \ \textit{uniformly on } \mathfrak{P}, \qquad |\Lambda_{\text{state}}^{[s]}| \geq 1 - \varepsilon_{\text{state}}. \tag{8.5}$$

Comments. *QI: massless spin–s representations appear if the background allows; QII: state SSB (global: HS NG sector; gauged: BEH–like eating); QIII: IR healing of irrelevant explicit breakings in the law channel; QIV: persistent explicit mass/mixing; spins fixed by Lemma 8.19.*

Intuition. The quadrant logic is spin–agnostic; only the witnesses differ. Tolerance semantics ensures consistency with the certified–plateau framework used throughout.

8.1.5 Hydrodynamics Witnesses

Definition 8.21 (Hydrodynamic witnesses (tolerance form))**.** Work on a certified plateau $\mathfrak{P}$ and in $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ with BRST–closed scale tags [82, 91]. Let $G^R_{nn}(\omega, \mathbf{k})$ denote the retarded density correlator near $\omega, \mathbf{k} \to 0$ [119, 102]. On $\mathfrak{P}$ (isotropic IR window $K^{(\ell)}_{\rm IR}$ so that $k \sim \ell^{-1}$),

$$G^R_{nn}(\omega, \mathbf{k}) \;\simeq\; \frac{\chi\, D(\ell)\, k^2}{-i\omega + D(\ell)k^2 + \Gamma(\ell)}\,,$$

which is the standard diffusive pole structure for conserved densities in linear response [119, 102]. Define the *law* visibility and adopt plateau tolerances $\varepsilon_{\rm law}, \varepsilon_{\rm state} \in (0, 1)$:

$$\Lambda^{[\rm hydro]}_{\rm law}(\ell) \;:=\; \frac{D(\ell)k^2}{D(\ell)k^2 + \Gamma(\ell)}\Big|_{k\sim\ell^{-1}}, \qquad \text{“law symmetric”} \iff |\Lambda^{[\rm hydro]}_{\rm law}| \;\geq\; 1 - \varepsilon_{\rm law}.$$

For the *state* witness:

$$\text{“state symmetric”} \iff |\Lambda^{[\rm hydro]}_{\rm state}| \;\geq\; 1 - \varepsilon_{\rm state} \quad \text{(pure diffusion near } k \to 0),$$

$$\text{“state SSB”} \iff |\Lambda^{[\rm hydro]}_{\rm state}| \;\leq\; \varepsilon_{\rm state} \quad \text{(Goldstone sound: } \omega = \pm c_s k - i\gamma k^2 + \cdots)$$

where diffusive and sound modes are the standard hydrodynamic poles associated with conserved charges and spontaneously broken symmetries [119, 102, 112]. *Convention.* In this hydrodynamic block we use an *isotropic* IR window $K^{(\ell)}_{\rm IR}$ (so $k \sim \ell^{-1}$), in contrast to the *anisotropic* $K^{(\vec{\ell})}_{\rm IR}$ employed for the fracton/subsystem sector.

Explanatory remarks. The definition sets up hydrodynamic witnesses in complete analogy with the other sectors of the quadrant scheme, but specialized to the long–wavelength, low–frequency behavior of a conserved density. The working arena is a certified plateau $\mathfrak{P}$ and the physical BRST cohomology $\mathcal{H}_{\rm phys} = H^0(\hat{Q}_{\rm BRST})$ with BRST–closed IR/UV tags. This guarantees that all correlators and Ward identities entering the witnesses are already projected to the physical sector and are insensitive to gauge–parameter choices, within the plateau tolerances [82, 91].

The basic observable is the retarded correlator $G^R_{nn}(\omega, \mathbf{k})$ of a conserved density n, evaluated in the hydrodynamic regime $\omega, \mathbf{k} \to 0$ within an isotropic IR window $K^{(\ell)}_{\rm IR}$ so that the momentum scale is effectively $k \sim \ell^{-1}$. In this regime the correlator is assumed to exhibit the standard diffusive pole structure

$$G^R_{nn}(\omega, \mathbf{k}) \;\simeq\; \frac{\chi\, D(\ell)\, k^2}{-i\omega + D(\ell)k^2 + \Gamma(\ell)}\,,$$

where χ is the static susceptibility, $D(\ell)$ is a possibly scale–dependent diffusion constant, and $\Gamma(\ell)$ is an effective relaxation rate encoding explicit violation of the associated conservation law [119, 102]. The denominator $-i\omega + Dk^2 + \Gamma$ thus separates reversible diffusive transport (Dk^2) from irreversible leakage (Γ).

On this basis, the hydrodynamic *law* witness

$$\Lambda_{\text{law}}^{[\text{hydro}]}(\ell) := \frac{D(\ell)k^2}{D(\ell)k^2 + \Gamma(\ell)}\Big|_{k\sim\ell^{-1}}$$

is introduced as a dimensionless visibility in $[0,1]$ which measures the fraction of the decay rate attributable to diffusion rather than explicit leakage. When $\Gamma(\ell)$ is negligible compared to $D(\ell)k^2$ at the probed scale, the ratio is close to 1 and the law channel is effectively symmetric. Conversely, sizable $\Gamma(\ell)$ drives $\Lambda_{\text{law}}^{[\text{hydro}]}$ away from 1, indicating a persistent law–deficit. The plateau tolerance ε_{law} then provides the precise semantics: "law symmetric'' corresponds to $|\Lambda_{\text{law}}^{[\text{hydro}]}| \geq 1 - \varepsilon_{\text{law}}$, while significant deficits appear as violations of this bound [119, 112].

The *state* witness is defined at the same conceptual level but keyed to the qualitative nature of the hydrodynamic poles. In the symmetric state, the density mode is purely diffusive in the long–wavelength limit $k \to 0$; in the spontaneously broken phase, the hydrodynamic spectrum contains a propagating sound–mode Goldstone with dispersion $\omega = \pm c_s k - i\gamma k^2 + \cdots$. The visibility $\Lambda_{\text{state}}^{[\text{hydro}]}$ is not given by an explicit formula here, but its tolerance semantics are fixed: "state symmetric'' corresponds to $|\Lambda_{\text{state}}^{[\text{hydro}]}| \geq 1 - \varepsilon_{\text{state}}$ (diffusive regime), and "state SSB'' corresponds to $|\Lambda_{\text{state}}^{[\text{hydro}]}| \leq \varepsilon_{\text{state}}$ (sound Goldstone regime). In this way, the diffusive versus sound character of the long–wavelength excitation is compressed into a binary state–channel predicate, compatible with the global quadrant diagnostic scheme [119, 102, 112].

Finally, the convention of an isotropic IR window $K_{\text{IR}}^{(\ell)}$ (so that $k \sim \ell^{-1}$) is recorded explicitly to distinguish the hydrodynamic sector from the anisotropic IR windows $K_{\text{IR}}^{(\vec{\ell})}$ required later for fracton and subsystem–symmetric sectors, where different components of $\vec{k}$ scale differently with the IR lengths. This ensures that the hydrodynamic witnesses are interpreted within a standard isotropic scaling framework while remaining fully compatible with the BRST/plateau infrastructure of the broader formalism [102, 112].

Lemma 8.22 (Hydrodynamic law predicate (tolerance equivalences))**.** *On $\mathfrak{P}$ and at $k \sim \ell^{-1}$,*

$$|\Lambda_{\text{law}}^{[\text{hydro}]}| \;\geq\; 1 - \varepsilon_{\text{law}} \quad\Longleftrightarrow\quad \Gamma(\ell) \;\leq\; \frac{\varepsilon_{\text{law}}}{1 - \varepsilon_{\text{law}}}\, D(\ell)\, k^2.$$

In particular, the sharp limit $\varepsilon_{\text{law}} \to 0$ reproduces $\Gamma(\ell) = 0$ (no relaxation term in the continuity equation on the band).

Proof sketch. From $\Lambda_{\text{law}} = Dk^2/(Dk^2 + \Gamma)$ one has $1 - \Lambda_{\text{law}} = \Gamma/(Dk^2 + \Gamma)$. The inequality $1 - \Lambda_{\text{law}} \leq \varepsilon_{\text{law}}$ is equivalent to $\Gamma \leq \frac{\varepsilon_{\text{law}}}{1-\varepsilon_{\text{law}}} Dk^2$. Taking $\varepsilon_{\text{law}} \to 0$ yields $\Gamma = 0$. □

Proposition 8.23 (Hydrodynamic quadrant assignment (tolerance form))**.** *On a certified*

plateau $\mathfrak{P}$ *(with* $k \sim \ell^{-1}$*):*

$$\begin{aligned}
&\textit{QI:} \quad |\Lambda_{\mathrm{law}}^{[\mathrm{hydro}]}| \;\geq\; 1-\varepsilon_{\mathrm{law}},\\
&\qquad\; |\Lambda_{\mathrm{state}}^{[\mathrm{hydro}]}| \;\geq\; 1-\varepsilon_{\mathrm{state}} \quad \textit{(pure diffusion)},\\[2ex]
&\textit{QII:} \quad |\Lambda_{\mathrm{law}}^{[\mathrm{hydro}]}| \;\geq\; 1-\varepsilon_{\mathrm{law}},\\
&\qquad\; |\Lambda_{\mathrm{state}}^{[\mathrm{hydro}]}| \;\leq\; \varepsilon_{\mathrm{state}} \quad \textit{(Goldstone sound present)},\\[2ex]
&\textit{QIII:} \quad 1-|\Lambda_{\mathrm{law}}^{[\mathrm{hydro}]}(\ell)| \;\leq\; C\,\ell^{\,\beta} \quad (\ell\to\infty)\\
&\qquad\qquad \textit{(equivalently } \Gamma(\ell) \ll D(\ell)k^2 \textit{ at } k\sim\ell^{-1}),\\
&\qquad\; |\Lambda_{\mathrm{state}}^{[\mathrm{hydro}]}| \;\geq\; 1-\varepsilon_{\mathrm{state}},\\[2ex]
&\textit{QIV:} \quad \exists\,\delta_\star\in(\varepsilon_{\mathrm{law}},1):\; |\Lambda_{\mathrm{law}}^{[\mathrm{hydro}]}| \;\leq\; 1-\delta_\star \;\; \textit{uniformly on } \mathfrak{P}\\
&\qquad\qquad \Big(\Leftrightarrow\; \Gamma(\ell) \;\geq\; \frac{\delta_\star}{1-\delta_\star}\,D(\ell)k^2\Big),\\
&\qquad\; |\Lambda_{\mathrm{state}}^{[\mathrm{hydro}]}| \;\geq\; 1-\varepsilon_{\mathrm{state}}.
\end{aligned}$$

Proof sketch. Combine the pole structure of G^R_{nn} with Lemma 8.22. QIII vs. QIV corresponds to *decay vs. persistent gap* of the law deficit on $\mathfrak{P}$: either $1-\Lambda_{\mathrm{law}}^{[\mathrm{hydro}]}(\ell)\to 0$ with a positive power as $\ell\to\infty$ (healing under IR dilation, equivalently $\Gamma \ll Dk^2$ at $k\sim\ell^{-1}$) or it remains uniformly bounded away from 0, which translates to the stated lower bound on Γ/Dk^2. □

8.1.6 Second Sound in the Hydrodynamic Sector (Matrix Formulation)

The longitudinal hydrodynamic sector admits a richer structure than the single–density setting of Definition 8.21. On a certified plateau $\mathfrak{P}$ and within the BRST–physical subspace $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, the same UV/IR instrumentation $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ ensures that all retarded correlators, Ward identities, and transport data are evaluated in a gauge–parameter–independent manner [82, 91]. In this regime, hydrodynamics is governed by the low–frequency, long–wavelength behaviour of conserved densities and their reversible/dissipative couplings, which admit a unified matrix formulation in terms of their retarded two–point functions [450, 102].

In contrast to the single-density case—where diffusion provides the sole hydrodynamic pole—the coupled longitudinal sector requires the 2×2 matrix of retarded correlators for a pair of conserved or thermodynamic densities, such as (n,s) or (n,ε). On the isotropic IR window $K_{\mathrm{IR}}^{(\ell)}$ (so that $k\sim\ell^{-1}$), the inverse correlator admits the standard hydrodynamic expansion with three ingredients: a positive–definite susceptibility matrix $\boldsymbol{\chi}$, a dissipative matrix $\mathbf{D}$ containing diffusion and thermo-electric coefficients, and a relaxation matrix $\boldsymbol{\Gamma}\geq 0$ encoding explicit violations of the continuity equations on the band [450, 119, 112]. The hydrodynamic poles are then determined by the secular condition

$$\det\!\Big(\mathbf{G}^{\mathrm{R}}(\omega,\mathbf{k})^{-1}\Big) = 0,$$

whose solutions capture both diffusive modes and possible propagating sound branches.

A key structural feature of this block is the existence of *two* possible propagating modes. When the reversible couplings generate a nondegenerate elastic matrix $\mathcal{K}$ in the longitudinal sector, the linear–in–k propagating solutions have speeds given by the positive eigenvalues of the generalised stiffness matrix $S = \chi^{-1}\mathcal{K}$. This reproduces, in particular, the well–known first–sound and second–sound branches of two–fluid hydrodynamics [450, 451, 452]. The attenuations arise at order k^2 through Rayleigh quotients involving the dissipative matrix $\mathbf{D}$, ensuring nonnegative damping consistent with thermodynamic stability [450].

Second sound is thus naturally understood as the presence of a *second*, linearly dispersing hydrodynamic mode in the longitudinal block. Its absence corresponds either to a purely diffusive sector or to a single sound branch, while explicit breaking generates "pseudo–sound" behaviour in which the linear dispersion is retained but shifted or gapped at $\mathcal{O}(\epsilon)$, analogously to pseudo–Goldstone modes in other sectors [112]. This matrix formulation therefore upgrades the scalar hydrodynamic witness to a spectral witness capable of diagnosing first versus second sound on the same certified plateau $\mathfrak{P}$, while remaining fully compatible with BRST closure, IR/UV windowing, causality, and the law/state visibility interpretation used throughout the quadrant framework.

All statements are evaluated on a certified plateau $\mathfrak{P}$ and on the BRST–physical sector $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$, with the same UV/IR instrumentation $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)})$ and notation as in Definition 8.21, Lemma 8.22, and Proposition 8.23. Causality/cone preservation and band safety are as in Proposition 6.281.

Definition 8.24 (Longitudinal two–variable hydrodynamic block)**.** Let $A, B \in \{n, s\}$ label a *longitudinal* pair of conserved/scalar densities (e.g. particle/charge density n and entropy density s; one may equally use $A, B \in \{n, \varepsilon\}$ with energy density ε). Define the 2×2 matrix of retarded correlators

$$\mathbf{G}^{\mathrm{R}}_{AB}(\omega, \mathbf{k}) \;:=\; \begin{pmatrix} G^{\mathrm{R}}_{nn} & G^{\mathrm{R}}_{ns} \\ G^{\mathrm{R}}_{sn} & G^{\mathrm{R}}_{ss} \end{pmatrix}(\omega, \mathbf{k})\,, \qquad \mathbf{k} = k\,\hat{\mathbf{k}}, \quad k \to 0,$$

on the isotropic IR window $K_{\mathrm{IR}}^{(\ell)}$ so that $k \sim \ell^{-1}$. Near $(\omega, \mathbf{k}) \to (0, \mathbf{0})$, its inverse admits the hydrodynamic expansion

$$\mathbf{G}^{\mathrm{R}}(\omega, \mathbf{k})^{-1} \;\simeq\; -i\omega\,\boldsymbol{\chi} \;+\; k^2\,\mathbf{D} \;+\; \boldsymbol{\Gamma} \;+\; \mathcal{O}(\omega^2, \omega k^2, k^3)\,, \tag{8.6}$$

where $\boldsymbol{\chi}$ is the static susceptibility matrix (positive–definite on $\mathfrak{P}$), $\mathbf{D}$ collects dissipative transport coefficients (diffusivities and thermo–electric cross terms), and $\boldsymbol{\Gamma} \geq 0$ encodes relaxation terms that break the exact continuity equations on the band (as in Definition 8.21). The *hydrodynamic poles* are the solutions of

$$\det\Big(\mathbf{G}^{\mathrm{R}}(\omega, \mathbf{k})^{-1}\Big) = 0\,. \tag{8.7}$$

Remark 8.25 (Generator/secular form)**.** Equivalently to the expansion (8.6), the secular equation (8.7) can be written in the "generator" form

$$\det\Big(-\,i\omega\,\mathbf{1} - \mathbf{H}(k)\Big) = 0, \qquad \mathbf{H}(k) = \mathbf{R}\,k - \mathbf{D}\,k^2 - \boldsymbol{\Gamma}, \quad \mathbf{R}^{\dagger} = -\mathbf{R},$$

which makes the linear-in-k propagating roots manifest and yields the same sound branches $(\omega = \pm c_j k - i\gamma_j k^2 + \cdots)$ in the longitudinal sector; see [450].

Definition 8.26 (Second–sound predicate (spectral))**.** On $\mathfrak{P}$, *second sound is present* in the longitudinal hydrodynamic block if and only if there exist two distinct propagating branches

$$\omega_{\pm}^{(j)}(\mathbf{k}) \;=\; \pm\, c_j\, k \;-\; i\,\gamma_j\, k^2 \;+\; o(k^2)\,, \qquad c_j > 0,\ \gamma_j \geq 0, \quad j = 1, 2, \tag{8.8}$$

among the solutions of (8.7). The case $j = 1$ is the usual (first) sound; $j = 2$ is *second sound*. Absence of a second linear branch (with the remainder diffusive or gapped) means no second sound in this block.

Lemma 8.27 (Speeds from susceptibilities and reversible couplings)**.** *Assume thermodynamic stability on* $\mathfrak{P}$ *so that* $\chi > 0$ *and that the reversible couplings induce a nondegenerate symmetric* elastic *matrix* $\mathcal{K}$ *for the longitudinal sector (see Remark 8.28). Then the leading sound speeds are the positive square roots of the eigenvalues of the generalised stiffness matrix*

$$S \;:=\; \chi^{-1}\,\mathcal{K}\,, \qquad c_1^2,\ c_2^2 \;=\; \mathrm{Spec}\big(S\big) \;\subset\; \mathbb{R}_{>0}\,, \tag{8.9}$$

and the attenuations are $\gamma_j = \frac{1}{2}\,\mathbf{v}_j^{\top}\,\chi^{-1}\mathbf{D}\,\mathbf{v}_j \geq 0$ *for the* S*–orthonormal eigenvectors* $\mathbf{v}_j$*.*

Remark 8.28 (Thermoelastic parameters)**.** For (n, s) variables, $\mathcal{K}$ is expressed via isentropic/isothermal compressibilities and thermo–elastic cross derivatives [450]. In a two–fluid superfluid, $\mathcal{K}$ reduces to Landau's coefficients [451, 452].

Sketch. Insert the ansatz (8.8) into (8.7). The $\mathcal{O}(k^2)$ real part yields $\det\big(c^2\,\chi - \mathcal{K}\big) = 0$, whose positive roots give (8.9); the $\mathcal{O}(k^3)$ imaginary part fixes γ_j from the Rayleigh quotient with $\mathbf{D}$ [450]. Positivity follows from $\chi > 0$ and $\mathbf{D} \geq 0$ on $\mathfrak{P}$. □

Proposition 8.29 (Hydrodynamic diagnosis with two longitudinal variables)**.** *With the block of Definition 8.24 and under the plateau tolerances of Definition 8.21:*

(i) QI.
No NG/pNG in the block; if present, at most one linear branch and it is symmetry–allowed.

(ii) QII.
Second sound present*: two branches (8.8) with* $c_{1,2} > 0$*.*

(iii) QIII.
No persistent *NG/pNG; as* $k \to 0$ *one or both branches revert to diffusion (healing).*

(iv) QIV.
"Pseudo–sound": linear structure retained but gapped/relaxing at $\mathcal{O}(\epsilon)$*.*

In the sense that $\omega_{\pm}^{(2)}(k) = \pm c_2 k - i\gamma_2 k^2$ *in QII is replaced by*

$$\omega_{\pm}^{(2)}(k) = \pm c_2 k - i\gamma_2 k^2 \;\underline{- i\, m_{\mathrm{ph}}^2/c_2}$$

in QIV, with $m_{\mathrm{ph}}^2 = \mathcal{O}(\epsilon)$ *(pseudo–phonon/pseudo–sound), while QIII enforces the decay of any such gapless structure under IR dilation (cf. Proposition 8.23).*

Remark 8.30 (Canonical superfluid formula for c_2)**.** In the Landau two–fluid limit (normal and superfluid components with densities ρ_n, ρ_s, entropy density s, temperature T, and specific heat at constant pressure c_p), the general expression (8.9) reproduces the textbook second–sound speed [451, 452, 450]:

$$c_2^2 \;=\; \frac{\rho_s}{\rho_n}\,\frac{s^2\,T}{c_p}\,, \tag{8.10}$$

with attenuation γ_2 fixed by the relevant dissipative coefficients (thermal conductivity, mutual friction, viscosities) [450].

Operational takeaway. To *explicitly include* second sound in the hydrodynamic sector, replace the single-scalar density witness of Definition 8.21 by the longitudinal 2×2 block of Definition 8.24 and diagnose second sound via the presence of two linear hydrodynamic poles (8.8), whose speeds follow from the generalised stiffness (8.9). This formulation is self–contained (no parasymmetry invoked) and sits on the same certified plateau $\mathfrak{P}$, preserving the law/state interpretation and the QI–QIV logic of Proposition 8.23.

8.1.7 Boundary Soft/Edge Modes Witnesses

The boundary sector admits a natural analogue of the bulk visibility framework, tailored to soft and edge modes localized near $\partial\mathcal{X}$. The working arena is a certified *boundary plateau* $\mathfrak{P}_\partial$, equipped with a tangential IR window $K^{(L)}_{\mathrm{IR},\partial}$ of size L along the boundary, and with insertions evaluated in the BRST–physical subspace $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ using BRST–closed UV/IR tags [82, 91]. This infrastructure ensures that boundary Ward identities and correlation functions are defined modulo BRST–exact terms and are insensitive to gauge–parameter choices within the plateau tolerances, in precise analogy with the bulk constructions [112, 102].

Within this setting, the tagged boundary Ward identity

$$\nabla_{\parallel} \cdot J^{(\partial)}_{\parallel} \;=\; S_\partial$$

encodes both the tangential boundary current $J^{(\partial)}_{\parallel}$ and a boundary source S_∂ that measures explicit breaking of the would–be conserved quantity at the edge: for example through leakage into the bulk, boundary driving, or explicit symmetry violation at $\partial\mathcal{X}$ [112, 102]. The boundary *law* visibility $\Lambda^{[\partial]}_{\mathrm{law}}(L)$ is then defined as a normalized deficit

$$1 - \frac{\|S_\partial\|_{\mathfrak{P}_\partial}}{\|\nabla_{\parallel} \cdot J^{(\partial)}_{\parallel}\|_{\mathrm{ref},\mathfrak{P}_\partial}},$$

providing a dimensionless measure of how strongly the boundary Ward identity is violated at the probed scale. Plateau tolerances $\varepsilon_{\mathrm{law}}$ convert this into a binary predicate: "boundary law symmetric'' whenever $|\Lambda^{[\partial]}_{\mathrm{law}}(L)| \geq 1 - \varepsilon_{\mathrm{law}}$, and law–deficit otherwise [112, 102].

The *state* channel is diagnosed through the presence or absence of boundary spontaneous symmetry breaking. A boundary state is declared symmetric when $|\Lambda^{[\partial]}_{\mathrm{state}}| \geq 1 - \varepsilon_{\mathrm{state}}$, and spontaneously broken when $|\Lambda^{[\partial]}_{\mathrm{state}}| \leq \varepsilon_{\mathrm{state}}$, in which case an edge Goldstone mode is

present on $\partial\mathcal{X}$ [92, 94, 102, 112]. The joint behaviour of $\Lambda^{[\partial]}_{\mathrm{law}}(L)$ and $\Lambda^{[\partial]}_{\mathrm{state}}$ under IR dilation $L \to \infty$ then feeds into the quadrant assignment: healing versus persistent boundary sources distinguish QIII from QIV in the law channel, while the existence of an edge Goldstone separates QII from QI in the state channel. In this way, boundary soft/edge modes are incorporated into the same BRST–safe, tolerance–based quadrant scheme that governs the bulk witnesses.

Definition 8.31 (Boundary witnesses (tolerance form))**.** Work on the certified boundary plateau $\mathfrak{P}_\partial$ with a tangential IR window $K^{(L)}_{\mathrm{IR},\partial}$ of size L along $\partial\mathcal{X}$, and evaluate in the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ with BRST–closed tags. Let the tagged boundary Ward identity be $\nabla_\parallel \cdot J^{(\partial)}_\parallel = S_\partial$ (modulo BRST–exact improvements). Define the boundary *law* visibility

$$\Lambda^{[\partial]}_{\mathrm{law}}(L) \;:=\; 1 - \frac{\|S_\partial\|_{\mathfrak{P}_\partial}}{\|\nabla_\parallel \cdot J^{(\partial)}_\parallel\|_{\mathrm{ref},\mathfrak{P}_\partial}} \in [0,1],$$

with plateau–uniform, BRST–safe norms on $\mathfrak{P}_\partial$. Let $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ be the certified tolerances (cf. the plateau criterion). For the *state* witness we adopt tolerance semantics:

$$\begin{aligned} \text{“boundary state symmetric”} \quad &\Longleftrightarrow \quad |\Lambda^{[\partial]}_{\mathrm{state}}| \;\geq\; 1 - \varepsilon_{\mathrm{state}}, \\ \text{“boundary SSB”} \quad &\Longleftrightarrow \quad |\Lambda^{[\partial]}_{\mathrm{state}}| \;\leq\; \varepsilon_{\mathrm{state}} \;\; \text{(edge Goldstone present)}. \end{aligned}$$

All insertions are evaluated as $P_x(\lambda_{\mathrm{UV}})\, K^{(L)}_{\mathrm{IR},\partial}(\cdot)\, K^{(L)}_{\mathrm{IR},\partial}\, P_x(\lambda_{\mathrm{UV}})$ and understood modulo BRST–exact improvements.

Proposition 8.32 (Boundary quadrant assignment (tolerance form))**.** *On $\mathfrak{P}_\partial$:*

(i) QI.
$|\Lambda^{[\partial]}_{\mathrm{law}}(L)| \;\geq\; 1 - \varepsilon_{\mathrm{law}}, \qquad |\Lambda^{[\partial]}_{\mathrm{state}}| \;\geq\; 1 - \varepsilon_{\mathrm{state}}.$

(ii) QII.
$|\Lambda^{[\partial]}_{\mathrm{law}}(L)| \;\geq\; 1 - \varepsilon_{\mathrm{law}}, \qquad |\Lambda^{[\partial]}_{\mathrm{state}}| \;\leq\; \varepsilon_{\mathrm{state}}$ *(edge Goldstone present).*

(iii) QIII.
$1 - |\Lambda^{[\partial]}_{\mathrm{law}}(L)| \;\leq\; C\, L^{-\beta} \;\; (L \to \infty), \qquad |\Lambda^{[\partial]}_{\mathrm{state}}| \;\geq\; 1 - \varepsilon_{\mathrm{state}}.$

(iv) QIV.
$\exists\, \delta_\star \in (\varepsilon_{\mathrm{law}}, 1) : \; |\Lambda^{[\partial]}_{\mathrm{law}}(L)| \;\leq\; 1 - \delta_\star$ *uniformly on* $\mathfrak{P}_\partial$, $\qquad |\Lambda^{[\partial]}_{\mathrm{state}}| \;\geq\; 1 - \varepsilon_{\mathrm{state}}.$

Proof sketch. From the boundary Ward identity, the boundary law deficit is proportional to $\|S_\partial\|_{\mathfrak{P}_\partial}$. The tolerance inequalities translate the sharp conditions $S_\partial = 0$ (QI/QII) and the IR healing/persistence (QIII/QIV) into plateau–uniform bounds on $1 - \Lambda^{[\partial]}_{\mathrm{law}}(L)$: either it decays like $L^{-\beta}$ as $L \to \infty$ (healing) or stays uniformly bounded away from 0 (persistent source). The state channel is fixed by the presence/absence of an edge Goldstone mode, expressed via the tolerance predicate. □

8.1.8 Anyons (Chern-Simons) Witnesses

Anyons and Chern–Simons (CS) responses in 2+1 dimensions provide a natural topological analogue of the bulk visibility framework. On the certified bulk plateau $\mathfrak{P}$, the effective response is encoded in a band–limited, BRST–clean effective action $S_{\text{eff}}[A, B; \cdot]$ for background gauge fields: a 1–form A for ordinary $U(1)_0$ charge and a 2–form B for $U(1)_1$ (higher–form charge) [102, 112]. Evaluation is performed in the BRST–physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$, with BRST–closed IR/UV tags ensuring that all visible couplings, Ward identities, and anomaly constraints are gauge–parameter independent [82, 91]. Within this structure, the symmetry $X \in \{P, T, U(1)_0, U(1)_1\}$ is probed through its variation $\delta_X S_{\text{eff}}$, which captures both topological CS responses and explicit symmetry–breaking terms. Because CS levels and mixed Chern–Simons couplings are quantized, symmetry violation is often discrete and persistent unless cancelled by multi–sector inflow or anomaly matching [102, 112].

The resulting *law* witness $\Lambda_{\text{law}}^{[\text{anyon};X]}$ thus distinguishes two regimes: (i) exact symmetry under X, detected by the vanishing of $\delta_X S_{\text{eff}}$, including the absence of symmetry–violating CS or gravitational–CS responses (e.g. $k_{\text{tot}} = 0$, $c_- = 0$); and (ii) persistent explicit breaking, where quantized CS or anomaly terms remain even after band projection, leading to $\Lambda_{\text{law}}^{[\text{anyon};X]} = 0$ [102, 112]. Intermediate cases, where explicit X–breaking terms are RG–irrelevant on $\mathfrak{P}$, correspond to $\Lambda_{\text{law}}^{[\text{anyon};X]}(\ell) \to 1$ as $\ell \to \infty$, in alignment with the QIII healing pattern of the general quadrant framework.

The *state* witness $\Lambda_{\text{state}}^{[\text{anyon};X]}$ distinguishes whether the ground sector preserves X at large scales. In the X–symmetric case, symmetry defects $D_X(\gamma)$ act trivially on large Wilson lines or correlation functions, and no X–charged order parameter acquires an expectation value. In the spontaneously broken case, the defect acts nontrivially or a charged order parameter signals X–SSB, producing $\Lambda_{\text{state}}^{[\text{anyon};X]} = 0$ [102, 112]. Together, the law and state witnesses supply a binary visibility pair governing the X–quadrant assignment, integrating anyonic and CS responses seamlessly into the BRST–safe, plateau–stabilized quadrant framework.

Definition 8.33 (Anyonic witnesses for a chosen symmetry X)**.** Work in 2+1D on the bulk plateau $\mathfrak{P}$. Fix $X \in \{P, T, U(1)_0, U(1)_1\}$. Couple the appropriate background fields (a 1-form A for $U(1)_0$, a 2-form B for $U(1)_1$) and let $S_{\text{eff}}[A, B; \cdot]$ be the band-limited, BRST-clean effective action. Define

$$\Lambda_{\text{law}}^{[\text{anyon};X]} := \begin{cases} 1, & \delta_X S_{\text{eff}} = 0 \text{ on } \mathfrak{P}, \\ 0, & \delta_X S_{\text{eff}} \neq 0 \text{ on } \mathfrak{P}, \end{cases}$$

$$\Lambda_{\text{state}}^{[\text{anyon};X]} := \begin{cases} 1, & X\text{-symmetric ground sector on } \mathfrak{P}, \\ 0, & X\text{-SSB on } \mathfrak{P}. \end{cases}$$

For P/T: $\delta_X S_{\text{eff}} = 0$ iff the net CS and gravitational-CS responses vanish, i.e. $k_{\text{tot}} = 0$ and $c_- = 0$ (modulo X-allowed counterterms and inflow).

Operationally: for P/T, $\Lambda_{\text{law}}^{[\text{anyon};X]} = 1$ iff no symmetry-violating CS/gravitational-CS terms remain (e.g. net level $k_{\text{tot}} = 0$ and $c_- = 0$ modulo allowed counterterms); for $U(1)_0$ and $U(1)_1$, it equals 1 iff the corresponding Ward identities hold for S_{eff} (equivalently, invariance under $A \mapsto A + \mathrm{d}\alpha$ or $B \mapsto B + \mathrm{d}\beta$). The state witness can be read, e.g., from symmetry

defects $D_X(\gamma)$ acting trivially on correlators at large scales or from the absence of X-charged order parameters. *Here c_- denotes the chiral central charge (gravitational Chern–Simons response / thermal Hall coefficient).*

Proposition 8.34 (Anyonic quadrant assignment for X)**.** *With the witnesses of Definition 8.33, the quadrant for the chosen X is*

(i) QI.
$(1,1)$.

(ii) QII.
$(1,0)$.

(iii) QIII.
$\Lambda_{\mathrm{law}}^{[\mathrm{anyon};X]}(\ell) \to 1, \quad \Lambda_{\mathrm{state}}^{[\mathrm{anyon};X]} = 1.$

(iv) QIV.
$\Lambda_{\mathrm{law}}^{[\mathrm{anyon};X]} = 0$ *(persistent law deficit).*

Proof sketch. Evaluate the X-Ward/constraint under $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ in S_{eff}. If symmetry-violating terms survive (e.g. quantized CS or gravitational-CS that flips under P/T; an uncanceled mixed anomaly; or an X-violating coupling that is not RG-irrelevant on $\mathfrak{P}$), then $\Lambda_{\mathrm{law}}^{[\mathrm{anyon};X]} = 0$ and the law channel sits in **QIV**. If all explicit X-breaking contributions become irrelevant or cancel (e.g. sector sum with $k_{\mathrm{tot}} = 0$), then $\Lambda_{\mathrm{law}}^{[\mathrm{anyon};X]}(\ell) \to 1$ giving **QIII**. When the law is symmetric, the state predicate alone distinguishes **QI** vs **QII**. □

Remark 8.35 (Quantization locks and topological order)**.** (i) For P/T in pure CS TQFTs, level quantization typically makes the law deficit persistent (**QIV**) unless a multi-sector cancellation or inflow restores X (then **QIII**). (ii) Stability of modular data/topological order is orthogonal to the quadrant label and may be tracked by separate diagnostics (does not enter $\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$).

8.1.9 Fractons Witnesses

Subsystem and fracton phases provide paradigmatic examples of anisotropic and higher–moment conservation laws, where charges can be immobile or restricted to lower–dimensional foliations, and where dipole (or higher multipole) conservation plays a central role in the long–distance dynamics [102, 112]. Within the present framework, such phases are analysed on a certified plateau $\mathfrak{P}$ and in the BRST–physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, using BRST–closed UV/IR tags so that Ward identities and coarse–grained correlators are insensitive to gauge–parameter choices [82, 91]. The key structural difference from ordinary hydrodynamics is the use of *anisotropic* IR windows $K_{\mathrm{IR}}^{(\vec{\ell})}$ with $\vec{\ell} = (\ell_\parallel, \ell_\perp, \dots)$ adapted to the foliation or subsystem structure: longitudinal momenta scale as $\mathbf{k}_\parallel \sim \ell_\parallel^{-1}$, while transverse components scale as $\mathbf{k}_\perp \sim \ell_\perp^{-1}$, reflecting the restricted mobility and direction–dependent screening characteristic of fracton–like systems [102, 112].

In a rank–2 $U(1)$ description, the relevant Ward identities include both the ordinary charge continuity equation and a dipole (or higher–moment) continuity equation, schematically $\partial_t \rho + \nabla \cdot \mathbf{J} = S^{(1)}$, $\partial_t \mathbf{P} + \nabla \cdot \mathbf{J}^{(2)} = S^{(2)}$, with $S^{(1)}, S^{(2)}$ encoding explicit violations of the

corresponding subsystem symmetries. The subsystem *law* witness $\Lambda^{[\mathrm{sub}]}_{\mathrm{law}}(\vec{\ell})$ is defined as a dimensionless visibility that compares the norm of the residuals $W_{\mathrm{sub}} = (S^{(1)}, S^{(2)})$ to reference norms of the continuity operators, evaluated at $\mathbf{k} \sim \vec{\ell}^{-1}$. Values of $\Lambda^{[\mathrm{sub}]}_{\mathrm{law}}$ near unity indicate exact or approximate multipole conservation at the anisotropic scales set by $K^{(\vec{\ell})}_{\mathrm{IR}}$, while significant deficits signal persistent explicit breaking that does not wash out under anisotropic coarse–graining [112, 102]. Tolerance parameters $\varepsilon_{\mathrm{law}}$ implement this distinction in the same way as in the bulk and hydrodynamic sectors.

The subsystem *state* witness $\Lambda^{[\mathrm{sub}]}_{\mathrm{state}}$ captures spontaneous breaking of the subsystem symmetry through appropriate order parameters or long–distance correlators. In the symmetric regime, $|\Lambda^{[\mathrm{sub}]}_{\mathrm{state}}| \geq 1 - \varepsilon_{\mathrm{state}}$ and no crystalline or foliated pattern carries a nonzero expectation value; in the broken regime, $|\Lambda^{[\mathrm{sub}]}_{\mathrm{state}}| \leq \varepsilon_{\mathrm{state}}$, and the system exhibits fracton–like ordering tied to the subsystem symmetry [102, 112]. The combined behaviour of $\Lambda^{[\mathrm{sub}]}_{\mathrm{law}}(\vec{\ell})$ under anisotropic dilation and of $\Lambda^{[\mathrm{sub}]}_{\mathrm{state}}$ then feeds directly into the quadrant assignment: decay versus persistence of the law deficit under $\min(\vec{\ell}) \to \infty$ distinguishes QIII from QIV, while the presence or absence of subsystem SSB separates QII from QI, thereby embedding fracton and subsystem–symmetric phases into the same BRST–safe, plateau–stabilized quadrant framework.

Definition 8.36 (Subsystem witnesses (anisotropic arena, tolerance form))**.** Work on a certified plateau $\mathfrak{P}$ and in $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ with BRST–closed scale tags. Adopt *anisotropic* IR windows $K^{(\vec{\ell})}_{\mathrm{IR}}$ with $\vec{\ell} = (\ell_{\parallel}, \ell_{\perp}, \dots)$ that respect the foliation/subsystem structure; probe momenta obey $\mathbf{k}_{\parallel} \sim \ell_{\parallel}^{-1}$ and $\mathbf{k}_{\perp} \sim \ell_{\perp}^{-1}$ on $\mathfrak{P}$. For rank–2 $U(1)$, the tagged continuity equations read

$$\partial_t \rho + \nabla \cdot \mathbf{J} = S^{(1)}, \qquad \partial_t \mathbf{P} + \nabla \cdot \mathbf{J}^{(2)} = S^{(2)}.$$

Let $W_{\mathrm{sub}} := (S^{(1)}, S^{(2)})$ collect the subsystem Ward residuals, and let $\| \cdot \|_{\mathfrak{P}}$ be a plateau–uniform, BRST–safe norm. Define the *law* visibility

$$\Lambda^{[\mathrm{sub}]}_{\mathrm{law}}(\vec{\ell}) := 1 - \frac{\|W_{\mathrm{sub}}\|_{\mathfrak{P}}}{\| \, \partial_t \rho + \nabla \cdot \mathbf{J} \, \|_{\mathrm{ref},\mathfrak{P}} + \| \, \partial_t \mathbf{P} + \nabla \cdot \mathbf{J}^{(2)} \, \|_{\mathrm{ref},\mathfrak{P}}} \in [0,1],$$

evaluated at $\mathbf{k} \sim \vec{\ell}^{-1}$. Let $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ be the certified tolerances. For the *state* witness we adopt tolerance semantics via appropriate subsystem order parameters/correlators:

$$\text{“state symmetric”} \iff |\Lambda^{[\mathrm{sub}]}_{\mathrm{state}}| \geq 1 - \varepsilon_{\mathrm{state}}, \qquad \text{“state SSB”} \iff |\Lambda^{[\mathrm{sub}]}_{\mathrm{state}}| \leq \varepsilon_{\mathrm{state}}.$$

All insertions are evaluated as $P_x(\lambda_{\mathrm{UV}})\, K^{(\vec{\ell})}_{\mathrm{IR}}(\cdot)\, K^{(\vec{\ell})}_{\mathrm{IR}}\, P_x(\lambda_{\mathrm{UV}})$ and are understood modulo BRST–exact improvements.

Intuition. The law predicate tests exact or approximate multipole conservation *at anisotropic scales* set by $K^{(\vec{\ell})}_{\mathrm{IR}}$; the state predicate detects crystalline/foliated ordering that breaks the subsystem symmetry. Tolerance semantics ($|\Lambda| \geq 1 - \varepsilon$ on $\mathfrak{P}$) keeps this block consistent with the global framework.

Lemma 8.37 (Subsystem IR healing criterion (tolerance form))**.** *If all explicit violations of the subsystem Ward identities are RG–irrelevant with respect to the anisotropic dilation induced by* $K_{\mathrm{IR}}^{(\vec{\ell})}$*, then there exists* $\beta > 0$ *such that, on* $\mathfrak{P}$*,*

$$1 - |\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}(\vec{\ell})| \;\le\; C\,\min(\ell_{\parallel}, \ell_{\perp}, \dots)^{-\beta}, \qquad \text{as } \min(\vec{\ell}) \to \infty,$$

hence $|\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}(\vec{\ell})| \to 1$ *and the law channel is "within tolerance" for large enough* $\vec{\ell}$*.*

Proof sketch. Treat the residuals W_{sub} as insertions of higher–dimension operators with *anisotropic* scaling dimensions. Irrelevance implies their tagged norm decays with the coarse–graining volume associated with $K_{\mathrm{IR}}^{(\vec{\ell})}$. Normalizing by the fixed reference denominator yields the stated power–law bound and the approach to unity of $\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}$. □

Proposition 8.38 (Subsystem quadrant assignment (tolerance form))**.** *On* $\mathfrak{P}$ *with* $K_{\mathrm{IR}}^{(\vec{\ell})}$*:*

(i) QI.
$|\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}(\vec{\ell})| \;\ge\; 1 - \varepsilon_{\mathrm{law}}, \qquad |\Lambda_{\mathrm{state}}^{[\mathrm{sub}]}| \;\ge\; 1 - \varepsilon_{\mathrm{state}}.$

(ii) QII.
$|\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}(\vec{\ell})| \;\ge\; 1 - \varepsilon_{\mathrm{law}}, \qquad |\Lambda_{\mathrm{state}}^{[\mathrm{sub}]}| \;\le\; \varepsilon_{\mathrm{state}}.$

(iii) QIII.
$1 - |\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}(\vec{\ell})| \;\le\; C\,\min(\vec{\ell})^{-\beta} \;\Big(\min(\vec{\ell}) \to \infty\Big), \qquad |\Lambda_{\mathrm{state}}^{[\mathrm{sub}]}| \;\ge\; 1 - \varepsilon_{\mathrm{state}}.$

(iv) QIV.
$\exists\, \delta_\star \in (\varepsilon_{\mathrm{law}}, 1) : \; |\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}(\vec{\ell})| \;\le\; 1 - \delta_\star$ *uniformly on* $\mathfrak{P}$, $\qquad |\Lambda_{\mathrm{state}}^{[\mathrm{sub}]}| \;\ge\; 1 - \varepsilon_{\mathrm{state}}.$

Proof sketch. Combine the tolerance definition of $\Lambda_{\mathrm{law}}^{[\mathrm{sub}]}$ with Lemma 8.37. The state channel is fixed by subsystem order parameters/correlators using the same plateau tolerances. QIII vs. QIV is determined by *decay vs. persistent gap* of the law deficit under anisotropic coarse–graining. □

Corollary 8.39 (IR healing ⇒ QIII (restatement of eq. (7.746)))**.** *Let* X *be any symmetry sector read on the bulk plateau* $\mathfrak{P}$ *with witnesses* $\big(\Lambda_{\mathrm{law}}^{[X]}, \Lambda_{\mathrm{state}}^{[X]}\big)$ *as in Definition 7.35. If the explicit* X*-breaking deformations* $\{\epsilon_k \mathcal{O}_k\}$ *are RG-irrelevant—so that*

$$1 - |\Lambda_{\mathrm{law}}^{[X]}(\ell)| = \mathcal{O}\Big(\ell^{\Delta - (d+z)}\Big) \quad \text{with } \Delta > d+z \qquad (\textit{cf. eq. } (7.746)),$$

and the state is X*-symmetric on* $\mathfrak{P}$ *(i.e.* $\Lambda_{\mathrm{state}}^{[X]} = 1$*), then the quadrant assignment given by Definition 7.685 is* **QIII***.*

Proof sketch. By eq. (7.746), the law deficit decays to zero under IR dilation, hence $\Lambda_{\mathrm{law}}^{[X]}(\ell) \to 1$. With $\Lambda_{\mathrm{state}}^{[X]} = 1$, the pair falls into the "law heals, state symmetric" cell, i.e. **QIII**, by Definition 7.685.

Corollary 8.40 (BRST reduction yields gauge-safe quadrants)**.** (Restatement of Propositions 6.276 and 7.644 and Theorem 7.646.) *Let* $\mathcal{H}_{\mathrm{phys}} = H^0(Q_{\mathrm{BRST}})$ *be the physical cohomology*

and let $\left(\Lambda_{\mathrm{law}}^{[\mathrm{gauge}]}, \Lambda_{\mathrm{state}}^{[\mathrm{gauge}]}\right)$ *be the visibility pair of Definition 7.35 evaluated* after *projection to* $\mathcal{H}_{\mathrm{phys}}$ *and band-limiting by* $P_x(\lambda_{\mathrm{UV}}) \circ K_{\mathrm{IR}}^{(\ell)}$. *Then the quadrant assignment*

$$\mathrm{Quad}\left(\Lambda_{\mathrm{law}}^{[\mathrm{gauge}]}, \Lambda_{\mathrm{state}}^{[\mathrm{gauge}]}\right)$$

is independent of gauge-fixing choices and coincides across all admissible gauges in the band-limited theory. Moreover, "gauge SSB" does not occur: only BRST-invariant global *remnants can furnish* $\Lambda_{\mathrm{state}}^{[\mathrm{gauge}]} = 0$ *(state SSB), while local gauge redundancy cannot move the system between quadrants.*

Proof sketch. By Proposition 6.276, the visibilities defined on $\mathcal{H}_{\mathrm{phys}}$ are BRST-safe and gauge-parameter independent; by Proposition 7.644, spectral data used to compute them are Nielsen-stable; by Theorem 7.646, explicit deformations shift poles/residues analytically without introducing gauge dependence. Hence the decision rule of Definition 7.685 yields a gauge-invariant quadrant label. Finally, Elitzur/BRST implies local gauge symmetries do not spontaneously break; any SSB signal arises only from BRST-invariant (global) symmetry content, so gauge-fixing cannot induce a quadrant change.

8.1.10 Higher-Forms and Non-Invertible Symmetries

Higher-form and non-invertible symmetries generalize the familiar notion of global symmetry in two complementary directions. A p-form global symmetry acts on extended p-dimensional operators $W(M_p)$ rather than pointlike fields, and is generated by a conserved $(p{+}1)$-form current $J^{(p+1)}$ whose integral over codimension-$(p{+}1)$ surfaces implements the symmetry action [102, 112]. Coupling such a symmetry to a background $(p{+}1)$-form gauge field B_{p+1} makes the associated Ward identities and possible anomalies manifest at the level of the effective action, in close analogy with the familiar $p = 0$ case [82, 91]. In this setting, the *law* predicate $\Lambda_{\mathrm{law}}^{[\mathcal{S}]}$ tests the exactness of the higher-form conservation law $\mathrm{d}{*}J^{(p+1)} = 0$ and the invariance of the BRST–clean effective action under background gauge transformations $B_{p+1} \mapsto B_{p+1} + \mathrm{d}\Lambda_p$, while the *state* predicate $\Lambda_{\mathrm{state}}^{[\mathcal{S}]}$ encodes the large-distance behaviour of $W(M_p)$ in terms of perimeter- versus area-law scaling, using τ_{p+1} and π_p to distinguish unbroken from spontaneously broken higher-form symmetry phases [102, 112].

Non-invertible (categorical) symmetries provide a further generalization in which the symmetry is implemented not by group-like operators but by topological defect operators $\{D_a\}$ obeying fusion and junction rules encoded in $\mathcal{D}_{\mathcal{S}}$ [102, 112]. In this case, the "law'' channel is captured by the topological invariance and fusion consistency of the defect network on the certified plateau $\mathfrak{P}$: $\Lambda_{\mathrm{law}}^{[\mathcal{S}]}$ is set to 1 precisely when the expected topological relations among the D_a hold in the band-limited, BRST–projected effective theory. The "state'' channel probes whether these defects act trivially in the infrared on local operators separated from the defect worldvolume. This is quantified by $\Delta_a(L)$, which measures the maximal change in correlators induced by inserting a defect $D_a(\gamma)$ of size L away from a local observable. Vanishing $\Delta_a(L)$ as $L \to \infty$ signals a non-invertible symmetry that remains unbroken in the state sector, whereas a nonzero $\limsup_{L\to\infty} \Delta_a(L)$ indicates spontaneous breaking of the non-invertible structure at large scales [102, 112]. In this way, the predicates $\Lambda_{\mathrm{law}}^{[\mathcal{S}]}$ and $\Lambda_{\mathrm{state}}^{[\mathcal{S}]}$ extend the law/state visibility framework to higher-form and non-invertible symmetries within the same BRST–safe, plateau– stabilized diagnostic scheme.

Definition 8.41 (Predicates for a symmetry object $\mathcal{S}$)**.** Let $\mathcal{S}$ be either:

- a p-form global symmetry with conserved $(p{+}1)$-form current $J^{(p+1)}$ and charged p-dimensional operators $W(M_p)$, or
- a non-invertible (categorical) symmetry with topological defect set $\{D_a\}$ and fusion/junction data $\mathcal{D}_{\mathcal{S}}$.

After band-limiting and BRST projection to $\mathcal{H}_{\text{phys}}$, define:

$$\Lambda_{\text{law}}^{[\mathcal{S}]} := \begin{cases} \mathbf{1}\Big[\, \mathrm{d}{*}J^{(p+1)} = 0 \text{ and } \delta S[B_{p+1}] = 0 \\ \qquad \text{for background } B_{p+1} \,\Big], & \mathcal{S} = p\text{-form}, \\ \mathbf{1}\Big[\, \text{defect topological invariance \& fusion of } \{D_a\} \\ \qquad \text{hold on } \mathfrak{P} \,\Big], & \mathcal{S} = \text{non-invertible}. \end{cases}$$

$$\Lambda_{\text{state}}^{[\mathcal{S}]} := \begin{cases} 1, & \mathcal{S} = p\text{-form and } \tau_{p+1} > 0 \text{ and } \pi_p = 0 \quad \text{(unbroken)}, \\ 0, & \mathcal{S} = p\text{-form and } \tau_{p+1} = 0 \text{ and } \pi_p > 0 \quad \text{(SSB)}, \\ 1, & \mathcal{S} = \text{non-invertible and } \forall a:\ \lim_{L\to\infty} \Delta_a(L) = 0, \\ 0, & \mathcal{S} = \text{non-invertible and } \exists a:\ \limsup_{L\to\infty} \Delta_a(L) > 0. \end{cases}$$

$$\tau_{p+1} := \lim_{\ell\to\infty} \inf_{\text{size}(M_p)\sim\ell} \frac{-\log|\langle W(M_p)\rangle|}{\text{Vol}_{p+1}(\text{Fill}(M_p))}, \qquad \pi_p := \lim_{\ell\to\infty} \inf_{\text{size}(M_p)\sim\ell} \frac{-\log|\langle W(M_p)\rangle|}{\text{Vol}_p(M_p)}.$$

with $\Delta_a(L) := \sup_{\text{size}(\gamma)\sim L} \big|\langle D_a(\gamma)\,\mathcal{O}\rangle - \langle\mathcal{O}\rangle\big|$ for any local $\mathcal{O}$ supported away from the loop γ.

Here $\text{Fill}(M_p)$ *denotes a choice of minimal* $(p{+}1)$*-chain with* $\partial\,\text{Fill}(M_p) = M_p$ *(used to define the area-law volume).*

8.1.11 Anomaly Witnesses

Anomalies provide a structural obstruction to exact symmetry at the quantum level: even when the classical action is invariant, the path–integral measure or regularized effective action may transform nontrivially under a global symmetry X [82, 91]. This obstruction manifests in the X–Ward identity as a nonvanishing anomaly density $\mathcal{A}_X$, whose presence is protected by 't Hooft anomaly–matching and therefore cannot be removed by RG flow or local counterterms unless an appropriate inflow mechanism cancels it [102, 112]. After BRST projection to $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$, the anomalous Ward identity takes the form

$$\nabla_\mu J_X^\mu \;=\; \mathcal{A}_X^{\text{net}} \;+\; \sum_k \epsilon_k\, \langle \mathcal{S}_{k,X}^{(\lambda_{\text{UV}})} \rangle_{\mathbf{\Psi}},$$

where $\mathcal{A}_X^{\text{net}}$ is the anomaly remaining after adding all admissible inflow and counterterms, and the sum over $\mathcal{S}_{k,X}^{(\lambda_{\text{UV}})}$ represents explicit symmetry–breaking operators. The quantity $\mathcal{A}_X^{\text{net}}$ is therefore the intrinsic quantum obstruction to exact X–symmetry: it vanishes if and only if the effective action is fully X–invariant at the quantum level.

Within the visibility framework, the law predicate $\Lambda^{[X]}_{\text{law}}$ cleanly separates two distinct sources of symmetry violation. The RG–scaling of explicit symmetry–breaking operators is captured by the usual power–law behaviour $1 - |\Lambda^{[X]}_{\text{law}}(\ell)| = \mathcal{O}(\ell^{\Delta-(d+z)})$ when all relevant breakings are RG–irrelevant [112]. In contrast, a nonzero anomaly density $\mathcal{A}^{\text{net}}_X \neq 0$ produces a *persistent* deficit in the X–Ward identity: unlike irrelevant operators, this contribution cannot decay under coarse–graining, and pins the law channel to a symmetry–asymmetric classification [102]. Thus QIII corresponds to the situation $\mathcal{A}^{\text{net}}_X = 0$ with explicit breakings healing in the IR, while QIV corresponds either to a genuine anomaly or to explicit breakings that remain non-negligible on the plateau.

The state predicate $\Lambda^{[X]}_{\text{state}}$ is independent of this quantum obstruction and is evaluated through symmetry–charged order parameters or symmetry defects in the usual fashion [82, 91]. Accordingly, the full quadrant assignment for X combines the (anomaly–sensitive) law visibility with the state visibility: if the state sector also breaks X, the pair $(\Lambda^{[X]}_{\text{law}}, \Lambda^{[X]}_{\text{state}})$ lies in the "law asym, state asym" quadrant of the canonical decision rule. In this manner, anomalies integrate naturally into the BRST–safe, plateau–stabilized visibility framework, providing a sharp diagnostic for persistent quantum violations of global symmetries.

Corollary 8.42 (Anomaly ⇒ persistent law asymmetry unless net inflow cancels)**.** *Fix a global symmetry X and evaluate the X–Ward identity on the plateau $\mathfrak{P}$ after BRST projection:*

$$\nabla_\mu J^\mu_X \;=\; \mathcal{A}^{\text{net}}_X \;+\; \sum_k \epsilon_k \left\langle \mathcal{S}^{(\lambda_{\text{UV}})}_{k,X} \right\rangle_{\mathbf{\Psi}},$$

where $\mathcal{A}^{\text{net}}_X$ is the net *quantum anomaly density (including possible inflow/counterterm contributions so that $\mathcal{A}^{\text{net}}_X = 0$ iff the effective action is strictly X-invariant at the quantum level). Then the law channel for X is classified as:*

$$\begin{cases} \textit{QIII}, & \textit{if } \mathcal{A}^{\text{net}}_X = 0 \;\; \textit{and} \;\; 1 - |\Lambda^{[X]}_{\text{law}}(\ell)| = \mathcal{O}\big(\ell^{\Delta-(d+z)}\big) \;\; \textit{(explicit breakings heal)}, \\ \textit{QIV}, & \textit{if } \mathcal{A}^{\text{net}}_X \neq 0 \;\; \textit{(persistent anomaly)} \;\; \textit{or the explicit deficit persists on } \mathfrak{P}. \end{cases}$$

The state channel is read independently via Definition 7.35; if the state also breaks X, the pair $\left(\Lambda^{[X]}_{\text{law}}, \Lambda^{[X]}_{\text{state}}\right)$ lies in the "law asym, state asym" cell by Definition 7.685.

Intuition. In this setup, nonzero $\mathcal{A}^{\text{net}}_X$ is a *quantum* law deficit that cannot "fade out" under RG ('t Hooft matching). QIII reflects IR healing of *explicit* breakings once the net anomaly is zero; otherwise the anomaly pins the law channel to QIV.

8.1.12 Non-equilibrium (Floquet/Lindblad) Witnesses

Non-equilibrium quantum dynamics introduces qualitatively new mechanisms for symmetry preservation and symmetry breaking that do not appear in stationary Hamiltonian settings. Periodically driven (Floquet) systems and open (Lindblad) quantum systems furnish two prominent classes [396, 448, 449, 112, 102]. In both cases, symmetry properties must be assessed directly at the level of the one-period propagator $U(T)$ (Floquet) or the Liouvillian generator $\mathcal{L}$ (open), rather than at the Hamiltonian level. The present formulation places these systems on the same footing as the equilibrium sectors by working on a certified plateau $\mathfrak{P}$

and projecting to the BRST-physical subspace $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, ensuring gauge-parameter independence and well-defined Ward-type constraints [82, 91]. BRST-closed IR/UV tags guarantee that all operator norms, symmetry channels, and steady-state diagnostics remain stable under admissible coarse-graining, exactly as in the equilibrium sectors [112, 102].

In the Floquet setting, law symmetry is captured by the invariance of the one-period propagator under the symmetry action U_X, quantified by the normalized defect $\|U_X^\dagger U(T) U_X - U(T)\|_{\mathfrak{P}}$. A vanishing defect within tolerance expresses that the effective stroboscopic evolution respects the symmetry to the same standard used elsewhere in the quadrant scheme. State symmetry, by contrast, probes whether an extremal periodic steady state $\rho_\star(t)$ remains invariant under the same symmetry operation throughout the drive cycle, measured in trace distance. Spontaneous breaking in the non-equilibrium steady state therefore appears as symmetry violation at the level of the cycle-resolved density matrix rather than the underlying generator. This distinction mirrors the law/state separation used in equilibrium QFT, where the Ward identity and the vacuum sector provide independent criteria [82, 91].

Open quantum systems governed by a Liouvillian $\mathcal{L}$ require an analogous construction. Law symmetry is diagnosed by the commutator defect $\|\mathcal{L} \circ \mathcal{U}_X - \mathcal{U}_X \circ \mathcal{L}\|_{\diamond,\mathfrak{P}}$, which reduces, for continuous symmetries, to the approximate conservation condition $\|\mathcal{L}^\dagger(Q_X)\|_{\mathfrak{P}} \ll 1$. State symmetry tests whether an extremal steady state ρ_∞ satisfies $U_X \rho_\infty U_X^\dagger = \rho_\infty$ up to tolerance. In this way, the non-equilibrium sector inherits the full BRST-safe, plateau-stabilized visibility structure of the equilibrium theory, permitting the same fourfold quadrant classification [112, 102].

This formulation also accommodates discrete time-translation symmetry as a special choice of X, treating time-crystalline phases as spontaneous breaking in the *state* channel of the corresponding non-equilibrium witness, consistently with [396, 448, 449]. This aligns with the general principle that order parameters (or extremal steady states in the Lindblad/Floquet setting) provide the state-sector verdict, while invariance of the effective evolution operator or Liouvillian provides the law-sector verdict, in full analogy with the symmetries of equilibrium quantum field theory [82, 91].

Definition 8.43 (Non-equilibrium witnesses (Floquet/Lindblad; tolerance form))**.** Work on a certified (bulk or boundary) plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ with BRST-closed scale tags. Let $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ be the plateau tolerances (cf. the plateau criterion). We write sector tags as superscripts and reserve subscripts for $\Lambda_{\mathrm{law}}, \Lambda_{\mathrm{state}}$.

Floquet (period T). Let $U(T)$ be the one-period propagator and U_X the unitary implementing the symmetry X on $\mathcal{H}_{\mathrm{phys}}$. Define the *law* visibility via the normalized invariance defect

$$\Lambda_{\mathrm{law}}^{[\mathrm{Floquet};X]} := 1 - \frac{\left\| U_X^\dagger U(T) U_X - U(T) \right\|_{\mathfrak{P}}}{c_{\mathrm{F}}}, \qquad 0 \le \Lambda_{\mathrm{law}}^{[\mathrm{Floquet};X]} \le 1,$$

where $\|\cdot\|_{\mathfrak{P}}$ is a plateau-uniform, BRST-safe operator norm and $c_{\mathrm{F}} > 0$ a fixed reference (e.g. $c_{\mathrm{F}} = 2$ for the operator norm on unitaries). Law symmetry on $\mathfrak{P}$ means $|\Lambda_{\mathrm{law}}^{[\mathrm{Floquet};X]}| \ge 1 - \varepsilon_{\mathrm{law}}$, equivalently $\|U_X^\dagger U(T) U_X - U(T)\|_{\mathfrak{P}} \le \varepsilon_{\mathrm{law}}\, c_{\mathrm{F}}$. Let $\rho_\star(t)$ be an *extremal* periodic steady state ($\rho_\star(t+T) = \rho_\star(t)$) selected by the protocol. Define the *state* predicate by trace-distance

tolerance:

$$\sup_{t\in[0,T)} \tfrac{1}{2}\Big\| U_X \rho_\star(t) U_X^\dagger - \rho_\star(t) \Big\|_1 \begin{cases} \le \varepsilon_{\mathrm{state}}, & \text{state symmetric on } \mathfrak{P}, \\ > \varepsilon_{\mathrm{state}}, & \text{state SSB of } X \text{ on } \mathfrak{P}, \end{cases}$$

(stroboscopic testing at $t = nT$ is a weaker but admissible alternative when continuous monitoring is unavailable).

Lindblad (open). Let $\mathcal{L}$ be the Liouvillian and $\mathcal{U}_X(\cdot) := U_X(\cdot)U_X^\dagger$ the symmetry channel. Define the *law* visibility by the superoperator commutator defect

$$\Lambda_{\mathrm{law}}^{[\mathrm{Lindblad};X]} := 1 - \frac{\big\| \mathcal{L}\circ\mathcal{U}_X - \mathcal{U}_X\circ\mathcal{L} \big\|_{\diamond,\mathfrak{P}}}{c_{\mathrm{L}}}, \qquad 0 \le \Lambda_{\mathrm{law}}^{[\mathrm{Lindblad};X]} \le 1,$$

with a plateau-uniform diamond-norm bound and fixed $c_{\mathrm{L}} > 0$. Law symmetry means $|\Lambda_{\mathrm{law}}^{[\mathrm{Lindblad};X]}| \ge 1 - \varepsilon_{\mathrm{law}}$. For continuous $U(1)$, an equivalent test is the (approximate) conserved charge condition $\|\mathcal{L}^\dagger(Q_X)\|_{\mathfrak{P}} \le \varepsilon_{\mathrm{law}}\, c_Q$. Let ρ_∞ be an extremal steady state ($\mathcal{L}\rho_\infty = 0$). Define the *state* predicate by

$$\tfrac{1}{2}\Big\| U_X \rho_\infty U_X^\dagger - \rho_\infty \Big\|_1 \begin{cases} \le \varepsilon_{\mathrm{state}}, & \text{state symmetric on } \mathfrak{P}, \\ > \varepsilon_{\mathrm{state}}, & \text{state SSB of } X \text{ on } \mathfrak{P}. \end{cases}$$

All statements are understood modulo BRST-exact improvements; norms are plateau-uniform.

Corollary 8.44 (Quadrants out of equilibrium (tolerance form))**.** *With the witnesses of Definition 8.43, the canonical decision rule yields the same four classes on* $\mathfrak{P}$*:*

(i) QI.
$|\Lambda_{\mathrm{law}}^{[\cdot;X]}| \ge 1 - \varepsilon_{\mathrm{law}}$ *and* $|\Lambda_{\mathrm{state}}^{[\cdot;X]}| \ge 1 - \varepsilon_{\mathrm{state}}$.

(ii) QII.
$|\Lambda_{\mathrm{law}}^{[\cdot;X]}| \ge 1 - \varepsilon_{\mathrm{law}}$ *and* $|\Lambda_{\mathrm{state}}^{[\cdot;X]}| \le \varepsilon_{\mathrm{state}}$.

(iii) QIII.
$1 - |\Lambda_{\mathrm{law}}^{[\cdot;X]}(\ell)| \le C\,\ell^{-\beta}$ *as* $\ell \to \infty$, *and* $|\Lambda_{\mathrm{state}}^{[\cdot;X]}| \ge 1 - \varepsilon_{\mathrm{state}}$.

(iv) QIV.
There exists $\delta_\star \in (\varepsilon_{\mathrm{law}}, 1)$ *such that* $|\Lambda_{\mathrm{law}}^{[\cdot;X]}| \le 1 - \delta_\star$ *uniformly on* $\mathfrak{P}$, *and* $|\Lambda_{\mathrm{state}}^{[\cdot;X]}| \ge 1 - \varepsilon_{\mathrm{state}}$.

Remarks. (i) If multiple extremal periodic/steady states exist, the readout is performed on the experimentally selected one (protocol dependence); tolerance semantics ensures reproducibility on $\mathfrak{P}$. (ii) Choosing X to be *discrete time translation* classifies time-crystalline order in the same grid (SSB in the *state* channel of X), consistently with [396, 448, 449].

8.1.13 Universal Quadrant Coverage

Theorem 8.45 (Universal quadrant coverage and invariance for sector-conditioned predicates)**.** *Let $\mathscr{S}$ be an admissible sector in the sense of Definition 8.9, realised on a certified plateau $\mathfrak{P}$ (bulk) or $\mathfrak{P}_\partial$ (boundary), with BRST–closed scale tags $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}$ and sector–appropriate witnesses $\Lambda^{[\mathscr{S}]}_{\mathrm{law}}, \Lambda^{[\mathscr{S}]}_{\mathrm{state}}$. Fix plateau tolerances $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ (cf. Section 6.12.4).*

Define the sector–conditioned binary predicates *by*

$$\chi^{[\mathscr{S}]}_{\mathrm{law}} := \mathbf{1}\Big[\,|\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| \geq 1-\varepsilon_{\mathrm{law}}\,\Big], \qquad \chi^{[\mathscr{S}]}_{\mathrm{state}} := \mathbf{1}\Big[\,|\Lambda^{[\mathscr{S}]}_{\mathrm{state}}| \geq 1-\varepsilon_{\mathrm{state}}\,\Big],$$

and the sector decision map $\mathrm{Quad}^{[\mathscr{S}]}$ *by Definition 7.685, with the QIII/QIV refinement: either the law deficit $d^{[\mathscr{S}]}_{\mathrm{law}} := 1 - |\Lambda^{[\mathscr{S}]}_{\mathrm{law}}|$* heals *under the sector's IR dilation (QIII) or it is* uniformly bounded away from 0 *(QIV).*

Then, on the relevant plateau:

(i) Exclusive, exhaustive partition up to thresholds

$\mathrm{Quad}^{[\mathscr{S}]}$ *partitions the admissible configurations of $\mathscr{S}$ into four disjoint classes* QI to QIV*, and their union is exhaustive up to threshold sets*

$$\mathfrak{T}_{\mathrm{law}} := \Big\{|\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| = 1-\varepsilon_{\mathrm{law}}\Big\}, \quad \mathfrak{T}_{\mathrm{state}} := \Big\{|\Lambda^{[\mathscr{S}]}_{\mathrm{state}}| = 1-\varepsilon_{\mathrm{state}}\Big\},$$

which are negligible under the plateau regularity bounds of Proposition 6.298.

(ii) Cohomological/gauge-fermion invariance

$\mathrm{Quad}^{[\mathscr{S}]}$ *is invariant under ζ–exact gauge–fixing deformations and under gauge–parameter scans: for all admissible $\Psi \mapsto \Psi + \{\hat{Q}_{\mathrm{BRST}}, B\}$,*

$$\partial_\xi \,\mathrm{Quad}^{[\mathscr{S}]} = 0\,, \qquad \mathrm{Quad}^{[\mathscr{S}]}[\Psi] = \mathrm{Quad}^{[\mathscr{S}]}[\Psi + \{\hat{Q}_{\mathrm{BRST}}, B\}],$$

by Propositions 6.264 and 6.276 and Corollary 6.265.

(iii) Sector dilation and QIII/QIV decision

Let r denote the sector's IR dilation parameter: $r = \ell$ (bulk), $r = L$ (boundary), $r = \min(\vec{\ell})$ (anisotropic), or the appropriate coarse–graining variable (e.g. stroboscopic window for Floquet, cf. Definition 8.43). Then

$$\textit{QIII} \iff \exists\, \beta > 0,\ C < \infty :\ d^{[\mathscr{S}]}_{\mathrm{law}}(r) \leq C\, r^{-\beta}\ (r \to \infty),$$

$$\textit{QIV} \iff \exists\, \delta_\star \in (\varepsilon_{\mathrm{law}}, 1) :\ d^{[\mathscr{S}]}_{\mathrm{law}}(r) \geq \delta_\star \textit{ uniformly on } \mathfrak{P}.$$

(For concrete sectors this reduces to the previously proved criteria: hydro Lemma 8.22 and Proposition 8.23; boundary Definition 8.31 and Proposition 8.32; subsystem/fracton Lemma 8.37 and Proposition 8.38; SUSY/fermion/HS/p–form via Proposition 6.277 and the sector blocks.)

(iv) Cone/functorial stability

$\mathrm{Quad}^{[\mathscr{S}]}$ *is unchanged by (i) admissible changes of tags $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}$ within the certified band (Corollary 6.265), (ii) holosymmetric lifts and sector functors (p–form duality, etc.; Propositions 6.257 and 8.16 and Corollary 6.259), and (iii) direct sums/triadic decompositions (Proposition 6.257); thus the diagnosis does not alter causal cones.*

Proof. **Step 1 (Well-defined binary predicates).** By Proposition 6.264 the sector witnesses are evaluated in $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ and are BRST/Nielsen–invariant under changes of Ψ. On a certified plateau (Section 6.12.4), the norms are uniform and the visibilities are stable within tolerances (Corollary 6.265). Hence $\chi_{\mathrm{law}}^{[\mathscr{S}]}, \chi_{\mathrm{state}}^{[\mathscr{S}]} \in \{0,1\}$ are well defined modulo the threshold sets $\mathfrak{T}_{\mathrm{law/state}}$.

Step 2 (Exclusivity and exhaustiveness). The decision map (Definition 7.685) is the Cartesian product $\{0,1\} \times \{0,1\} \to \{\mathbf{QI}, \mathbf{QII}, \mathbf{QIII}, \mathbf{QIV}\}$ with the QIII/QIV refinement determined by the asymptotic law–deficit test. Exclusivity follows since the images are disjoint. Exhaustiveness holds because every point lies in exactly one preimage unless it belongs to $\mathfrak{T}_{\mathrm{law}} \cup \mathfrak{T}_{\mathrm{state}}$. By the oscillation/finite–difference bounds (Proposition 6.298), these threshold sets are negligible (knife–edges of measure zero under smooth parameter variations).

Step 3 (QIII vs QIV by sector dilation). Let $d_{\mathrm{law}}^{[\mathscr{S}]}(r) := 1 - |\Lambda_{\mathrm{law}}^{[\mathscr{S}]}(r)|$. For sectors whose explicit breakings are RG–irrelevant, the Duhamel/RG estimates and sector–specific healing lemmas yield $d_{\mathrm{law}}^{[\mathscr{S}]}(r) \le C r^{-\beta}$ (bulk Proposition 6.277; hydro Proposition 8.23; boundary Proposition 8.32; subsystem Lemma 8.37). Conversely, if some relevant/marginal explicit breaking survives, Proposition 6.277 supplies a uniform lower bound $\delta_\star > 0$ on $d_{\mathrm{law}}^{[\mathscr{S}]}$ (persistent deficit), which is plateau–uniform by Remark 6.254. This exactly realises the QIII/QIV dichotomy.

Step 4 (Cohomological/gauge invariance). By Proposition 6.276 and Proposition 6.264, all sector witnesses and their channel/sector reductions are invariant under ζ–exact deformations and gauge–parameter scans; therefore $\chi_{\mathrm{law}}^{[\mathscr{S}]}, \chi_{\mathrm{state}}^{[\mathscr{S}]}$ and the asymptotic test are invariant, and so is $\mathrm{Quad}^{[\mathscr{S}]}$.

Step 5 (Cone/functorial stability). Holosymmetric lifts are functorial and cone–preserving (Proposition 6.257 and Corollary 6.259), and p–form duality preserves witnesses (Proposition 8.16); thus transport along these maps cannot change the quadrant. Variations of tags within the certified band preserve plateau bounds (Corollary 6.265), so the decision is stable.

Step 6 (Law–state exhaustion link). Finally, the sector statement is a direct corollary of law–state exhaustion on $\mathfrak{P}$ (Theorem 8.1) applied to the sector–conditioned predicates, with the QIII/QIV refinement supplied by Step 3. This completes the proof. □

What the theorem asserts. Fix any admissible sector $\mathscr{S}$ (bulk, boundary, hydrodynamic, fermionic, SUSY, p-form, higher–spin, subsystem/fracton, Floquet/Lindblad, *etc.*) in the sense of Definition 8.9 and certify its plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$) by the plateau criterion and bounds (Section 6.12.4, Proposition 6.298, and Corollary 6.265). On that plateau, the two BRST–safe, cone–preserving visibilities

$$\Lambda_{\mathrm{law}}^{[\mathscr{S}]}, \qquad \Lambda_{\mathrm{state}}^{[\mathscr{S}]}$$

constructed in the sector–conditioned arenas (Section 8.1 and Definition 6.275) tell us everything needed to assign the quadrant for *that sector*. Plugging them into the canonical decision rule yields a *two–bit* label (QI–QIV) (Definition 7.685 and Remark 7.686) that is (i) *exclusive*—no configuration lands in two quadrants at once—and (ii) *exhaustive up to thresholds*— the only undecidable cases sit at the tolerance boundaries of the plateau (knife–edges or exactly marginal/healing loci, cf. Theorem 8.1). Within each sector, the QIII/QIV split is decided by the sector's IR dilation (bulk $\ell \to \infty$, boundary $L \to \infty$,

anisotropic $\min(\vec{\ell}) \to \infty$, stroboscopic coarse–graining in Floquet, *etc.*; see Theorem 6.253, Remark 6.254, and Sections 6.12.3 and 6.12.5): if the law–deficit heals under that dilation it means that we are in QIII; if it stays uniformly nonzero we are in QIV. Because the witnesses are *sector–conditioned* and computed in $\mathcal{H}_{\mathrm{phys}}$, the statement is universal across sectors and gauge choices, by BRST/cohomological invariance (Propositions 6.264 and 6.276); there is *no fifth quadrant* once the sector and plateau are fixed.

Operational reading (how to use it). *Step 1: certify the arena.* Choose the sector $\mathscr{S}$ and certify its plateau $\mathfrak{P}$ (or $\mathfrak{P}_\partial$) so that readouts are stable within tolerances and tags are BRST–closed, using Section 6.12.4, Propositions 6.264 and 6.298, and Corollary 6.265. *Step 2: compute the two numbers.* Evaluate $(\Lambda^{[\mathscr{S}]}_{\mathrm{law}}, \Lambda^{[\mathscr{S}]}_{\mathrm{state}})$ with the sector's natural probes as defined in the sector blocks (e.g. goldstino vs super–Higgs for SUSY, Definition 8.12 and Proposition 8.14; diffusion vs sound for hydrodynamics, Definition 8.21 and Proposition 8.29; edge modes on $\partial\mathcal{X}$, Definition 8.31 and Proposition 8.32; dualized scalar/vector data for p–forms, Proposition 8.16; anisotropic Ward residuals for subsystem symmetries, Definition 8.36 and Proposition 8.38; higher–spin and fermionic sectors via Definition 8.18 and Proposition 6.277; non–equilibrium via Definition 8.43 and Corollary 8.44). *Step 3: apply the grid.* If $|\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| \approx 1$ (within $\varepsilon_{\mathrm{law}}$), then we are in QI or QII and the state channel decides, according to the canonical rule (Definition 7.685 and Theorem 6.231). If $|\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| < 1$, perform the large–window test in that arena, using the relevant dilation parameter and scaling estimates (Theorem 6.253, Remark 6.254, Lemmas 8.22 and 8.37, Propositions 8.29 and 8.38, Definition 8.43, and Corollary 8.44): healing $\Rightarrow$ QIII, persistent gap $\Rightarrow$ QIV. *Step 4: record the label.* The resulting $\mathrm{Quad}^{[\mathscr{S}]}$ is BRST/Nielsen–safe and does not alter cones or mix channels, by the invariance and functoriality results (Propositions 6.257, 6.264 and 6.276 and Corollary 6.259).

Proof strategy at a glance (why it is true). First, on a certified plateau the visibilities are stable and BRST/Nielsen–invariant (Propositions 6.264 and 6.276 and Corollary 6.265), so their thresholded versions define well–posed binary predicates (law/state) as in Definitions 6.275, 7.35 and 8.9. Their Cartesian product is a two–bit partition; exclusivity is immediate, and exhaustiveness fails only on the negligible threshold sets where a tolerance is saturated, controlled by the plateau bounds (Proposition 6.298 and Remark 6.254) and the law–state exhaustion theorem (Theorem 8.1). Second, sector dilation distinguishes healing vs persistence of the law–deficit by power–law bounds or uniform lower gaps proved in the sector blocks (bulk and fermionic/SUSY/HS/p–form sectors via Theorems 6.253 and 7.630, Corollary 7.631, and Proposition 6.277; hydrodynamic, boundary, subsystem and non–equilibrium sectors via Propositions 8.29, 8.32 and 8.38 and Corollary 8.44). Third, functoriality and cone preservation guarantee that holosymmetric lifts, dualities, and admissible retagging cannot change the quadrant—diagnostics *measure* the sector; they do not move it (Propositions 6.257 and 8.16 and Corollaries 6.259 and 6.265). Finally, this sector statement is the sector–conditioned instance of the law–state exhaustion principle (Theorems 8.1 and 8.45), completing the argument.

Mental model (why no surprises occur). Think of each sector as a lab with its own calibrated apparatus (its witnesses and IR windowing, Sections 6.12.3, 6.12.5, 8.1 and 8.2). We bring in a sample (the configuration), put it on the certified plateau (the plateau, Section 6.12.4 and Proposition 6.298), and read two dials: *law* and *state*. Dials near "1" mean symmetry, away from "1" mean a deficit, as encoded in the visibility semantics (Definition 7.35 and Remarks 6.254 and 7.686). Turn the IR knob: if the law dial drifts back to "1" then we call it emergent (QIII); if it refuses, it's explicit (QIV), in line with the scaling criteria of Theorem 6.253, Propositions 6.277, 8.29 and 8.38, and Corollary 8.44. Because the apparatus is BRST–clean and cone–preserving (Propositions 6.257, 6.264 and 6.276 and Corollary 6.259), we can trust that the reading reflects the sample, not the gauge choice or the diagnostic realized reference configuration itself. Across all such labs, the same two–dial logic applies—hence the universal four–cell map of Theorems 6.231 and 8.45.

Corollary 8.46 (Operational checklist)**.** *To classify any admissible sector $\mathscr{S}$ using sector–conditioned predicates on a certified plateau:*

(i) Fix the arena and certify the plateau

Choose bulk $\mathfrak{P}$, boundary $\mathfrak{P}_\partial$, or anisotropic $K_{\mathrm{IR}}^{(\vec{\ell})}$ (fracton/subsystem). Pick BRST–closed tags $P_x(\lambda_{\mathrm{UV}})$, K_{IR} and tolerances $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$. Verify plateau stability via Section 6.12.4 and Proposition 6.298 and gauge–parameter independence via Propositions 6.264 and 6.276 and Corollary 6.265.

(ii) Instantiate sector witnesses

Construct

$$(\Lambda_{\mathrm{law}}^{[\mathscr{S}]}, \Lambda_{\mathrm{state}}^{[\mathscr{S}]})$$

with BRST–safe, plateau–uniform norms using the sector recipe (e.g. Definitions 8.21, 8.31 and 8.36 and the fermionic/SUSY/p–form/HS blocks). Record the reference normalizations.

(iii) Apply the canonical decision rule (law/state)

Declare

$$\chi_{\mathrm{law}}^{[\mathscr{S}]} = \mathbf{1}\big[|\Lambda_{\mathrm{law}}^{[\mathscr{S}]}| \geq 1 - \varepsilon_{\mathrm{law}}\big], \qquad \chi_{\mathrm{state}}^{[\mathscr{S}]} = \mathbf{1}\big[|\Lambda_{\mathrm{state}}^{[\mathscr{S}]}| \geq 1 - \varepsilon_{\mathrm{state}}\big],$$

and map to QI/QII provisionally by Definition 7.685 when $\chi_{\mathrm{law}}^{[\mathscr{S}]} = 1$.

(iv) [Decide QIII vs QIV by large–window scaling in the chosen arena]Let r be the sector's IR dilation parameter (bulk $r = \ell$, boundary $r = L$, anisotropic $r = \min(\vec{\ell})$, or the appropriate coarse–graining variable in non–equilibrium). With $d_{\mathrm{law}}^{[\mathscr{S}]}(r) := 1 - |\Lambda_{\mathrm{law}}^{[\mathscr{S}]}(r)|$:

$$\textit{QIII} \iff \exists\, \beta > 0,\ C < \infty :\ d_{\mathrm{law}}^{[\mathscr{S}]}(r) \leq C\, r^{-\beta}\ (r \to \infty),$$

$$\textit{QIV} \iff \exists\, \delta_\star \in (\varepsilon_{\mathrm{law}}, 1) :\ d_{\mathrm{law}}^{[\mathscr{S}]}(r) \geq \delta_\star \textit{ uniformly on the plateau.}$$

(Use the sector criteria: hydro Lemma 8.22 and Proposition 8.23, boundary Proposition 8.32, subsystem Lemma 8.37 and Proposition 8.38, and the bulk blocks via Proposition 6.277.)

(v) Threshold handling
If either visibility lies within an indifference band around the tolerance (i.e. $\left||\Lambda_\bullet^{[\mathscr{S}]}| - (1-\varepsilon_\bullet)\right| \le \eta$*), flag the case as* threshold/undecided*; tighten tags or enlarge the window and re–certify the plateau (Proposition 6.298).*

(vi) Cross–checks (optional but recommended)
Validate the quadrant with the equivalent diagnostics: scale–tagged Ward statements and light–sector spectrum/residues (Theorem 7.687); discrepancies indicate a failed plateau certification.

(vii) Record provenance
Report $\mathrm{Quad}^{[\mathscr{S}]}$*, the tolerance pair* $(\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}})$*, the dilation law used for QIII/QIV, and the certified band* B*; by Corollaries 6.259 and 6.265 and Proposition 6.257 this label is BRST/Nielsen–safe and cone–stable.*

Intuition. The grid (QI–QIV) is universal; only the witnesses and the arena change. The law channel is decided first (exact within tolerance vs. deficit), and if a deficit exists, the large–window scaling discriminates emergent (QIII) from persistent (QIV). The state channel then selects QI vs QII when the law is (approximately) symmetric. All steps are BRST–clean and plateau–stable, so the outcome is reproducible and gauge–parameter independent.

8.2 The Synthesis of Laws and States

Definition 8.47 (Paraconsistent context and consequence)**.** A *paraconsistent context* is a tuple

$$\mathcal{C} \;=\; \big\langle \mathcal{L}_{\mathcal{C}},\ \vdash_{\mathrm{pc}},\ \Lambda_{\mathcal{C}},\ \mathrm{Adm}_{\mathcal{C}} \big\rangle,$$

where $\mathcal{L}_{\mathcal{C}}$ is a formal language, $\vdash_{\mathrm{pc}}$ is a structural consequence relation on $\mathcal{L}_{\mathcal{C}}$ that *rejects explosion* (i.e. there exists an inconsistent Γ with $\Gamma \nvdash_{\mathrm{pc}} \psi$ for some ψ), $\Lambda_{\mathcal{C}}$ is the set of admissible loci, and $\mathrm{Adm}_{\mathcal{C}}$ are the admissible inference/reporting practices. We assume *Adjunction* ($\varphi, \psi \vdash_{\mathrm{pc}} \varphi \wedge \psi$), *Conjunction Elimination*, *Weakening*, and *Cut*, but not *Explosion* (ECQ) (*cf.* Section 1.2.6).

Definition 8.48 (Non-explosion witness)**.** A *non-explosion witness* for $\vdash_{\mathrm{pc}}$ is data

$$\Pi_{\mathrm{pc}} \;=\; \langle \mathfrak{s},\ v,\ \mathsf{D} \rangle$$

such that $\mathfrak{s}$ is a semantics (algebraic/relational/valuational) for $\mathcal{L}_{\mathcal{C}}$, v is a valuation/interpretation on $\mathfrak{s}$, and D is a set of designated truth-values with the properties: (i) there is φ with $v(\varphi)$ and $v(\neg\varphi)$ both designated (inconsistency), but (ii) there exists ψ with $v(\psi)$ *not* designated (non-triviality). When convenient we instantiate $\mathfrak{s}$ as a four-valued LP/FDE matrix with values $\{\mathbf{T}, \mathbf{F}, \mathbf{B}, \mathbf{N}\}$ and designated $\{\mathbf{T}, \mathbf{B}\}$ (*cf.* Synthesis' paraconsistent clauses in Section 1.2.3 and Definition 1.3).

Definition 8.49 (Logical propagation)**.** Fix a paraconsistent base $\langle \mathcal{L}_{\mathcal{C}}, \vdash_{\mathrm{pc}}, \Pi_{\mathrm{pc}} \rangle$ with valuation v on $\mathfrak{s}$ and designated set D. We say that *logical propagation* holds from a set of seed formulas $\Gamma \subseteq \mathcal{L}_{\mathcal{C}}$ when the following two mechanisms determine the status of all formulas built from Γ by the allowed connectives and rules:

(Semantics) Truth-functionality in FDE/LP: for all χ, α, β,

$$v(\neg\chi) \text{ is determined by } v(\chi), \qquad v(\alpha \wedge \beta) \text{ is determined by } v(\alpha), v(\beta),$$

with designatedness preserved (and $\mathbf{B}$ fixed under $\neg$ and closed under $\wedge$ when both inputs are $\mathbf{B}$).

(Proof theory) Premise-soundness of $\vdash_{\mathrm{pc}}$ w.r.t. Π_{pc}: if $\Gamma \vdash_{\mathrm{pc}} \psi$ and $v(\gamma) \in \mathsf{D}$ for all $\gamma \in \Gamma$, then $v(\psi) \in \mathsf{D}$.

In particular, under *Simultaneous Synthesis* with $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$, logical propagation yields

$$v(\neg\varphi_L) = v(\neg\varphi_S) = \mathbf{B}, \qquad v(\mathrm{I}), v(\mathrm{II}), v(\mathrm{III}), v(\mathrm{IV}) \in \mathsf{D},$$

and (by the witness property of Π_{pc}) joint non-triviality of $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\}$.

Definition 8.50 (Paired dialectical defenses)**.** Fix a formula φ and locus $\lambda \in \Lambda_{\mathcal{C}}$. We write

$$\mathcal{J}^{\pm}_{\mathrm{A}}(\varphi), \qquad \mathcal{J}^{\pm}_{\mathrm{N}}(\varphi; \lambda)$$

for *paired Aristotelian* ($+$ for thesis/affirmation; $-$ for antithesis/denial) and *paired Nyāya* arguments (five-membered scheme; allows perception, inference, testimony, and anupalabdhi), each being well-formed derivations in $\vdash_{\mathrm{pc}}$ whose conclusions are, respectively, φ and $\neg\varphi$. We say the pair is *co-tenable* iff their joint adoption does not yield triviality in $\vdash_{\mathrm{pc}}$ (witnessed by Π_{pc}). (*Cf.* status machinery and corner-selection alignment in Section 1.2.6 and Proposition 1.15.)

Definition 8.51 (Synthesis, cf. Section 1.2.3 and Definition 1.3)**.** Let $\mathcal{C}$ be paraconsistent (Def. 8.47) and $\lambda \in \Lambda_{\mathcal{C}}$. The *Synthesis* of φ at $\langle \mathcal{C}, \lambda \rangle$ is the structured act

$$\mathbf{SynTh}(\varphi; \mathcal{C}, \lambda) := \Big\langle \underbrace{\varphi}_{\text{Asti/Sat}}, \underbrace{\neg\varphi}_{\text{Nāsti/Asat}}, \underbrace{\mathcal{J}^{+}_{\mathrm{A}}(\varphi), \mathcal{J}^{-}_{\mathrm{A}}(\varphi)}_{\text{Aristotelian pair}}, \underbrace{\mathcal{J}^{+}_{\mathrm{N}}(\varphi; \lambda), \mathcal{J}^{-}_{\mathrm{N}}(\varphi; \lambda)}_{\text{Nyāya pair}}, \underbrace{\Pi_{\mathrm{pc}}}_{\text{non-explosion witness}} \Big\rangle$$

subject to: (i) *Co-affirmation*: both φ and $\neg\varphi$ are adopted at the same locus λ (same sense/symmetry); (ii) *Scope hygiene*: no equivocation on φ or λ; (iii) *Paraconsistent discipline*: Π_{pc} attests non-explosion for $\{\varphi, \neg\varphi\}$ (*cf.* Section 1.2.6); (iv) *Paired justification*: the four arguments are valid in $\vdash_{\mathrm{pc}}$ and co-tenable (*cf.* Proposition 1.15).

Lemma 8.52 (Non-explosion of Synthesis)**.** *If* $\mathbf{SynTh}(\varphi; \mathcal{C}, \lambda)$ *holds, then for some* ψ *we have* $\big(\{\varphi, \neg\varphi\} \vdash_{\mathrm{pc}} \psi\big)$*. In particular* $\vdash_{\mathrm{pc}}$ *is non-trivial in the presence of the contradiction* $\varphi \wedge \neg\varphi$ *(*cf. *Section 1.2.6).*

Proof. Immediate from Π_{pc} (Def. 8.48): choose ψ with $v(\psi) \notin \mathsf{D}$ while $v(\varphi), v(\neg\varphi) \in \mathsf{D}$. Soundness of $\vdash_{\mathrm{pc}}$ w.r.t. $\mathfrak{s}$ then prevents derivability of ψ from $\{\varphi, \neg\varphi\}$. □

Object-level predicates for symmetry. Fix a kinematical symmetry group G and an action $T : G \curvearrowright \mathsf{Desc}$ on *law descriptors* (e.g. Lagrangians/Hamiltonians), and $\alpha : G \curvearrowright \mathsf{A}$ on an observable algebra A. Introduce in $\mathcal{L}_{\mathcal{C}}$ the predicates:

$$\mathrm{Sym}(L) :\Longleftrightarrow \forall g \in G \;\; T_g(L) = L, \tag{8.11}$$

$$\mathrm{Break}(L) :\Longleftrightarrow \exists\, \mathcal{O}_{\mathrm{break}}\; \exists g \in G \;\; T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}} \;\wedge\; \mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L), \tag{8.12}$$

$$\mathrm{Sym}(w;\lambda) :\Longleftrightarrow \forall g \in G \;\; w\restriction_\lambda \circ \alpha_g \;=\; w\restriction_\lambda, \tag{8.13}$$

$$\mathrm{Break}(w;\lambda) :\Longleftrightarrow \exists\, \mathcal{O} \in \mathsf{A}\; \exists g \in G \;\; \alpha_g(\mathcal{O}) \neq \mathcal{O} \;\wedge\; w\restriction_\lambda(\mathcal{O}) \neq 0. \tag{8.14}$$

(*Cf.* duality lifts and status dualization Definition 1.11 and Section 1.2.6 for transport across dualized predicates.) Gauge "symmetry" is treated as redundancy: all four predicates are understood via *gauge-invariant* representatives in A and Desc.

Definition 8.53 (Law-level proposition)**.** Let $\varphi_L := \mathrm{Sym}(L)$ be the formula "The Law is Symmetric" (with fixed G and fixed sense of invariance as in (8.11)).

Lemma 8.54 (Scope hygiene for the Law)**.** *If φ_L and $\neg\varphi_L$ are to be co-affirmed under* **SynTh***, then both must refer to the* same *group G, the* same *action $T : G \curvearrowright \mathsf{Desc}$, and the* same *descriptor L. In particular,* $\mathrm{Break}(L)$ *in* (8.12) *must exhibit an operator $\mathcal{O}_{\mathrm{break}}$ with* $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$ *and $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$ for some $g \in G$ (not merely in a different descriptor or under different symmetry data).*

Proof. Assume $\mathbf{SynTh}(\varphi_L;\mathcal{C})$ with $\varphi_L := \mathrm{Sym}(L)$ (Def. 8.53). By Definition 8.51(i)–(ii), there must be derivations in $\vdash_{\mathrm{pc}}$ of φ_L and of its *literal* negation $\neg\varphi_L$, and the two sides must concern the *same* proposition (anti-equivocation).

Unfolding (8.11), φ_L abbreviates $\forall g \in G\; T_g(L) = L$ for the fixed data (G, T, L). The object-language witness for $\neg\varphi_L$ is $\mathrm{Break}(L)$, defined in (8.12) by the existence of $\mathcal{O}_{\mathrm{break}}$ and $g \in G$ such that $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$ and $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$. This predicate is *well-formed at* (G, T, L) and, at that fixed data, entails $\neg\,\mathrm{Sym}(L)$.

If any component were changed—say $G \to G'$, $T \to T'$, or $L \to L'$—the breaking predicate would be $\mathrm{Break}(L')$, which (even if true) entails $\neg\,\mathrm{Sym}(L')$, *not* $\neg\,\mathrm{Sym}(L)$. The pair $\{\varphi_L, \neg\varphi_L\}$ would then equivocate across respects, violating Definition 8.51(ii), rather than forming a genuine glut about the *same* proposition.

Therefore, to co-affirm $\{\varphi_L, \neg\varphi_L\}$ under **SynTh**, both sides must refer to the same G, the same T, and the same L. In particular, the witness in (8.12) must supply $\mathcal{O}_{\mathrm{break}}$ with $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$ and $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$ for some $g \in G$. □

Proposition 8.55 (Synthesis of the Law)**.** *Assume in $\mathcal{C}$ that both* $\mathrm{Sym}(L)$ *and* $\mathrm{Break}(L)$ *are derivable and that there exist co-tenable paired defenses*

$$\mathcal{J}^+_{\mathrm{A}}(\varphi_L),\; \mathcal{J}^-_{\mathrm{A}}(\varphi_L), \qquad \mathcal{J}^+_{\mathrm{N}}(\varphi_L),\; \mathcal{J}^-_{\mathrm{N}}(\varphi_L),$$

together with a non-explosion witness Π_{pc} with a valuation v such that $v(\varphi_L) = \mathbf{B}$. Then

$$\mathbf{SynTh}(\varphi_L;\mathcal{C})$$

holds. In Tetralemma terms, this is the both-selection *status for the dyad associated to φ_L (*cf. *Proposition 1.15).*

Proof. By hypothesis, $\mathrm{Sym}(L)$ and $\mathrm{Break}(L)$ are both derivable in $\mathcal{C}$. Fix the *same* symmetry data (G, T) and the *same* descriptor L as in (8.11)–(8.12) (scope hygiene). In the object language, $\mathrm{Sym}(L)$ asserts $T_g(L) = L$ for all $g \in G$ (8.11), while $\mathrm{Break}(L)$ asserts the existence of an operator $\mathcal{O}_{\mathrm{break}}$ and an element $g \in G$ such that $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$ and $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$ (8.12). Hence, at fixed (G, T, L) we have $\mathrm{Break}(L) \Rightarrow \neg\,\mathrm{Sym}(L)$, and therefore derivations of φ_L and $\neg\varphi_L$ in $\mathcal{L}_{\mathcal{C}}$.

The paired Aristotelian and Nyāya defenses

$$\mathcal{J}^{+}_{\mathrm{A}}(\varphi_L),\ \mathcal{J}^{-}_{\mathrm{A}}(\varphi_L), \qquad \mathcal{J}^{+}_{\mathrm{N}}(\varphi_L),\ \mathcal{J}^{-}_{\mathrm{N}}(\varphi_L)$$

are, by assumption, valid in $\vdash_{\mathrm{pc}}$ and co-tenable. Together with the non-explosion witness Π_{pc} and the valuation condition $v(\varphi_L) = \mathbf{B}$, these satisfy items (i)–(iv) of Definition 8.51. Therefore the structured act $\mathbf{SynTh}(\varphi_L; \mathcal{C})$ holds by direct application of Definition 8.51. Finally, Lemma 8.52 yields the "without triviality" clause. □

Law-level Synthesis, in plain terms. Fix the proposition $\varphi_L := \mathrm{Sym}(L)$. Applying the Synthesis modality to φ_L yields the structured act $\mathbf{SynTh}(\varphi_L; \mathcal{C})$, i.e., a disciplined *co-commitment* that the Law is both symmetric and asymmetric in the *same* context $\mathcal{C}$ and for the *same* symmetry data (G, descriptor L). Formally this is exactly the content of Definitions 1.3 and 8.51 instantiated at the law level, and it is captured as a theorem in Proposition 8.55.

What makes the "both" legitimate. The co-affirmation clause of Definition 8.51 requires that $\mathrm{Sym}(L)$ and its denial refer to an identical sense of invariance (same G, same T, same L); this is the "scope hygiene" that blocks equivocating shifts of sense or locus. In a classical, explosive setting, adopting $\mathrm{Sym}(L)$ together with its negation would trivialize the theory. By contrast, under a paraconsistent consequence relation $\vdash_{\mathrm{pc}}$ the joint adoption is stable: explosion fails, and the contradiction does not entail everything (Definitions 8.47 and 8.48 and Lemma 8.52; see also [453, 454, 455]). Thus, Synthesis replaces collapse with a controlled, non-trivial "both/and".

How the evidence is organized. Synthesis at the law level is not a license for ambiguity; it is *warranted* by paired defenses (Definition 8.50). On the positive side, $\mathcal{J}^{+}_{\mathrm{A}}(\varphi_L)$ and $\mathcal{J}^{+}_{\mathrm{N}}(\varphi_L)$ adduce reasons for $\mathrm{Sym}(L)$ (e.g., invariance postulates, selection rules, Ward identities; cf. (8.11)). On the negative side, $\mathcal{J}^{-}_{\mathrm{A}}(\varphi_L)$ and $\mathcal{J}^{-}_{\mathrm{N}}(\varphi_L)$ exhibit definite breaking structure (an operator $\mathcal{O}_{\mathrm{break}}$ and element $g \in G$ with $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$, and $\mathcal{O}_{\mathrm{break}}$ occurring in L; cf. (8.12)). A familiar heuristic is the decomposition $L = L_{\mathrm{sym}} + \varepsilon\,\mathcal{O}_{\mathrm{break}}$ with $T_g(L_{\mathrm{sym}}) = L_{\mathrm{sym}}$ and $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$: within $\vdash_{\mathrm{pc}}$, this supports both $\mathrm{Sym}(L)$ (structural/approximate invariants) and $\mathrm{Break}(L)$ (explicit breaking), delivering $v(\varphi_L) = \mathbf{B}$ as required in Proposition 8.55.

UpShot. The law-level Synthesis therefore characterizes a regime that is neither purely symmetric nor merely explicitly broken. It encodes a *justified duality*: the Law carries simultaneously valid symmetric and asymmetric aspects, held together by paraconsistent discipline and paired epistemic warrants. In the Tetralemma vocabulary, this is precisely the "both-selection'' status for the law-dyad (Proposition 1.15), and by Lemma 8.52 it does so *without* logical collapse.

Definition 8.56 (State-level proposition)**.** Let $\varphi_S := \mathrm{Sym}(w;\lambda)$ be "The State is Symmetric at λ" (with fixed G and fixed locus λ), as in (8.13).

Lemma 8.57 (Scope hygiene for the State)**.** *If φ_S and $\neg\varphi_S$ are to be co-affirmed under* **SynTh***, then both must refer to the* same *group G, the* same *action α, the* same *state w, and the* same *locus λ. In particular,* $\mathrm{Break}(w;\lambda)$ *in* (8.14) *must exhibit an order parameter or symmetry-violating expectation value evaluated at λ (not merely at a different locus).*

Proof. Assume $\mathbf{SynTh}(\varphi_S;\mathcal{C},\lambda)$ with $\varphi_S := \mathrm{Sym}(w;\lambda)$. By Definition 8.51(i)–(ii), there must be derivations in $\vdash_{\mathrm{pc}}$ of φ_S and of its *literal* negation $\neg\varphi_S$, and the two sides must concern the *same* proposition (anti-equivocation).

Unfolding (8.13), φ_S abbreviates

$$\forall g \in G \;\; w\restriction_\lambda \circ\alpha_g \;=\; w\restriction_\lambda .$$

Thus $\neg\varphi_S$ is the denial of invariance for this very data (G,α,w,λ). The object-language witness we use for $\neg\varphi_S$ is $\mathrm{Break}(w;\lambda)$, defined in (8.14) by the existence of $\mathcal{O}\in\mathsf{A}$ and $g\in G$ such that $\alpha_g(\mathcal{O})\neq\mathcal{O}$ and $w\restriction_\lambda(\mathcal{O})\neq 0$. This predicate is *well-formed at* (G,α,w,λ) and, at that fixed data, entails $\neg\,\mathrm{Sym}(w;\lambda)$.

If any component were changed—say $G\to G'$, $\alpha\to\alpha'$, $w\to w'$, or $\lambda\to\lambda'$—the breaking predicate would be $\mathrm{Break}(w';\lambda')$, which (even if true) entails $\neg\,\mathrm{Sym}(w';\lambda')$, *not* $\neg\,\mathrm{Sym}(w;\lambda)$. The pair $\{\varphi_S,\neg\varphi_S\}$ would then be an equivocation across respects/locations, violating Definition 8.51(ii), rather than a genuine glut about the *same* proposition.

Therefore, to co-affirm $\{\varphi_S,\neg\varphi_S\}$ under **SynTh**, both sides must refer to the same G, the same α, the same w, and the same locus λ. In particular, the witness in (8.14) must evaluate $w\restriction_\lambda$ at that very λ. □

Proposition 8.58 (Synthesis of the State)**.** *Assume* $\mathrm{Sym}(w;\lambda)$ *and* $\mathrm{Break}(w;\lambda)$ *are both derivable in $\mathcal{C}$, with paired defenses*

$$\mathcal{J}^{+}_{\mathrm{A}}(\varphi_S),\ \mathcal{J}^{-}_{\mathrm{A}}(\varphi_S),\qquad \mathcal{J}^{+}_{\mathrm{N}}(\varphi_S;\lambda),\ \mathcal{J}^{-}_{\mathrm{N}}(\varphi_S;\lambda),$$

and a non-explosion witness Π_{pc} giving $v(\varphi_S)=\mathbf{B}$. Then

$$\mathbf{SynTh}(\varphi_S;\mathcal{C},\lambda)$$

holds. Hence the State is both *symmetric and asymmetric at λ without triviality (*cf. *Section 1.2.6).*

Proof. By hypothesis, $\mathrm{Sym}(w;\lambda)$ and $\mathrm{Break}(w;\lambda)$ are both derivable in $\mathcal{C}$, and Lemma 8.57 fixes the *same* G, α, w, and λ. In the object language, $\mathrm{Sym}(w;\lambda)$ asserts invariance of the restricted state under all $g\in G$ (8.13), while $\mathrm{Break}(w;\lambda)$ asserts the existence of $\mathcal{O}\in\mathsf{A}$ and $g\in G$ with $\alpha_g(\mathcal{O})\neq\mathcal{O}$ and a nonvanishing expectation at the same locus, $w\restriction_\lambda(\mathcal{O})\neq 0$ (8.14). Hence, at fixed (G,α,w,λ), $\mathrm{Break}(w;\lambda)$ entails $\neg\,\mathrm{Sym}(w;\lambda)$, so we have derivations of φ_S and $\neg\varphi_S$ in $\mathcal{L}_{\mathcal{C}}$.

The paired Aristotelian and Nyāya defenses

$$\mathcal{J}^{+}_{\mathrm{A}}(\varphi_S),\ \mathcal{J}^{-}_{\mathrm{A}}(\varphi_S),\qquad \mathcal{J}^{+}_{\mathrm{N}}(\varphi_S;\lambda),\ \mathcal{J}^{-}_{\mathrm{N}}(\varphi_S;\lambda)$$

are, by assumption, valid in $\vdash_{\mathrm{pc}}$ and co-tenable. Together with the non-explosion witness Π_{pc} and the valuation condition $v(\varphi_S) = \mathbf{B}$, these satisfy items (i)–(iv) of Definition 8.51. Therefore the structured act $\mathbf{SynTh}(\varphi_S; \mathcal{C}, \lambda)$ holds by direct application of Definition 8.51. Finally, Lemma 8.52 yields the "without triviality" clause. □

Remark 8.59 (Physical instantiation note)**.** In finite volume (or with symmetry-restoring terms) there can be coherent superpositions of symmetry-broken vacua supporting $\mathrm{Break}(w; \lambda)$ alongside symmetric diagnostics; in strict thermodynamic limits, distinct vacua often become superselection sectors. The logical construction remains valid; the physical witness for $\mathrm{Break}(w; \lambda)$ may then be mixture/sector structure rather than literal coherence.

State-level Synthesis, in plain terms. Fix the proposition $\varphi_S := \mathrm{Sym}(w; \lambda)$ (Definition 8.56). Applying the Synthesis modality to φ_S yields the structured act $\mathbf{SynTh}(\varphi_S; \mathcal{C}, \lambda)$: a disciplined *co-commitment* that, at the same locus λ and for the same symmetry data (G, α), the State is both symmetric and asymmetric. Formally, this is Definition 8.51 instantiated at the state level and realized by Proposition 8.58.

What makes the "both" legitimate. The co-affirmation and scope-hygiene clauses of Definition 8.51 (items (i)–(ii)) together with Lemma 8.57 require that $\mathrm{Sym}(w; \lambda)$ and its denial refer to the *same* group G, action α, state w, and locus λ. Thus the "both" is not an equivocation across respects or locations. In a classical (explosive) setting, adopting φ_S and $\neg\varphi_S$ would trivialize the theory; under a paraconsistent consequence relation $\vdash_{\mathrm{pc}}$, backed by a non-explosion witness Π_{pc}, the joint adoption is logically stable (Definitions 8.47 and 8.48 and Lemma 8.52).

How the evidence is organized. Synthesis at the state level is *warranted* by paired dialectical defenses (Definition 8.50). On the positive side, arguments $\mathcal{J}^+_{\mathrm{A}}(\varphi_S)$ and $\mathcal{J}^+_{\mathrm{N}}(\varphi_S; \lambda)$ support $\mathrm{Sym}(w; \lambda)$ via symmetry-invariant diagnostics (e.g., Ward-type constraints and symmetric correlators), as formalized in (8.13). On the negative side, $\mathcal{J}^-_{\mathrm{A}}(\varphi_S)$ and $\mathcal{J}^-_{\mathrm{N}}(\varphi_S; \lambda)$ exhibit symmetry-breaking response at the *same* locus, such as a nonzero order parameter $w\restriction_\lambda(\mathcal{O}) \neq 0$ for some $\mathcal{O} \in \mathsf{A}$, as in (8.14). Co-tenability of these paired defenses ensures that adopting both sides does not collapse $\vdash_{\mathrm{pc}}$.

UpShot. The state-level Synthesis transcends the simple dichotomy "invariant vs. non-invariant." It formally accommodates states with a dialectical character in which symmetric and symmetry-breaking descriptions are *simultaneously* applicable and jointly warranted. This is precisely the content of Proposition 8.58: at fixed λ, the State can be both symmetric and asymmetric without triviality, a reading that also matches the physical nuances noted in the remark on finite volume and superselection (Proposition 8.58 and the subsequent remark).

Proposition 8.60 (Duality transport)**.** *Let $\mathbf{D}_{\mathcal{C}}$ be the Axiom-of-Duality involution acting functorially on formulas and arguments within $\mathcal{C}$. If $\mathbf{SynTh}(\varphi; \mathcal{C}, \lambda)$ holds, then $\mathbf{SynTh}(\mathbf{D}_{\mathcal{C}}\varphi; \mathcal{C}, \lambda)$ holds, with paired defenses transported by $\mathbf{D}_{\mathcal{C}}$ and the same Π_{pc} (*cf. *Section 1.2.6 and Definition 1.11).*

Proof. Assume $\mathbf{SynTh}(\varphi; \mathcal{C}, \lambda)$. By Definition 8.51, there exist paired defenses

$$\mathcal{J}^+_{\mathrm{A}}(\varphi),\ \mathcal{J}^-_{\mathrm{A}}(\varphi), \qquad \mathcal{J}^+_{\mathrm{N}}(\varphi; \lambda),\ \mathcal{J}^-_{\mathrm{N}}(\varphi; \lambda)$$

which are derivations in $\vdash_{\mathrm{pc}}$ with conclusions φ and $\neg\varphi$, are *co-tenable*, and are backed by the same non-explosion witness Π_{pc} (so that adopting both does not trivialize $\vdash_{\mathrm{pc}}$).

By hypothesis, $\mathbf{D}_{\mathcal{C}}$ is an Axiom-of-Duality *involution* acting *functorially* on formulas and arguments in $\mathcal{C}$. Hence: (i) $\mathbf{D}_{\mathcal{C}}$ maps derivations in $\vdash_{\mathrm{pc}}$ to derivations in $\vdash_{\mathrm{pc}}$ and commutes with the logical operations, so $\mathbf{D}_{\mathcal{C}}(\neg\varphi) = \neg\mathbf{D}_{\mathcal{C}}\varphi$; (ii) $\mathbf{D}_{\mathcal{C}}$ transports the Aristotelian/Nyāya arguments to

$$\mathbf{D}_{\mathcal{C}}\mathcal{J}^{+}_{\mathrm{A}}(\varphi),\ \mathbf{D}_{\mathcal{C}}\mathcal{J}^{-}_{\mathrm{A}}(\varphi), \qquad \mathbf{D}_{\mathcal{C}}\mathcal{J}^{+}_{\mathrm{N}}(\varphi;\lambda),\ \mathbf{D}_{\mathcal{C}}\mathcal{J}^{-}_{\mathrm{N}}(\varphi;\lambda),$$

which are well-formed defenses in $\vdash_{\mathrm{pc}}$ with conclusions $\mathbf{D}_{\mathcal{C}}\varphi$ and $\neg\mathbf{D}_{\mathcal{C}}\varphi$ at the *same* locus λ (duality lifts preserve the object-level meanings and loci).

Co-tenability is preserved: if the transported pair trivialized $\vdash_{\mathrm{pc}}$, then applying the inverse (also $\mathbf{D}_{\mathcal{C}}$) would make the original pair trivial, contradicting the premise. Finally, the same Π_{pc} witnesses non-explosion after transport (duality is semantics-compatible and does not alter designatedness or the rule set of $\vdash_{\mathrm{pc}}$).

Thus items (i)–(iv) of Definition 8.51 hold for $\mathbf{D}_{\mathcal{C}}\varphi$ with the transported paired defenses and the same Π_{pc}. Therefore $\mathbf{SynTh}(\mathbf{D}_{\mathcal{C}}\varphi;\mathcal{C},\lambda)$ holds. □

Definition 8.61 (Quadrant formulas)**.** Set $\varphi_L := \mathrm{Sym}(L)$ and $\varphi_S := \mathrm{Sym}(w;\lambda)$. Define

$$\mathrm{I} := \varphi_L \wedge \varphi_S, \qquad \mathrm{II} := \varphi_L \wedge \neg\varphi_S,$$
$$\mathrm{III} := \neg\varphi_L \wedge \varphi_S, \quad \mathrm{IV} := \neg\varphi_L \wedge \neg\varphi_S.$$

These correspond to the four *cells* of the symmetry–asymmetry permutations matrix (table 6.1): (I) Unbroken, (II) SSB, (III) Emergent/Accidental, (IV) Explicit Breaking.

Remark 8.62 (Terminology hygiene: quadrants vs. tetralemma corners)**.** The labels I–IV refer to the matrix in table 6.1, not to the four modal corners $\langle \mathsf{Th}, \mathsf{AntiTh}, \mathsf{SynTh}, \mathsf{HoloTh}\rangle$ of the Tetralemma of Algebra (Definition 1.5). We reserve "Tetralemma corners" for the modal unit $\mathring{\mathbf{\Lambda}}$ and "quadrants" for the law/state matrix.

Theorem 8.63 (Quadrant co-tenability under Synthesis)**.** *Suppose* $\mathbf{SynTh}(\varphi_L;\mathcal{C})$ *and* $\mathbf{SynTh}(\varphi_S;\mathcal{C},\lambda)$ *both hold with a common witness* $\Pi_{\mathrm{pc}} = \langle \mathfrak{s}, v, \mathsf{D}\rangle$ *such that* $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$. *Then each of* $\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}$ *of Definition 8.61 is designated under* v *and hence individually adoptable in* $\vdash_{\mathrm{pc}}$. *Moreover, the set* $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\}$ *is non-trivial: there exists* ψ *with* $\Big(\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\} \vdash_{\mathrm{pc}} \psi\Big)$ *(*cf. *Section 1.2.6).*

Proof. Assume $\mathbf{SynTh}(\varphi_L;\mathcal{C})$ and $\mathbf{SynTh}(\varphi_S;\mathcal{C},\lambda)$ with a common witness $\Pi_{\mathrm{pc}} = \langle \mathfrak{s}, v, \mathsf{D}\rangle$ such that $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$, and with the usual scope hygiene (same $G, T, \alpha, L, w, \lambda$ where relevant).

Step 1: Derive the four cells *as in Definition 8.61.* By Definition 8.51, Synthesis supplies paired, co-tenable derivations in $\vdash_{\mathrm{pc}}$ of each side and its *literal* negation:

$$\varphi_L,\ \neg\varphi_L \qquad \text{and} \qquad \varphi_S,\ \neg\varphi_S.$$

Using Adjunction (and Weakening if needed), form the four conjunctions

$$\mathrm{I} := \varphi_L \wedge \varphi_S, \quad \mathrm{II} := \varphi_L \wedge \neg\varphi_S, \quad \mathrm{III} := \neg\varphi_L \wedge \varphi_S, \quad \mathrm{IV} := \neg\varphi_L \wedge \neg\varphi_S,$$

which are exactly the four *cells* in Definition 8.61. Hence each of I–IV is derivable in $\vdash_{\mathrm{pc}}$ from $\mathcal{C}$.

Step 2: Designatedness under v. In LP/FDE with $\mathsf{D} = \{\mathbf{T}, \mathbf{B}\}$, $v(\neg\chi) = \mathbf{B}$ whenever $v(\chi) = \mathbf{B}$, and $v(\chi \wedge \psi) \in \mathsf{D}$ iff $v(\chi) \in \mathsf{D}$ and $v(\psi) \in \mathsf{D}$. Since $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$, we also have $v(\neg\varphi_L) = v(\neg\varphi_S) = \mathbf{B}$; thus each of I–IV evaluates to a designated value. Therefore, each cell is individually adoptable in $\vdash_{\mathrm{pc}}$.

Step 3: Joint non-triviality. By clause (ii) of Definition 8.48, choose ψ with $v(\psi) \notin \mathsf{D}$. If, for contradiction, $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\} \vdash_{\mathrm{pc}} \psi$, then by soundness of $\vdash_{\mathrm{pc}}$ w.r.t. Π_{pc} we would have $v(\psi) \in \mathsf{D}$ whenever v designates all premises. But Step 2 gives $v(\mathrm{I}), \ldots, v(\mathrm{IV}) \in \mathsf{D}$, contradicting $v(\psi) \notin \mathsf{D}$. Hence there exists ψ with $\not\left(\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\} \vdash_{\mathrm{pc}} \psi\right)$, so the set of the four cells is non-trivial.

This establishes designatedness of each cell and joint non-triviality under the common Π_{pc}. □

Remark 8.64 (Operational witnesses)**.** When desired, the object-language predicates $\mathrm{Break}(L)$ and $\mathrm{Break}(w; \lambda)$ (at fixed symmetry data and locus) entail $\neg\varphi_L$ and $\neg\varphi_S$, respectively. They may thus serve as *witnesses* for the negated conjuncts in the cells, without altering Definition 8.61.

Aristotelian templates (Law). $\mathcal{J}^{+}_{\mathrm{A}}(\varphi_L)$: Syllogistic/axiomatic derivation of (8.11) from invariance postulates (selection rules, Ward identities). $\mathcal{J}^{-}_{\mathrm{A}}(\varphi_L)$: Negative demonstration via explicit $g \in G$ and *gauge-invariant* $\mathcal{O}_{\mathrm{break}}$ with $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$ *and* $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$, entailing $\neg\,\mathrm{Sym}(L)$.

Nyāya templates (Law). $\mathcal{J}^{+}_{\mathrm{N}}(\varphi_L)$: Five-membered argument with testimony (Noether/Ward), perception (null amplitudes), and inference (closure under G).

$\mathcal{J}^{-}_{\mathrm{N}}(\varphi_L)$: Five-membered argument with perception of symmetry-violating responses, inference from RG-generated *gauge-invariant* $\mathcal{O}_{\mathrm{break}}$ with $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$, and testimony of anomaly constraints where applicable.

Aristotelian templates (State). $\mathcal{J}^{+}_{\mathrm{A}}(\varphi_S)$: Derive (8.13) from symmetric correlators/cluster decomposition and Ward identities. $\mathcal{J}^{-}_{\mathrm{A}}(\varphi_S)$: Reductio via exhibited *gauge-invariant* order parameter $\mathcal{O}$ with $w\restriction_{\lambda}(\mathcal{O}) \neq 0$ *and* $\alpha_g(\mathcal{O}) \neq \mathcal{O}$ for some $g \in G$.

Nyāya templates (State). $\mathcal{J}^{+}_{\mathrm{N}}(\varphi_S; \lambda)$: Perception (degenerate multiplets / forbidden transitions), testimony (symmetry constraints), and inference to (8.13). $\mathcal{J}^{-}_{\mathrm{N}}(\varphi_S; \lambda)$: Perception of symmetry-breaking response, *anupalabdhi* of symmetric nulls where expected, and inference to (8.14).

Corollary 8.65 (Unified dialectical reading)**.** *Under Theorem 8.63, the four "table quadrants" are not disjoint metaphysical kinds but* modalities *within one paraconsistent structure—fully compatible with Duality transport and the atomic prismatic unit of the Tetralemma (Proposition 8.60 and Definition 1.5).*

Proof of Corollary 8.65. By Theorem 8.63, each of the four *cells*

$$\mathrm{I} := \varphi_L \wedge \varphi_S, \quad \mathrm{II} := \varphi_L \wedge \neg\varphi_S, \quad \mathrm{III} := \neg\varphi_L \wedge \varphi_S, \quad \mathrm{IV} := \neg\varphi_L \wedge \neg\varphi_S$$

is designated under the common witness $\Pi_{\mathrm{pc}} = \langle \mathfrak{s}, v, \mathsf{D} \rangle$, and the set $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\}$ is jointly non-trivial in $\vdash_{\mathrm{pc}}$.

Modal reading within one paraconsistent structure. Let $\mathcal{M} := \langle \mathcal{L}_{\mathcal{C}}, \vdash_{\mathrm{pc}}, \Pi_{\mathrm{pc}} \rangle$. Since each cell is a well-formed formula of $\mathcal{L}_{\mathcal{C}}$, individually adoptable (designated) yet jointly non-trivial, they function as distinct *modalities* of description inside the single structure $\mathcal{M}$ rather than as disjoint metaphysical kinds.

Compatibility with Duality transport. From $\mathbf{SynTh}(\varphi_L; \mathcal{C})$ and $\mathbf{SynTh}(\varphi_S; \mathcal{C}, \lambda)$, Proposition 8.60 gives $\mathbf{SynTh}(\mathbf{D}_{\mathcal{C}}\varphi_L; \mathcal{C})$ and $\mathbf{SynTh}(\mathbf{D}_{\mathcal{C}}\varphi_S; \mathcal{C}, \lambda)$ with the *same* Π_{pc}. Functoriality of $\mathbf{D}_{\mathcal{C}}$ ensures $\mathbf{D}_{\mathcal{C}}(\neg\chi) = \neg\mathbf{D}_{\mathcal{C}}\chi$ and $\mathbf{D}_{\mathcal{C}}(\chi \wedge \psi) = \mathbf{D}_{\mathcal{C}}\chi \wedge \mathbf{D}_{\mathcal{C}}\psi$, so $\mathbf{D}_{\mathcal{C}}$ permutes the four cells into the corresponding four cells built from $\mathbf{D}_{\mathcal{C}}\varphi_L$ and $\mathbf{D}_{\mathcal{C}}\varphi_S$, preserving designatedness under the same witness. Hence the cell-wise modal reading is stable under Duality transport.

Compatibility with the atomic prismatic unit. The Tetralemma of Algebra (Definition 1.5) provides a minimal atomic prismatic unit that is invariant under admissible dualities/reindexings. Our use of the four cells does not re-define those corners; it merely organizes object-level law/state claims as co-tenable modalities inside $\mathcal{M}$. Since admissible (prismatic) maps act on the whole unit and respect dualities, the cell-wise modalities coexist compatibly with that unit (no clash of meanings, no extra identifications imposed).

Therefore, under Theorem 8.63, the four table cells are modalities within one paraconsistent structure, and this reading is fully compatible with both Duality transport and the atomic prismatic unit. □

Remark 8.66 (Anomalies and IR exactness; tightened)**.** Quadrant III ($\neg\varphi_L \wedge \varphi_S$) licenses a state-level symmetry *with* law-level breaking. Exactness of the state symmetry may hold only at IR fixed points; away from the fixed point, dangerously-irrelevant symmetry–violating operators or 't Hooft anomaly constraints can yield symmetry-breaking responses. Formally, these subtleties live in the *paired defenses*: the positive state-side defenses $\mathcal{J}^{+}_{\mathrm{A}/N}(\varphi_S; \lambda)$ must exhibit symmetry-invariant diagnostics at the *same* locus λ (scope hygiene), while the law-side negatives $\mathcal{J}^{-}_{\mathrm{A}/N}(\varphi_L)$ must witness $\mathrm{Break}(L)$ via a gauge-invariant $\mathcal{O}_{\mathrm{break}}$ with $\mathrm{OccursIn}(\mathcal{O}_{\mathrm{break}}, L)$ and $T_g(\mathcal{O}_{\mathrm{break}}) \neq \mathcal{O}_{\mathrm{break}}$. None of this alters the *logical* content of **SynTh**: co-tenability and non-explosion are governed by $\vdash_{\mathrm{pc}}$ and the witness Π_{pc}; the anomaly/IR issues affect only the evidential content inside $\mathcal{J}^{\pm}$, not the form of the modality.

This formal construction is a rigorous and lucid expansion of the principles articulated in Section 1.2.3. It preserves the modality-theoretic intent of *Synthesis* while making explicit the semantic and inferential constraints under which "both/and" assertions are admissible.

The provided definitions (Definitions 8.47, 8.48 and 8.50) precisely specify the logical machinery required for any coherent deployment of *Synthesis*. By isolating non-explosion as a formal witness Π_{pc}, the text shows how contradictions can be stably entertained without triviality—i.e., without validating $\varphi, \neg\varphi \vdash \psi$ for arbitrary ψ—in line with standard paraconsistent semantics such as Dunn–Belnap FDE and Priest's LP [453, 454, 455].

Furthermore, the introduction of explicit object-level predicates for the symmetry of a Law and a State— $\mathrm{Sym}(L)$ and $\mathrm{Sym}(w; \lambda)$, together with their breaking counterparts—

provides a necessary bridge from the abstract modality to concrete physical propositions. The accompanying templates for paired Aristotelian and Nyāya defenses ensure that an invocation of *Synthesis* is not merely verbal but carries epistemic warrant sourced in admissible evidence and argument forms, matching the methodological demands in the physics literature where symmetry claims and their violations are tied to observable diagnostics and Ward-type constraints [91, 100].

The capstone of this development, the Quadrant Co-tenability Theorem (Theorem 8.63), is especially clarifying. It formally establishes that the four ostensibly mutually exclusive **cells of the symmetry–asymmetry matrix** can be read as co-tenable modalities when the Law and the State are each in *Synthesis*. In that setting, the classical dichotomies dissolve: every quadrant becomes individually adoptable (designated) within a single paraconsistent model while non-explosion is preserved by Π_{pc} [453, 454]. This puts on firm footing the heuristic use of the matrix as a "dashboard" rather than a partition, consistent with established symmetry/SSB practice [91, 100].

As summarized in the concluding corollary (Corollary 8.65), the quadrants are thereby understood not as disjoint metaphysical kinds but as relational facets of a unified dialectical structure governed by **Duality transport** and **prismatic morphisms of the atomic prismatic unit**.

Setup 8.67 (Simultaneous Synthesis)**.** Let $\varphi_L := \mathrm{Sym}(L)$ and $\varphi_S := \mathrm{Sym}(w;\lambda)$ (cf. object-level predicates). Assume the two Synthesis acts (cf. Section 1.2.3 and Definition 1.3)

$$\mathbf{SynTh}(\varphi_L;\mathcal{C}) \qquad \text{and} \qquad \mathbf{SynTh}(\varphi_S;\mathcal{C},\lambda)$$

hold in the same $\mathcal{C}$, at *fixed symmetry data*: for the Law, the same G and action $T : G \curvearrowright \mathsf{Desc}$; for the State, the same G, action $\alpha : G \curvearrowright \mathsf{A}$, state w, and locus λ (scope hygiene). They are witnessed by $\Pi_{\mathrm{pc}} = \langle \mathfrak{s}, v, \mathsf{D}\rangle$ with $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$. Work in a sound paraconsistent base (e.g. Dunn–Belnap FDE / Priest's LP) with designated $\{\mathbf{T},\mathbf{B}\}$ [453, 454, 455]. Paraconsistent co-affirmation is the "Synthesis corner'' of the Tetralemma (Sections 1.2.3 and 1.2.6 and Definition 1.3).

Definition 8.68 (Quadrant formulas)**.** $\mathrm{I} := \varphi_L \wedge \varphi_S$, $\mathrm{II} := \varphi_L \wedge \neg\varphi_S$, $\mathrm{III} := \neg\varphi_L \wedge \varphi_S$, $\mathrm{IV} := \neg\varphi_L \wedge \neg\varphi_S$.

Lemma 8.69 (Truth-functional facts in FDE/LP)**.** *In Dunn–Belnap FDE (and hence in LP for these connectives), with values* $\{\mathbf{N},\mathbf{T},\mathbf{F},\mathbf{B}\}$ *and designated* $\{\mathbf{T},\mathbf{B}\}$*:*

(i) *If* $v(\chi) = \mathbf{B}$ *then* $v(\neg\chi) = \mathbf{B}$.

(ii) *If* $v(\alpha), v(\beta)$ *are designated then* $v(\alpha \wedge \beta)$ *is designated; moreover, if both are* $\mathbf{B}$*, then* $v(\alpha \wedge \beta) = \mathbf{B}$.

Proof. Use the standard set-of-classical-values semantics: identify each truth value with a subset of $\{T, F\}$ (so $\mathbf{N} = \varnothing$, $\mathbf{T} = \{T\}$, $\mathbf{F} = \{F\}$, $\mathbf{B} = \{T, F\}$). Negation swaps T and F; hence $\mathbf{B}$ is fixed by $\neg$, proving (i). Conjunction has $T \in v(\alpha \wedge \beta)$ iff $T \in v(\alpha)$ and $T \in v(\beta)$, and $F \in v(\alpha \wedge \beta)$ iff $F \in v(\alpha)$ or $F \in v(\beta)$ [453, 454]; thus (ii) follows, and if both inputs are $\mathbf{B}$, then both T and F are present, i.e. $v(\alpha \wedge \beta) = \mathbf{B}$. □

Theorem 8.70 (All four quadrants light up without triviality)**.** *Under Setup 8.67, each quadrant* I, II, III, IV *of Definition 8.68 is designated under* v*. Moreover, the set* $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\}$ *is non-trivial (does not entail everything).*

Proof. Since $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$, Lemma 8.69(i) gives $v(\neg\varphi_L) = v(\neg\varphi_S) = \mathbf{B}$. Apply Lemma 8.69(ii) to obtain

$$v(\mathrm{I}) = v(\varphi_L \wedge \varphi_S) = \mathbf{B}, \quad v(\mathrm{II}) = v(\varphi_L \wedge \neg\varphi_S) = \mathbf{B},$$

$$v(\mathrm{III}) = v(\neg\varphi_L \wedge \varphi_S) = \mathbf{B}, \quad v(\mathrm{IV}) = v(\neg\varphi_L \wedge \neg\varphi_S) = \mathbf{B}.$$

For non-triviality, use the witness clause in Setup 8.67: choose ψ with $v(\psi) \notin \mathsf{D}$ (e.g. $v(\psi) = \mathbf{N}$ in FDE). By *premise-soundness* of $\vdash_{\mathrm{pc}}$ w.r.t. Π_{pc}, if $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\} \vdash_{\mathrm{pc}} \psi$, then every valuation that designates all premises (in particular v) must designate ψ, i.e. $v(\psi) \in \mathsf{D}$—a contradiction. Hence $\not\big(\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\} \vdash_{\mathrm{pc}} \psi\big)$. □

Corollary 8.71 (Reading of the matrix)**.** *The usual* 2×2 *"Symmetry–Asymmetry" table remains the correct display, but it is no longer a partition: multiple cells (indeed, all four) may be simultaneously designated. The matrix is a* projection *of an underlying paraconsistent state of information, aligning with the Tetralemma's "both" corner for Synthesis and its operational ties to the four corners (Proposition 1.15 and Section 1.2.6).*

Proof of Corollary 8.71. Under Setup 8.67 we have

$$v(\varphi_L) = v(\varphi_S) = \mathbf{B}.$$

By Lemma 8.69(i)–(ii), each cell in Definition 8.68,

$$\mathrm{I} := \varphi_L \wedge \varphi_S, \quad \mathrm{II} := \varphi_L \wedge \neg\varphi_S, \quad \mathrm{III} := \neg\varphi_L \wedge \varphi_S, \quad \mathrm{IV} := \neg\varphi_L \wedge \neg\varphi_S,$$

is designated. Hence the usual 2×2 table is *not* a partition: multiple cells—indeed, all four—can be simultaneously designated.

"Projection" claim. The matrix entries are just the truth-functional combinations of the two object-level propositions φ_L, φ_S. Thus the table displays a projection of the underlying paraconsistent information state $(v(\varphi_L), v(\varphi_S))$ into the four conjunctions in Definition 8.68. When both components are $\mathbf{B}$, every cell lights up (while non-explosion is preserved by Setup 8.67), which aligns with the "both" status of *Synthesis* and its operational ties to the Tetralemma framework (Proposition 1.15).

Therefore the matrix is the correct display—but as a *dashboard* rather than a partition. □

Remark 8.72 (Hygiene, scope, and dual transport)**.** Both Synthesis acts must be applied at fixed symmetry data: the same group G and action $T : G \curvearrowright \mathsf{Desc}$ for the Law, and the same G, action $\alpha : G \curvearrowright \mathsf{A}$, state w, and locus λ for the State (scope hygiene; cf. Section 1.2.3 and Definition 1.3). Under the Axiom of Duality, the functorial involution $\mathbf{D}_{\mathcal{C}}$ preserves *Synthesis* (Proposition 8.60), transporting paired defenses and leaving the witness Π_{pc} intact; consequently, the dashboard is stable under duality lifts (Section 1.2.6 and Definition 1.11).

Projection insight. The present construction gives a rigorous and elegant proof of the core insight that the classical matrix of possibilities is a *projection* of a more complex, unified structure (Setup 8.67, Definition 8.68, Theorem 8.70, and Corollary 8.71). In the precise sense established below, the 2×2 display is no longer a mutually exclusive case split but a view of co-tenable modalities selected by the logic of *Synthesis* (Section 1.2.3 and Definition 1.3).

Logical propagation. The argument proceeds with transparent steps. (1) *Setup.* Both the Law φ_L and the State φ_S are assumed to be in the modality of *Synthesis*, witnessed by a non-explosive semantics Π_{pc} such that $v(\varphi_L) = v(\varphi_S) = \mathbf{B}$ (designated "both") in a sound paraconsistent base (FDE/LP) (Setup 8.67 and Definition 8.48; see [453, 454, 455]). (2) *Propagation via the truth-functions.* As recorded in Lemma 8.69, $\mathbf{B}$ is a fixed point of negation and conjunction preserves designatedness in the $(\neg, \wedge)$-fragment common to FDE and LP: $v(\neg\chi) = \mathbf{B}$ whenever $v(\chi) = \mathbf{B}$; and if $v(\chi_1), v(\chi_2)$ are designated then $v(\chi_1 \wedge \chi_2)$ is designated (*moreover*, if both are $\mathbf{B}$ then $v(\chi_1 \wedge \chi_2) = \mathbf{B}$) [453, 454]. (3) *Quadrant values.* It follows immediately that each quadrant formula in Definition 8.68—$\mathrm{I} = \varphi_L \wedge \varphi_S$, $\mathrm{II} = \varphi_L \wedge \neg\varphi_S$, $\mathrm{III} = \neg\varphi_L \wedge \varphi_S$, $\mathrm{IV} = \neg\varphi_L \wedge \neg\varphi_S$—also evaluates to $\mathbf{B}$. (4) *Non-triviality.* Because $\mathbf{B}$ is designated and Π_{pc} witnesses non-explosion, all four quadrants are simultaneously adoptable without collapse: there exists some ψ with $v(\psi)$ undesignated, so $\{\mathrm{I}, \mathrm{II}, \mathrm{III}, \mathrm{IV}\} \nvdash_{\text{pc}} \psi$ (Theorem 8.70 and Definition 8.48; cf. [453, 454]).

Dashboard reading. The corollary (Corollary 8.71) captures the main conceptual payoff: the familiar 2×2 "Symmetry–Asymmetry" table ceases to function as a partition and instead becomes a *dashboard* of co-tenable modalities. This makes precise a practice that is already implicit in symmetry/SSB reasoning—namely, that law-level and state-level diagnostics can jointly constrain, but need not classically determine, a single exclusive quadrant [91, 100]. In contexts where finite-volume or regulator effects are salient, this paraconsistent reading is especially faithful to how seemingly conflicting signatures (symmetric correlators alongside symmetry-breaking responses) coexist without logical explosion.

Ontological upshot. Accordingly, the classical categories of symmetry and breaking are not static boxes but interrelated *projections* of a single richer structure whose coherence is maintained by the logic of *Synthesis*. In this reading, the 2×2 matrix functions as a dashboard of co-tenable modalities rather than a partition: law-level and state-level claims may be jointly entertained without triviality, provided the paraconsistent discipline holds (Section 1.2.6). The perspective aligns with the Tetralemma's "both" corner and is stable under admissible duality transport (Proposition 8.60). When scale changes are relevant, renormalization-group flow supplies a canonical mechanism by which descriptions and apparent symmetries shift while remaining compatible with the paraconsistent envelope [415, 403].

8.2.1 Parasymmetric Synthesis of Laws and States

Modal sectors for the anchors. For each anchor $a \in \{L, S\}$ (Law, State) fix the two-dimensional modal sector

$$\mathcal{H}^{(a)} := \operatorname{span}\left\{|e_1\rangle_a,\ |e_2\rangle_a\right\} \qquad \text{with} \qquad |e_1\rangle_a \equiv |\,\mathrm{Sym}\rangle_a,\ \ |e_2\rangle_a \equiv |\,\mathrm{Break}\rangle_a.$$

Let $\mathrm{Id}^{(a)}_{(0,1)}$ denote the identity on $\mathcal{H}^{(a)}$, and set the local "parasymmetric/anti-parasymmetric" kets

$$|+\rangle_a := \tfrac{1}{\sqrt{2}}\big(|e_1\rangle_a + |e_2\rangle_a\big), \qquad |-\rangle_a := \tfrac{1}{\sqrt{2}}\big(|e_1\rangle_a - |e_2\rangle_a\big).$$

Definition 8.73 (Local parasymmetric projectors and valuation)**.** For each $a \in \{L, S\}$ define the rank-1 projectors

$$P^{(a)}_{\mathrm{para}} := |+\rangle_a\langle+|\,, \qquad P^{(a)}_{\mathrm{antipara}} := |-\rangle_a\langle-|$$

so that $P^{(a)}_{\mathrm{para}} + P^{(a)}_{\mathrm{antipara}} = P^{(a)}_{(0,1)}$. Given a density operator ρ_a on $\mathcal{H}^{(a)}$, the *local Synthesis valuation* is

$$v^{(a)}_{\mathrm{Synthesis}}(\rho_a) \;:=\; \mathrm{Tr}\Big(P^{(a)}_{\mathrm{para}}\rho_a\Big) \in [0,1].$$

Lemma 8.74 (Elementary properties)**.** *For each anchor a:* (i) $P^{(a)}_{\mathrm{para}}P^{(a)}_{\mathrm{antipara}} = 0$ *and* $\big(P^{(a)}_{\mathrm{para}}\big)^2 = P^{(a)}_{\mathrm{para}}$ *(similarly for $P^{(a)}_{\mathrm{antipara}}$).* (ii) *For the spectral decomposition $\rho_a = \sum_k p_k\,|\psi_k\rangle\langle\psi_k|$, $v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \sum_k p_k\,|\langle+|\psi_k\rangle|^2$.* (iii) *Writing ρ_a in the $\{|e_1\rangle_a, |e_2\rangle_a\}$ basis and using $\rho_{11}+\rho_{22}=1$,*

$$v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \tfrac{1}{2}(\rho_{11}+\rho_{22}) + \mathrm{Re}(\rho_{12}) = \tfrac{1}{2} + \mathrm{Re}(\rho_{12})\,,$$

so the valuation depends on the coherence ρ_{12} *and not only on populations.*

Proof. Fix $a \in \{L,S\}$ and abbreviate $|\pm\rangle := |\pm\rangle_a$, $P_{\mathrm{para}} := P^{(a)}_{\mathrm{para}} = |+\rangle\langle+|$, $P_{\mathrm{antipara}} := P^{(a)}_{\mathrm{antipara}} = |-\rangle\langle-|$.

(i) Orthogonality and idempotency. Since $|+\rangle = \frac{1}{\sqrt{2}}(|e_1\rangle + |e_2\rangle)$ and $|-\rangle = \frac{1}{\sqrt{2}}(|e_1\rangle - |e_2\rangle)$, we have $\langle+|-\rangle = 0$. Hence

$$P_{\mathrm{para}}P_{\mathrm{antipara}} = \Big(|+\rangle\langle+|\Big)\Big(|-\rangle\langle-|\Big) = |+\rangle\,\underbrace{\langle+|-\rangle}_{=0}\,\langle-| \;=\; 0,$$

and similarly $P_{\mathrm{antipara}}P_{\mathrm{para}} = 0$. Idempotency is immediate:

$$P^2_{\mathrm{para}} = \Big(|+\rangle\langle+|\Big)\Big(|+\rangle\langle+|\Big) = |+\rangle\,\langle+|+\rangle\,\langle+| = |+\rangle\langle+| = P_{\mathrm{para}},$$

and likewise for P_{antipara}.

(ii) Spectral/convex form of the valuation. By definition $v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \mathrm{Tr}(P_{\mathrm{para}}\rho_a)$. Using the spectral decomposition $\rho_a = \sum_k p_k|\psi_k\rangle\langle\psi_k|$ and linearity of the trace,

$$v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \sum_k p_k\;\mathrm{Tr}\Big(P_{\mathrm{para}}|\psi_k\rangle\langle\psi_k|\Big) = \sum_k p_k\,\langle\psi_k|P_{\mathrm{para}}|\psi_k\rangle = \sum_k p_k\,|\langle+|\psi_k\rangle|^2.$$

This shows convexity and basis-independence of the expression.

(iii) Matrix form and coherence dependence. In the ordered basis $\{|e_1\rangle_a, |e_2\rangle_a\}$, write $\rho_a = \left(\begin{smallmatrix}\rho_{11} & \rho_{12}\\ \rho_{21} & \rho_{22}\end{smallmatrix}\right)$ with $\rho_{21} = \overline{\rho_{12}}$, $\rho_{11}, \rho_{22} \geq 0$, $\rho_{11}+\rho_{22} = 1$. The projector onto $|+\rangle$ is

$$P_{\mathrm{para}} = |+\rangle\langle+| = \tfrac{1}{2}\left(\begin{smallmatrix}1 & 1\\ 1 & 1\end{smallmatrix}\right).$$

Then

$$v^{(a)}_{\text{Synthesis}}(\rho_a) = \mathrm{Tr}(P_{\text{para}}\rho_a) = \tfrac{1}{2}\,\mathrm{Tr}\begin{pmatrix} \rho_{11}+\rho_{21} & \rho_{12}+\rho_{22} \\ \rho_{11}+\rho_{21} & \rho_{12}+\rho_{22} \end{pmatrix} = \tfrac{1}{2}\Big(\rho_{11}+\rho_{22}+\rho_{12}+\rho_{21}\Big) = \tfrac{1}{2}+\mathrm{Re}(\rho_{12}),$$

as claimed. In particular, $v^{(a)}_{\text{Synthesis}}$ depends on the *real part of the off-diagonal* element (the coherence), not only on populations.

Range check. Positivity of ρ_a implies $|\rho_{12}|^2 \le \rho_{11}\rho_{22} \le \tfrac{1}{4}(\rho_{11}+\rho_{22})^2 = \tfrac{1}{4}$. Hence $-\tfrac{1}{2} \le \mathrm{Re}(\rho_{12}) \le \tfrac{1}{2}$, so $0 \le v^{(a)}_{\text{Synthesis}}(\rho_a) \le 1$, with $v^{(a)}_{\text{Synthesis}} = 1$ (resp. 0) iff $\rho_a = |+\rangle\langle+|$ (resp. $|-\rangle\langle-|$).

Equivalent Bloch-form (optional). Let $\sigma_x = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Then $P_{\text{para}} = \tfrac{1}{2}(I+\sigma_x)$ and

$$v^{(a)}_{\text{Synthesis}}(\rho_a) = \tfrac{1}{2}\Big(1+\mathrm{Tr}(\sigma_x\rho_a)\Big) = \tfrac{1}{2}+\mathrm{Re}(\rho_{12}),$$

consistent with the calculation above. □

Remark 8.75 (Coherent "both" vs. incoherent mixture)**.** If ρ_a is *diagonal* with equal populations ($\rho_{11} = \rho_{22} = \tfrac{1}{2}$) and hence zero coherence ($\rho_{12} = 0$), then $v^{(a)}_{\text{Synthesis}}(\rho_a) = \tfrac{1}{2}$. By contrast, the pure coherent superposition $|+\rangle_a$ gives $v = 1$. Thus parasymmetry separates coherent Synthesis from a mere mixture—something the purely logical **SynTh** layer cannot distinguish (Definition 8.51 and Lemma 8.52; cf. [453, 454, 455]).

Phase-resolved special case. For a pure equal-weight superposition

$$|\psi_\phi\rangle \;=\; \tfrac{1}{\sqrt{2}}\Big(|e_1\rangle_a + e^{i\phi}\,|e_2\rangle_a\Big),$$

one has $\rho_{12} = e^{-i\phi}/2$, and using Lemma 8.74 (iii),

$$v^{(a)}_{\text{Synthesis}}\Big(|\psi_\phi\rangle\langle\psi_\phi|\Big) \;=\; \tfrac{1}{2}+\mathrm{Re}(\rho_{12}) \;=\; \tfrac{1}{2}+\tfrac{1}{2}\cos\phi \;=\; \cos^2\Big(\tfrac{\phi}{2}\Big).$$

This interpolates continuously from 1 at $\phi = 0$ (the $|+\rangle_a$ state) to 0 at $\phi = \pi$ (the $|-\rangle_a$ state), explicitly exhibiting the coherence sensitivity of the parasymmetric valuation.

Definition 8.76 (Law–State parasymmetric subspaces)**.** On $\mathcal{H}^{(LS)} := \mathcal{H}^{(L)} \otimes \mathcal{H}^{(S)}$ define the (Bell-type) kets

$$|\Psi^{(LS)}_{\text{para}}\rangle = \tfrac{1}{\sqrt{2}}\Big(|e_1\rangle_L|e_2\rangle_S + |e_2\rangle_L|e_1\rangle_S\Big), \quad |\Psi^{(LS)}_{\text{antipara}}\rangle = \tfrac{1}{\sqrt{2}}\Big(|e_1\rangle_L|e_2\rangle_S - |e_2\rangle_L|e_1\rangle_S\Big),$$
$$|\Phi^{(LS)}_{\text{para}}\rangle = \tfrac{1}{\sqrt{2}}\Big(|e_1\rangle_L|e_1\rangle_S + |e_2\rangle_L|e_2\rangle_S\Big), \quad |\Phi^{(LS)}_{\text{antipara}}\rangle = \tfrac{1}{\sqrt{2}}\Big(|e_1\rangle_L|e_1\rangle_S - |e_2\rangle_L|e_2\rangle_S\Big),$$

with projectors $P^{(LS)}_{\text{para}} := |\Psi^{(LS)}_{\text{para}}\rangle\langle\Psi^{(LS)}_{\text{para}}|$, $P^{(LS)}_{\text{antipara}}$, $P^{(LS)}_{\Phi,\text{para}}$, $P^{(LS)}_{\Phi,\text{antipara}}$. We call the Ψ-pair the *opposition sector* (II/III plane) and the Φ-pair the *agreement sector* (I/IV plane), relative to the quadrant formulas (Definition 8.61).

Lemma 8.77 (Orthogonality and block decomposition)**.** *The four kets in Definition 8.76 are orthonormal. Moreover,*

$$\mathsf{S}_\Psi := \mathrm{span}\{|\Psi^{(LS)}_{\text{para}}\rangle, |\Psi^{(LS)}_{\text{antipara}}\rangle\}, \qquad \mathsf{S}_\Phi := \mathrm{span}\{|\Phi^{(LS)}_{\text{para}}\rangle, |\Phi^{(LS)}_{\text{antipara}}\rangle\}$$

are mutually orthogonal, and each is the minimal invariant subspace generated by the corresponding computational-basis pairs:

$$\mathsf{S}_\Psi = \mathrm{span}\{|e_1e_2\rangle, |e_2e_1\rangle\}, \qquad \mathsf{S}_\Phi = \mathrm{span}\{|e_1e_1\rangle, |e_2e_2\rangle\}.$$

Proof. For brevity write $|ij\rangle := |e_i\rangle_L|e_j\rangle_S$. Then

$$|\Psi_{\text{para}}\rangle = \tfrac{1}{\sqrt{2}}(|12\rangle + |21\rangle), \quad |\Psi_{\text{antipara}}\rangle = \tfrac{1}{\sqrt{2}}(|12\rangle - |21\rangle),$$

$$|\Phi_{\text{para}}\rangle = \tfrac{1}{\sqrt{2}}(|11\rangle + |22\rangle), \quad |\Phi_{\text{antipara}}\rangle = \tfrac{1}{\sqrt{2}}(|11\rangle - |22\rangle).$$

Orthonormality. Using $\langle ij|k\ell\rangle = \delta_{ik}\delta_{j\ell}$,

$$\langle\Psi_{\text{para}}|\Psi_{\text{para}}\rangle = \tfrac{1}{2}(\langle 12| + \langle 21|)(|12\rangle + |21\rangle) = 1,$$

$$\langle\Psi_{\text{antipara}}|\Psi_{\text{antipara}}\rangle = \tfrac{1}{2}(\langle 12| - \langle 21|)(|12\rangle - |21\rangle) = 1,$$

and $\langle\Psi_{\text{para}}|\Psi_{\text{antipara}}\rangle = \tfrac{1}{2}(\langle 12| + \langle 21|)(|12\rangle - |21\rangle) = 0$. The same computation shows $\langle\Phi_{\text{para}}|\Phi_{\text{para}}\rangle = \langle\Phi_{\text{antipara}}|\Phi_{\text{antipara}}\rangle = 1$ and $\langle\Phi_{\text{para}}|\Phi_{\text{antipara}}\rangle = 0$. Cross terms between the Ψ- and Φ-pairs vanish because the former live in $\text{span}\{|12\rangle, |21\rangle\}$ and the latter in $\text{span}\{|11\rangle, |22\rangle\}$, which are orthogonal. Hence the four kets form an orthonormal set.

Block projectors and orthogonal decomposition. Let

$$P_{\Psi\text{-block}} := P^{(LS)}_{\text{para}} + P^{(LS)}_{\text{antipara}}, \qquad P_{\Phi\text{-block}} := P^{(LS)}_{\Phi,\text{para}} + P^{(LS)}_{\Phi,\text{antipara}}.$$

A direct expansion gives

$$P_{\Psi\text{-block}} = |\Psi_{\text{para}}\rangle\langle\Psi_{\text{para}}| + |\Psi_{\text{antipara}}\rangle\langle\Psi_{\text{antipara}}| = |12\rangle\langle 12| + |21\rangle\langle 21|,$$

$$P_{\Phi\text{-block}} = |\Phi_{\text{para}}\rangle\langle\Phi_{\text{para}}| + |\Phi_{\text{antipara}}\rangle\langle\Phi_{\text{antipara}}| = |11\rangle\langle 11| + |22\rangle\langle 22|.$$

Therefore $\text{Ran}(P_{\Psi\text{-block}}) = \text{span}\{|12\rangle, |21\rangle\} =: \mathsf{S}_\Psi$ and $\text{Ran}(P_{\Phi\text{-block}}) = \text{span}\{|11\rangle, |22\rangle\} =: \mathsf{S}_\Phi$. Since these ranges are orthogonal and exhaust the computational basis, we have

$$P_{\Psi\text{-block}}P_{\Phi\text{-block}} = 0, \qquad P_{\Psi\text{-block}} + P_{\Phi\text{-block}} = \text{Id}_{\mathcal{H}^{(LS)}},$$

so $\mathcal{H}^{(LS)} = \mathsf{S}_\Psi \oplus \mathsf{S}_\Phi$.

Minimality and invariance. Each block projector is the identity on its range and annihilates the other block, hence S_Ψ and S_Φ are invariant under the algebra generated by the four rank-1 projectors (equivalently, under $P_{\Psi\text{-block}}, P_{\Phi\text{-block}}$). Moreover, S_Ψ is the *smallest* subspace containing $|12\rangle, |21\rangle$ that is invariant under this algebra—because $P_{\Psi\text{-block}}$ is precisely the orthogonal projector onto $\text{span}\{|12\rangle, |21\rangle\}$ (and similarly for S_Φ with $|11\rangle, |22\rangle$). Finally, within each block, $\{|\Psi_{\text{para}}\rangle, |\Psi_{\text{antipara}}\rangle\}$ and $\{|\Phi_{\text{para}}\rangle, |\Phi_{\text{antipara}}\rangle\}$ are related to their computational pairs by the unitary $\frac{1}{\sqrt{2}}\left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$, so they indeed form orthonormal bases of the respective minimal invariant subspaces. □

Definition 8.78 (Joint Synthesis valuations)**.** For a density operator ρ_{LS} on $\mathcal{H}^{(LS)}$ set

$$v^{(LS)}_{\text{Synthesis}}(\rho_{LS}) := \text{Tr}\Big(P^{(LS)}_{\text{para}}\rho_{LS}\Big), \qquad v^{(LS)}_{\text{Agreement}}(\rho_{LS}) := \text{Tr}\Big(P^{(LS)}_{\Phi,\text{para}}\rho_{LS}\Big).$$

These quantify coherent Law–State *opposition* and *agreement*, respectively.

Definition 8.79 (Unified parasymmetric generator on $L \oplus S$)**.** Define the Hermitian generator on $\mathcal{H}^{(LS)}$:

$$\begin{aligned}\hat{F}^{(LS)}_{\text{para}} &= \lambda_L \Big(P^{(L)}_{\text{para}} - P^{(L)}_{\text{antipara}}\Big) \otimes \mathrm{Id}^{(S)}_{(0,1)} \\ &\quad + \lambda_S \, \mathrm{Id}^{(L)}_{(0,1)} \otimes \Big(P^{(S)}_{\text{para}} - P^{(S)}_{\text{antipara}}\Big) \\ &\quad + \lambda_{LS} \Big(P^{(LS)}_{\text{para}} - P^{(LS)}_{\text{antipara}}\Big) \\ &\quad + \lambda_\Phi \Big(P^{(LS)}_{\Phi,\text{para}} - P^{(LS)}_{\Phi,\text{antipara}}\Big) + \cdots \end{aligned} \tag{8.15}$$

and the unitary $U^{(LS)}_t := \exp\Big(it\, \hat{F}^{(LS)}_{\text{para}}\Big)$. (Here the ellipsis allows additional symmetry-compatible couplings; cf. ladder-type exchanges below.)

Definition 8.80 (Exchange operators (optional))**.** On each anchor define $\hat{\sigma}^{(+)}_a := |e_1\rangle_a\langle e_2|$, $\hat{\sigma}^{(-)}_a := |e_2\rangle_a\langle e_1|$. A *direct excitation exchange* term has the Hermitian form

$$\hat{F}^{(\text{ex})} := \sum_\mu \Big(J_\mu \, \hat{\sigma}^{(+)}_L \hat{\sigma}^{(-)}_S + \overline{J_\mu} \, \hat{\sigma}^{(-)}_L \hat{\sigma}^{(+)}_S \Big),$$

and may be absorbed into $\hat{F}^{(LS)}_{\text{para}}$ with a coupling λ_X.

Proposition 8.81 (Invariance criteria & constants of motion)**.** *Let* $P \in \{\, P^{(L)}_{\text{para}} \otimes \mathrm{Id},\ \mathrm{Id} \otimes P^{(S)}_{\text{para}},\ P^{(LS)}_{\text{para}},\ P^{(LS)}_{\Phi,\text{para}} \,\}$. *For the evolution* $\rho_{LS}(t) = U^{(LS)}_t \, \rho_{LS}(0) \, U^{(LS)\dagger}_t$ *with* $U^{(LS)}_t = \exp\Big(it\, \hat{F}^{(LS)}_{\text{para}}\Big)$,

$$\frac{d}{dt}\, \mathrm{Tr}\Big(P\, \rho_{LS}(t)\Big) = i\, \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\text{para}}, P]\, \rho_{LS}(t)\Big).$$

In particular, if $[\hat{F}^{(LS)}_{\text{para}}, P] = 0$, *then* $\mathrm{Tr}\Big(P\, \rho_{LS}(t)\Big)$ *is conserved.*

Proof. Write $U := U^{(LS)}_t$, $\hat{F} := \hat{F}^{(LS)}_{\text{para}}$, and $\rho := \rho_{LS}(0)$. By definition $\rho(t) = U \rho U^\dagger$. Differentiate and use $\dot{U} = i\hat{F}U$, $\dot{U}^\dagger = -iU^\dagger \hat{F}$:

$$\frac{d}{dt}\, \mathrm{Tr}\Big(P\, \rho(t)\Big) = \mathrm{Tr}\Big(P\, \dot{U}\, \rho\, U^\dagger\Big) + \mathrm{Tr}\Big(P\, U\, \rho\, \dot{U}^\dagger\Big) = i\, \mathrm{Tr}\Big(P\, \hat{F}\, U \rho U^\dagger\Big) - i\, \mathrm{Tr}\Big(P\, U \rho U^\dagger \hat{F}\Big).$$

By cyclicity of trace, $\mathrm{Tr}\Big(P\, \hat{F}\, U \rho U^\dagger\Big) = \mathrm{Tr}\Big(\hat{F}\, U \rho U^\dagger P\Big)$ and $\mathrm{Tr}\Big(P\, U \rho U^\dagger \hat{F}\Big) = \mathrm{Tr}\Big(\hat{F}\, P\, U \rho U^\dagger\Big)$. Thus

$$\frac{d}{dt}\, \mathrm{Tr}\Big(P\, \rho(t)\Big) = i\, \mathrm{Tr}\Big(\, [\hat{F}, P]\, U \rho U^\dagger\Big) = i\, \mathrm{Tr}\Big([\hat{F}, P]\, \rho(t)\Big),$$

which is the claimed Heisenberg-form identity. If $[\hat{F}, P] = 0$ then the derivative vanishes, so $\mathrm{Tr}(P\rho(t))$ is constant in time. □

Lemma 8.82 (Commutation structure of the generator)**.** *Let* $Q_L := P^{(L)}_{\text{para}} - P^{(L)}_{\text{antipara}}$, $Q_S := P^{(S)}_{\text{para}} - P^{(S)}_{\text{antipara}}$, $Q_\Psi := P^{(LS)}_{\text{para}} - P^{(LS)}_{\text{antipara}}$, *and* $Q_\Phi := P^{(LS)}_{\Phi,\text{para}} - P^{(LS)}_{\Phi,\text{antipara}}$. *Then:*

(i) $[Q_\Psi, P^{(LS)}_{\text{para}}] = 0$ *and* $[Q_\Phi, P^{(LS)}_{\text{para}}] = 0$.

(ii) $[Q_L \otimes \mathrm{Id},\ P^{(LS)}_{\text{para}}] \neq 0$ *and* $[\mathrm{Id} \otimes Q_S,\ P^{(LS)}_{\text{para}}] \neq 0$ *in general.*

(iii) *For the exchange operator* $\hat{F}^{(\mathrm{ex})} = \sum_\mu \left(J_\mu \, \hat{\sigma}_L^{(+)} \hat{\sigma}_S^{(-)} + \overline{J_\mu} \, \hat{\sigma}_L^{(-)} \hat{\sigma}_S^{(+)} \right)$, $[\hat{F}^{(\mathrm{ex})}, P^{(LS)}_{\mathrm{para}}] = 0$ *and* $[\hat{F}^{(\mathrm{ex})}, P^{(LS)}_{\Phi,\mathrm{para}}] = 0$.

Proof. Set

$$|ij\rangle := |e_i\rangle_L \otimes |e_j\rangle_S, \qquad \mathsf{S}_\Psi := \mathrm{span}\{|12\rangle, \, |21\rangle\}.$$

In the orthonormal basis $\{|\Psi^{(LS)}_{\mathrm{para}}\rangle, \, |\Psi^{(LS)}_{\mathrm{antipara}}\rangle\}$ of S_Ψ,

$$P^{(LS)}_{\mathrm{para}} \restriction_{\mathsf{S}_\Psi} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix} \right).$$

(a) On S_Ψ, $Q_\Psi = \mathrm{diag}(1, -1)$, hence it commutes with $\mathrm{diag}(1, 0)$. On the orthogonal Φ-block $\mathsf{S}_\Phi = \mathrm{span}\{|11\rangle, |22\rangle\}$ we have $P^{(LS)}_{\mathrm{para}} = 0$, so $[Q_\Phi, P^{(LS)}_{\mathrm{para}}] = 0$ trivially and $[Q_\Psi, P^{(LS)}_{\mathrm{para}}] = 0$ blockwise.

(b) The local "tilt" $Q_L \otimes \mathrm{Id}$ maps $|12\rangle \mapsto |22\rangle$ and $|21\rangle \mapsto |11\rangle$, hence it couples S_Ψ to S_Φ. Therefore it does not commute with $P^{(LS)}_{\mathrm{para}}$, which projects onto S_Ψ. An analogous statement holds for $\mathrm{Id} \otimes Q_S$.

(c) Using $\hat{\sigma}_L^{(+)} \hat{\sigma}_S^{(-)} |12\rangle = |21\rangle$, $\hat{\sigma}_L^{(+)} \hat{\sigma}_S^{(-)} |21\rangle = |12\rangle$, and zero action on $|11\rangle, |22\rangle$, $\hat{F}^{(\mathrm{ex})}$ acts on S_Ψ as $\mathrm{diag}(+|J|, -|J|)$ in the $\{|\Psi_{\mathrm{para}}\rangle, |\Psi_{\mathrm{antipara}}\rangle\}$ basis and annihilates S_Φ. Hence it commutes with both $P^{(LS)}_{\mathrm{para}}$ and $P^{(LS)}_{\Phi,\mathrm{para}}$. □

Corollary 8.83 (When opposition/agreement "scores" are conserved)**.** *Let* $v^{(LS)}_{\mathrm{Synthesis}}(t) := \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}} \rho_{LS}(t) \Big)$ *and* $v^{(LS)}_{\mathrm{Agreement}}(t) := \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}} \rho_{LS}(t) \Big)$.

(i) If $\lambda_L = \lambda_S = 0$ *(no local tilts) and the generator consists of any combination of* Q_Ψ, Q_Φ, *and exchange terms* $\hat{F}^{(\mathrm{ex})}$, *then* $v^{(LS)}_{\mathrm{Synthesis}}(t)$ *and* $v^{(LS)}_{\mathrm{Agreement}}(t)$ *are constants of motion.*

(ii) If a local tilt is present (either $\lambda_L \neq 0$ *or* $\lambda_S \neq 0$*), then generically* $\frac{d}{dt} v^{(LS)}_{\mathrm{Synthesis}}(t) \neq 0$ *and* $\frac{d}{dt} v^{(LS)}_{\mathrm{Agreement}}(t) \neq 0$ *because* $Q_L \otimes \mathrm{Id}$ *and* $\mathrm{Id} \otimes Q_S$ *mix the* Ψ/Φ *blocks (Lemma 8.82(b)).*

Proof. Immediate from Proposition 8.81 and Lemma 8.82: in case (i), each listed term commutes with both $P^{(LS)}_{\mathrm{para}}$ and $P^{(LS)}_{\Phi,\mathrm{para}}$; in case (ii) at least one commutator is nonzero. □

Corollary 8.84 (Preserving local vs. relational parasymmetry)**.** *(a) If* $[\hat{F}^{(LS)}_{\mathrm{para}}, P^{(L)}_{\mathrm{para}} \otimes \mathrm{Id}] = 0 = [\hat{F}^{(LS)}_{\mathrm{para}}, \mathrm{Id} \otimes P^{(S)}_{\mathrm{para}}]$, *then the local valuations* $v^{(L)}_{\mathrm{Synthesis}}$ *and* $v^{(S)}_{\mathrm{Synthesis}}$ *are constants of motion. (b) If* $[\hat{F}^{(LS)}_{\mathrm{para}}, P^{(LS)}_{\mathrm{para}}] = 0$ *(resp.* $[\hat{F}^{(LS)}_{\mathrm{para}}, P^{(LS)}_{\Phi,\mathrm{para}}] = 0$*), then the joint valuations* $v^{(LS)}_{\mathrm{Synthesis}}$ *(resp.* $v^{(LS)}_{\mathrm{Agreement}}$*) are constants of motion.*

Proof. Write $\rho(t) := \rho_{LS}(t) = U_t^{(LS)} \, \rho(0) \, U_t^{(LS)\dagger}$.

(a) Local valuations. Using the partial trace identity,

$$v^{(L)}_{\mathrm{Synthesis}}(t) = \mathrm{Tr}\Big(P^{(L)}_{\mathrm{para}} \, \rho_L(t) \Big) = \mathrm{Tr}\Big((P^{(L)}_{\mathrm{para}} \otimes \mathrm{Id}) \, \rho(t) \Big),$$

and similarly $v^{(S)}_{\mathrm{Synthesis}}(t) = \mathrm{Tr}\Big((\mathrm{Id} \otimes P^{(S)}_{\mathrm{para}}) \, \rho(t) \Big)$. By Proposition 8.81,

$$\frac{d}{dt} \, v^{(L)}_{\mathrm{Synthesis}}(t) = i \, \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\mathrm{para}}, \, P^{(L)}_{\mathrm{para}} \otimes \mathrm{Id}] \, \rho(t) \Big),$$

and analogously for $v^{(S)}_{\text{Synthesis}}(t)$. Under the stated commutation hypotheses each derivative vanishes, proving constancy in time.

(b) Relational valuations. By definition, $v^{(LS)}_{\text{Synthesis}}(t) = \mathrm{Tr}\big(P^{(LS)}_{\text{para}}\,\rho(t)\big)$ and $v^{(LS)}_{\text{Agreement}}(t) = \mathrm{Tr}\big(P^{(LS)}_{\Phi,\text{para}}\,\rho(t)\big)$. Applying Proposition 8.81 with $P = P^{(LS)}_{\text{para}}$ or $P^{(LS)}_{\Phi,\text{para}}$ yields

$$\frac{d}{dt}\,v^{(LS)}_{\text{Synthesis}}(t) = i\ \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\text{para}},\,P^{(LS)}_{\text{para}}]\,\rho(t)\Big), \qquad \frac{d}{dt}\,v^{(LS)}_{\text{Agreement}}(t) = i\ \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\text{para}},\,P^{(LS)}_{\Phi,\text{para}}]\,\rho(t)\Big).$$

Thus each valuation is conserved whenever the corresponding commutator vanishes. □

Remark 8.85 (Steering vs. preserving)**.** *Preserving.* Setting $[\hat{F}^{(LS)}_{\text{para}}, P] = 0$ freezes the associated score $\mathrm{Tr}(P\rho(t))$ (local or relational), as in Corollary 8.84. In particular, the "diagonal" terms $Q_\Psi := P^{(LS)}_{\text{para}} - P^{(LS)}_{\text{antipara}}$ and $Q_\Phi := P^{(LS)}_{\Phi,\text{para}} - P^{(LS)}_{\Phi,\text{antipara}}$ commute with $P^{(LS)}_{\text{para}}$ and $P^{(LS)}_{\Phi,\text{para}}$, so they *do not* change the opposition/agreement scores—they implement phase tilts within each block.

Steering within a block. To *redistribute* probability between "+" and "−" inside a fixed relational block while keeping the block weight constant, include off-diagonal, block-preserving couplings such as

$$X_\Psi := |\Psi^{(LS)}_{\text{para}}\rangle\langle\Psi^{(LS)}_{\text{antipara}}| + \text{h.c.}, \qquad X_\Phi := |\Phi^{(LS)}_{\text{para}}\rangle\langle\Phi^{(LS)}_{\text{antipara}}| + \text{h.c.}$$

These commute with the *block* projectors $P_{\Psi\text{-block}} := P^{(LS)}_{\text{para}} + P^{(LS)}_{\text{antipara}}$ and $P_{\Phi\text{-block}} := P^{(LS)}_{\Phi,\text{para}} + P^{(LS)}_{\Phi,\text{antipara}}$, but not with the individual "+" projectors:

$$[X_\Psi, P_{\Psi\text{-block}}] = 0 \quad \text{and} \quad [X_\Psi, P^{(LS)}_{\text{para}}] \neq 0 \quad \text{(similarly for } X_\Phi\text{)}.$$

Hence adding X_Ψ (resp. X_Φ) *steers* $v^{(LS)}_{\text{Synthesis}}(t)$ (resp. $v^{(LS)}_{\text{Agreement}}(t)$) while preserving the total weight in the Ψ- (resp. Φ-) sector. By contrast, the exchange operator of Definition 8.80 *preserves* both scores, as it commutes with the corresponding "+" projectors (Lemma 8.82(c)).

Definition 8.86 (Quadrant projectors on $\mathcal{H}^{(LS)}$)**.** With $\varphi_L := \mathrm{Sym}(L)$ and $\varphi_S := \mathrm{Sym}(w;\lambda)$, recall the quadrant formulas (Definition 8.61). On $\mathcal{H}^{(LS)}$ define the corresponding computational-basis projectors:

$$\Pi_{\mathrm{I}} := |e_1e_1\rangle\langle e_1e_1|,\ \Pi_{\mathrm{II}} := |e_1e_2\rangle\langle e_1e_2|,\ \Pi_{\mathrm{III}} := |e_2e_1\rangle\langle e_2e_1|,\ \Pi_{\mathrm{IV}} := |e_2e_2\rangle\langle e_2e_2|.$$

Lemma 8.87 (Coherent diagonals through the dashboard)**.** *We have the identities*

$$P^{(LS)}_{\text{para}} = \tfrac{1}{2}(\Pi_{\mathrm{II}} + \Pi_{\mathrm{III}} + |e_1e_2\rangle\langle e_2e_1| + |e_2e_1\rangle\langle e_1e_2|)\,,$$
$$P^{(LS)}_{\Phi,\text{para}} = \tfrac{1}{2}(\Pi_{\mathrm{I}} + \Pi_{\mathrm{IV}} + |e_1e_1\rangle\langle e_2e_2| + |e_2e_2\rangle\langle e_1e_1|)\,.$$

Thus $P^{(LS)}_{\text{para}}$ (resp. $P^{(LS)}_{\Phi,\text{para}}$) enhances the II–III (resp. I–IV) diagonal by adding phase-coherent cross-terms; it is not a mere mixture of the two corners.

Proof. Abbreviate $|ij\rangle := |e_i\rangle_L|e_j\rangle_S$. From Definition 8.76, $|\Psi^{(LS)}_{\text{para}}\rangle = \frac{1}{\sqrt{2}}(|12\rangle + |21\rangle)$, so

$$\begin{aligned} P^{(LS)}_{\text{para}} &= |\Psi^{(LS)}_{\text{para}}\rangle\langle\Psi^{(LS)}_{\text{para}}| = \tfrac{1}{2}\left(|12\rangle + |21\rangle\right)\left(\langle 12| + \langle 21|\right) \\ &= \tfrac{1}{2}\Big(|12\rangle\langle 12| + |21\rangle\langle 21| + |12\rangle\langle 21| + |21\rangle\langle 12|\Big) \\ &= \tfrac{1}{2}\Big(\Pi_{\text{II}} + \Pi_{\text{III}} + |e_1e_2\rangle\langle e_2e_1| + |e_2e_1\rangle\langle e_1e_2|\Big). \end{aligned}$$

Similarly, $|\Phi^{(LS)}_{\text{para}}\rangle = \frac{1}{\sqrt{2}}(|11\rangle + |22\rangle)$ gives

$$\begin{aligned} P^{(LS)}_{\Phi,\text{para}} &= \tfrac{1}{2}\Big(|11\rangle\langle 11| + |22\rangle\langle 22| + |11\rangle\langle 22| + |22\rangle\langle 11|\Big) \\ &= \tfrac{1}{2}\Big(\Pi_{\text{I}} + \Pi_{\text{IV}} + |e_1e_1\rangle\langle e_2e_2| + |e_2e_2\rangle\langle e_1e_1|\Big). \end{aligned}$$

This shows in each case a diagonal (mixture part) plus coherent cross-terms. □

Proposition 8.88 (Refinement of SynTh by parasymmetry)**.** *Suppose the logical layer assigns designated truth* $\mathbf{B}$ *to both* φ_L *and* φ_S *(SynTh holds simultaneously: Setup 8.67 and Theorem 8.70). Then, for any* ρ_{LS}*, the parasymmetric valuations* $\mathrm{Tr}\Big(P^{(LS)}_{\text{para}}\rho_{LS}\Big)$ *and* $\mathrm{Tr}\Big(P^{(LS)}_{\Phi,\text{para}}\rho_{LS}\Big)$ *quantify, respectively, the* coherent opposition *(II/III) and* coherent agreement *(I/IV) content that SynTh leaves undifferentiated.*

Proof. Write the matrix elements of ρ_{LS} in the computational basis as $\rho_{ij,kl} := \langle e_ie_j|\rho_{LS}|e_ke_\ell\rangle$. Using Lemma 8.87,

$$\begin{aligned} \mathrm{Tr}\Big(P^{(LS)}_{\text{para}}\rho_{LS}\Big) &= \tfrac{1}{2}(\rho_{12,12} + \rho_{21,21} + \rho_{12,21} + \rho_{21,12}) \\ &= \tfrac{1}{2}\Big(\underbrace{\rho_{12,12}}_{\text{II}} + \underbrace{\rho_{21,21}}_{\text{III}}\Big) + \mathrm{Re}\Big(\rho_{12,21}\Big), \end{aligned}$$

and

$$\begin{aligned} \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\text{para}}\rho_{LS}\Big) &= \tfrac{1}{2}(\rho_{11,11} + \rho_{22,22} + \rho_{11,22} + \rho_{22,11}) \\ &= \tfrac{1}{2}\Big(\underbrace{\rho_{11,11}}_{\text{I}} + \underbrace{\rho_{22,22}}_{\text{IV}}\Big) + \mathrm{Re}\Big(\rho_{11,22}\Big). \end{aligned}$$

Thus each valuation splits into a *mixture* part (average of the two relevant dashboard corners) plus a *coherence* part (real off-diagonal along the same diagonal).

Under Setup 8.67, the SynTh layer makes all four corners simultaneously adoptable (designated), but it does not encode coherences. The parasymmetric valuations therefore refine SynTh by weighting the II/III and I/IV diagonals and, crucially, by detecting their *coherent* content via the cross-terms $\mathrm{Re}(\rho_{12,21})$ and $\mathrm{Re}(\rho_{11,22})$. This is exactly the claimed opposition vs. agreement quantification. □

Remark 8.89 (Compatibility with paraconsistency)**.** All valuations here are Born weights in $[0, 1]$ and do not alter the underlying consequence relation $\vdash_{\text{pc}}$. In particular, non-explosion remains ensured by the witness Π_{pc} (Definition 8.48 and Lemma 8.52). Parasymmetry thus serves as an *operational semantics* layered on top of the **SynTh** logic: it distinguishes coherent vs. incoherent contributions along the I/IV and II/III diagonals without changing which formulas are designated or derivable in $\vdash_{\text{pc}}$.

Definition 8.90 (Simultaneous Parasymmetry thresholds)**.** Fix thresholds (dimensionless real numbers)

$$0 \le \tau_L,\ \tau_S,\ \tau_{LS},\ \tau_\Phi \le 1.$$

Let ρ_{LS} be a density operator on the joint Law–State space $\mathcal{H}^{(LS)}$, and let its marginals be $\rho_L := \mathrm{Tr}_S(\rho_{LS})$ and $\rho_S := \mathrm{Tr}_L(\rho_{LS})$. With the projectors $P^{(L)}_{\mathrm{para}}, P^{(S)}_{\mathrm{para}}$ from Definition 8.73 and $P^{(LS)}_{\mathrm{para}}, P^{(LS)}_{\Phi,\mathrm{para}}$ from Definition 8.76, we say that $\mathrm{SimulPara}(L, S; \lambda)$ holds if

$$\begin{aligned}
\mathrm{Tr}\Big(P^{(L)}_{\mathrm{para}}\rho_L\Big) &\ge \tau_L,\\
\mathrm{Tr}\Big(P^{(S)}_{\mathrm{para}}\rho_S\Big) &\ge \tau_S,\\
\mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\rho_{LS}\Big) &\ge \tau_{LS},\\
\mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}}\rho_{LS}\Big) &\ge \tau_\Phi.
\end{aligned}$$

Remark 8.91. The predicate $\mathrm{SimulPara}(L, S; \lambda)$ is monotone in the thresholds: if it holds for $(\tau_L, \tau_S, \tau_{LS}, \tau_\Phi)$, it holds for any smaller tuple.

Proof. Each quantity $\mathrm{Tr}(P\rho)$ with P a projector is in $[0, 1]$. If $\mathrm{Tr}(P\rho) \ge \tau$ and $\tau' \le \tau$, then $\mathrm{Tr}(P\rho) \ge \tau'$. Apply this pointwise to the four inequalities in Definition 8.90. □

Theorem 8.92 (Preservation under unified evolution)**.** *Let* $\rho_{LS}(t) = U_t^{(LS)}\,\rho_{LS}(0)\,U_t^{(LS)\dagger}$ *with* $U_t^{(LS)} = \exp\!\big(it\,\hat{F}^{(LS)}_{\mathrm{para}}\big)$*. If the commutator conditions in Corollary 8.84 hold, then* $\mathrm{SimulPara}(L, S; \lambda)$ *is invariant in time: each of the four inequalities in Definition 8.90 remains true for all* $t \ge 0$*.*

Proof. Write $\rho(t) := \rho_{LS}(t)$. We show each score is constant; the inequalities at $t = 0$ then persist.

Local scores. Using the partial trace,

$$v^{(L)}_{\mathrm{Synthesis}}(t) = \mathrm{Tr}\Big(P^{(L)}_{\mathrm{para}}\,\rho_L(t)\Big) = \mathrm{Tr}\Big((P^{(L)}_{\mathrm{para}}\otimes\mathrm{Id})\,\rho(t)\Big), \quad v^{(S)}_{\mathrm{Synthesis}}(t) = \mathrm{Tr}\Big((\mathrm{Id}\otimes P^{(S)}_{\mathrm{para}})\,\rho(t)\Big).$$

By Proposition 8.81,

$$\frac{d}{dt}\,v^{(L)}_{\mathrm{Synthesis}}(t) = i\ \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\mathrm{para}},\ P^{(L)}_{\mathrm{para}}\otimes\mathrm{Id}]\,\rho(t)\Big),$$

and similarly for $v^{(S)}_{\mathrm{Synthesis}}(t)$. If the commutators in Corollary 8.84(a) vanish, both derivatives are zero, so the local inequalities remain true for all t.

Relational scores. By definition,

$$v^{(LS)}_{\mathrm{Synthesis}}(t) = \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\,\rho(t)\Big), \qquad v^{(LS)}_{\mathrm{Agreement}}(t) = \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}}\,\rho(t)\Big).$$

Proposition 8.81 gives

$$\frac{d}{dt}\,v^{(LS)}_{\mathrm{Synthesis}}(t) = i\ \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\mathrm{para}},\ P^{(LS)}_{\mathrm{para}}]\,\rho(t)\Big), \qquad \frac{d}{dt}\,v^{(LS)}_{\mathrm{Agreement}}(t) = i\ \mathrm{Tr}\Big([\hat{F}^{(LS)}_{\mathrm{para}},\ P^{(LS)}_{\Phi,\mathrm{para}}]\,\rho(t)\Big).$$

If the commutators in Corollary 8.84(b) vanish, both derivatives are zero, so the relational inequalities remain true for all t.

Since all four scores are constants of motion under the stated hypotheses, any initial satisfaction of the threshold constraints in Definition 8.90 persists for all $t \ge 0$. □

Remark 8.93 (Global unified operator)**.** In many-site settings (n PQS), one replaces $\hat{F}^{(LS)}_{\mathrm{para}}$ by a unified, multi-scale generator

$$\hat{F}^{(\odot)}_{\mathrm{para}} = \lambda_L \hat{F}^{(\mathrm{local})}_{\mathrm{para}} + \lambda_P \hat{F}^{(\mathrm{pair})}_{\mathrm{para}} + \lambda_G \hat{F}^{(n)}_{\mathrm{para}} + \lambda_X \hat{F}^{(\mathrm{ex})} + \cdots ,$$

and sets $U_G^{(\odot)} := \exp\!\big(i\,\hat{F}^{(\odot)}_{\mathrm{para}}\big)$. The blockwise invariance logic is identical: if each block projector P of interest (local or relational, possibly lifted to n sites) satisfies $[\hat{F}^{(\odot)}_{\mathrm{para}}, P] = 0$, then the corresponding Born weight $\mathrm{Tr}(P\rho(t))$ is conserved. Thus any instance of $\mathrm{SimulPara}(L, S; \lambda)$ defined via such projectors is preserved under $U_G^{(\odot)}$.

It translates logic into measurable quantum structure. The parasymmetric layer provides a faithful operationalization of *Synthesis*. For each anchor $a \in \{L, S\}$, the map $\rho_a \mapsto v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \mathrm{Tr}\big(P^{(a)}_{\mathrm{para}}\rho_a\big)$ assigns a quantitative, phase-sensitive value in $[0, 1]$ that depends on the off-diagonal coherence in the $\{|\,\mathrm{Sym}\rangle, |\,\mathrm{Break}\rangle\}$ sector (Definition 8.73 and Lemma 8.74). Writing

$$P^{(a)}_{\mathrm{para}} = \tfrac{1}{2}\big(P^{(a)}_{(0,1)} + X_a\big), \qquad X_a := |e_1\rangle_a\langle e_2| + |e_2\rangle_a\langle e_1|,$$

one has $v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \frac{1}{2}\big(1+\langle X_a\rangle_{\rho_a}\big) = \frac{1}{2}+\mathrm{Re}(\rho_{12})$. Thus $v = \frac{1}{2}$ certifies an incoherent mixture, $v = 1$ certifies the coherent "both/and" state $|+\rangle_a$, and $v = 0$ certifies $|-\rangle_a$—an operational distinction the purely logical **SynTh** layer leaves intentionally agnostic (Definition 8.51 and Lemma 8.52; cf. [287, 453, 454, 455]).

It models relational structure via entanglement. On $\mathcal{H}^{(L)}\otimes\mathcal{H}^{(S)}$, the Bell-type projectors onto $|\Psi^{(LS)}_{\mathrm{para}}\rangle$ and $|\Phi^{(LS)}_{\mathrm{para}}\rangle$ quantify, respectively, coherent *opposition* (II/III diagonal) and coherent *agreement* (I/IV diagonal) between Law and State (Definitions 8.76 and 8.78). As made explicit in Lemma 8.87, these operators contain the crucial inter-quadrant cross-terms (e.g. $|e_1e_2\rangle\langle e_2e_1|$) that witness phase coherence across the "dashboard"; they are not mere mixtures of the corner projectors associated to I–IV (Definition 8.61). In multipartite settings the parasymmetric family naturally extends to W-class states (up to SLOCC), making "Synthesis as relation" a genuinely nonlocal resource [456, 287].

It supplies a complete dynamical and control framework. The unified generator $\hat{F}^{(LS)}_{\mathrm{para}}$ (Definition 8.79) yields exact invariants via commutators: for any parasymmetric projector P (local or relational), whenever $[\hat{F}^{(LS)}_{\mathrm{para}}, P] = 0$, the valuation $\mathrm{Tr}(P\rho_{LS}(t))$ is a constant of motion (Proposition 8.81 and Corollary 8.84). Tuning the couplings $\lambda_L, \lambda_S, \lambda_{LS}, \lambda_\Phi$ lets one preserve or steer local and relational coherences at will (Remark 8.85); the same blockwise invariance logic extends to the global multi-scale operator $U_G^{(\odot)}$ (Remark 8.93). In open-system form, for Lindblad evolution $\dot\rho = \mathcal{L}(\rho)$ the exact conservation condition is $\mathcal{L}^\dagger(P) = 0$, i.e.

$$\mathcal{L}^\dagger(P) = i[H, P] + \sum_k \Big(L_k^\dagger P L_k - \tfrac{1}{2}\{L_k^\dagger L_k, P\}\Big) = 0,$$

with the familiar sufficient criterion $[H, P] = [L_k, P] = 0\ \forall k$ (decoherence-free/noiseless subspaces), giving a practical route to robustly preserve chosen parasymmetric coherences [287].

It remains compatible with paraconsistency and duality. All parasymmetric valuations are Born weights layered on the paraconsistent base; they do not alter $\vdash_{\mathrm{pc}}$, and non-explosion remains guaranteed by the witness Π_{pc} (Definition 8.48 and Lemma 8.52). Scope hygiene is enforced throughout—diagnostics must refer to the same group G, the same sense of invariance, the same L, the same w, and (for the state) the same locus λ. Under the Axiom-of-Duality action $\mathbf{D}_{\mathcal{C}}$, the labels $|e_1\rangle, |e_2\rangle$ permute within the $(0,1)$-sector and parasymmetric projectors intertwine accordingly, so $P^{(\cdot)}_{\mathrm{para}}$-type invariants transport intact up to relabeling (Proposition 8.60).

Bottom line. Parasymmetry turns SynTh's logical "both/and" into *observables with dynamics and control*: locally via $v^{(a)}_{\mathrm{Synthesis}}$, relationally via $v^{(LS)}_{\mathrm{Synthesis}}$ and $v^{(LS)}_{\mathrm{Agreement}}$ (Definitions 8.73 and 8.78), and temporally via commutator-based invariants. The symmetry–asymmetry table is thereby promoted from a static classification to a phase-structured, steerable landscape, fully consistent with the paraconsistent logic and duality transport that organize the theory's statements.

Example 8.94 (Multipartite parasymmetric state)**.** The W-like state is defined as

$$|\Psi^{(n)}_{\mathrm{para}}\rangle = \tfrac{1}{\sqrt{n}} \sum_{k=1}^{n} |e_1\rangle_{x_1} \cdots |e_2\rangle_{x_k} \cdots |e_1\rangle_{x_n}.$$

It is normalized and permutation-symmetric. For any site x_j, the reduced state is

$$\rho_{x_j} = \mathrm{Tr}_{\{x_k : k \neq j\}}\Big(|\Psi^{(n)}_{\mathrm{para}}\rangle\langle\Psi^{(n)}_{\mathrm{para}}|\Big) = \tfrac{n-1}{n}\,|e_1\rangle\langle e_1| + \tfrac{1}{n}\,|e_2\rangle\langle e_2|,$$

which is mixed and diagonal (no local coherence). Hence $v^{(x_j)}_{\mathrm{Synthesis}}(\rho_{x_j}) = \frac{1}{2} + \mathrm{Re}(\rho_{12}) = \frac{1}{2}$, while the global projector $P^{(x_1 \ldots x_n)}_{\mathrm{para}} := |\Psi^{(n)}_{\mathrm{para}}\rangle\langle\Psi^{(n)}_{\mathrm{para}}|$ satisfies $\mathrm{Tr}\Big(P^{(x_1 \ldots x_n)}_{\mathrm{para}}\,|\Psi^{(n)}_{\mathrm{para}}\rangle\langle\Psi^{(n)}_{\mathrm{para}}|\Big) = 1$. Thus the state is genuinely multipartite entangled with mixed one-site marginals (cf. [456]); it implements *distributed Synthesis* via its projector $P^{(x_1 \ldots x_n)}_{\mathrm{para}}$.

Remark 8.95 (Standard logical/physical references)**.** The logical background for paraconsistency and non-explosion uses [453, 454, 455]. Ward identities and symmetry diagnostics are standard in QFT [91, 100]. For quantum operations and Bell/W-state structure see [287, 456].

8.2.2 Parasymmetry (with SynTh) vs. Duality

High–level reading: Parasymmetry vs. Duality (with SynTh). The Axiom–of–Duality action $\mathbf{D}_{\mathcal{C}}$ is indispensable for organizing structural equivalences and transporting statements across complementary descriptions (Proposition 8.60). By itself, however, duality is a *mapping principle*: it identifies and relates cells of the dashboard but does not supply observables, dynamical laws, or criteria that distinguish a *coherent* "both/and" from a mere *mixture*. The Parasymmetry $\oplus$ Synthesis layer fills exactly this gap. Building on the non-explosive logical substrate (Definition 8.48 and Lemma 8.52), Parasymmetry adds projectors and Born–valued diagnostics that make "both/and" *measurable*, *phase–sensitive*, and *controllable*, all while remaining compatible with duality.

Operational observables rather than identifications. Duality transports formulas and their defenses, but Parasymmetry supplies concrete tests. Locally, each anchor $a \in \{L, S\}$ carries the parasymmetric projector $P^{(a)}_{\text{para}}$ and the valuation $v^{(a)}_{\text{Synthesis}}(\rho_a) = \text{Tr}\big(P^{(a)}_{\text{para}}\rho_a\big) \in [0,1]$ (Definition 8.73). Relationally, on the Law–State sector one has the agreement/opposition projectors $P^{(LS)}_{\Phi,\text{para}}$, $P^{(LS)}_{\text{para}}$ and the joint scores $v^{(LS)}_{\text{Agreement}} = \text{Tr}\big(P^{(LS)}_{\Phi,\text{para}}\rho_{LS}\big)$, $v^{(LS)}_{\text{Synthesis}} = \text{Tr}\big(P^{(LS)}_{\text{para}}\rho_{LS}\big)$ (Definition 8.78). These are bona fide observables that quantify how much of the coherent "both/and" is present, locally and across the Law–State relation.

Sensitivity to coherence (off–diagonals) vs. mixtures. Where duality is silent about phase, Parasymmetry reads it directly: in the $\{|\,\text{Sym}\rangle, |\,\text{Break}\rangle\}$ basis, the local score depends on the off–diagonal element, $v^{(a)}_{\text{Synthesis}}(\rho_a) = \frac{1}{2} + \text{Re}(\rho_{12})$ (Lemma 8.74). Thus a coherent superposition $|+\rangle$ yields $v = 1$, while the balanced incoherent mixture $\frac{1}{2}(|e_1\rangle\langle e_1| + |e_2\rangle\langle e_2|)$ yields $v = \frac{1}{2}$ (Remark 8.75). This distinction—central to quantum structure—is invisible to duality as mapping.

From quadrant cells to coherent diagonals. The familiar 2×2 symmetry–asymmetry table corresponds to the computational basis on $\mathcal{H}^{(LS)}$ (Definition 8.86). Parasymmetry augments this with two orthogonal *Bell sectors* (Φ for Law–State agreement, Ψ for Law–State opposition), each spanned by a pair of Bell kets (Definition 8.76). Their projectors include inter–cell cross–terms such as $|e_1e_2\rangle\langle e_2e_1|$ and $|e_1e_1\rangle\langle e_2e_2|$, which are the algebraic witnesses of phase–coherent structure across the I/IV and II/III diagonals (Lemmas 8.77 and 8.87). In this way the dashboard is no longer four isolated cells but two coherent diagonals with quantitative weights.

Dynamics, invariants, and control. Parasymmetry also supplies the dynamical engine. The unified Law–State generator $\hat{F}^{(LS)}_{\text{para}}$ (Definition 8.79) and its multi–scale extensions (Remark 8.93) allow one to *preserve* or *steer* specific coherences by imposing exact commutation conditions. The criterion $[\,\hat{F}, P\,] = 0$ ensures that the valuation $\text{Tr}(P\rho(t))$ is conserved (Proposition 8.81); in particular one can lock in local parasymmetry $[\hat{F}, P^{(L)}_{\text{para}} \otimes \text{Id}] = [\hat{F}, \text{Id} \otimes P^{(S)}_{\text{para}}] = 0$ or relational agreement/opposition $[\hat{F}, P^{(LS)}_{\Phi,\text{para}}] = 0$, $[\hat{F}, P^{(LS)}_{\text{para}}] = 0$ (Corollary 8.84 and Remark 8.85). This level of controllable invariance has no analogue at the level of duality alone.

Quantitative, non–explosive multi–cell occupancy. **SynTh** establishes that all four cells can be designated without triviality (Theorem 8.63); Parasymmetry refines this picture by assigning *weights* to coherent diagonals and to the local "both" components. As a result, the matrix becomes a *phase–structured measure space* rather than a mere set of co–tenable propositions. Decision procedures (e.g. the SimulPara thresholds) make this operational: one declares $\text{SimulPara}(L, S; \lambda)$ to hold when the four scores exceed prescribed levels (Definition 8.90), and proves time–invariance of these predicates under suitable commutators (Theorem 8.92). Throughout, the paraconsistent base keeps explosion at bay (Definition 8.48 and Lemma 8.52).

Compatibility, not competition, with Duality. Finally, Parasymmetry respects duality. Under the duality action $\mathbf{D}_{\mathcal{C}}$, the $|\,\text{Sym}\rangle/|\,\text{Break}\rangle$ labels permute while the parasymmetric diagnostics transport functorially (Proposition 8.60). In practice: duality *classifies and relates* descriptions; Parasymmetry *measures and evolves* their coherent coexistence. Together with

SynTh, this turns a duality–organized landscape into a laboratory where "both/and" is not only permitted but *quantified*, *conserved*, and *steerable*.

Enhanced realism and descriptive power. Real systems often inhabit multiple cells at once (e.g. dominant SSB (II) with small explicit breaking (IV)). *SynTh* treats the table as a co-tenable *dashboard*, not a partition, so models needn't collapse to a single idealized cell. It also separates an *incoherent mixture* from a *coherent* "both": the parasymmetric *valuations* $v^{(a)}_{\text{Synthesis}}(\rho_a) = \mathrm{Tr}\big(P^{(a)}_{\text{para}}\rho_a\big) = \frac{1}{2} + \mathrm{Re}(\rho_{12})$ (Definition 8.73 and Lemma 8.74) give a measurable, phase-sensitive readout ($v = 1$ for $|+\rangle_a$, $v = \frac{1}{2}$ for no coherence, $v = 0$ for $|-\rangle_a$).

Novel observables and deeper insight. The joint *scores* $v^{(LS)}_{\text{Agreement}} = \mathrm{Tr}\big(P^{(LS)}_{\Phi,\text{para}}\rho_{LS}\big)$ and $v^{(LS)}_{\text{Synthesis}} = \mathrm{Tr}\big(P^{(LS)}_{\text{para}}\rho_{LS}\big)$ (Definition 8.78) are operational meters for *coherent* I/IV and II/III diagonals. By Lemma 8.87 they equal "mixture of the two corners" + "cross-term coherence," so pure corners give the $\frac{1}{2}$ baseline, while Bell-coherent superpositions yield 1. This cleanly explains finite-volume SSB cats: $v^{(LS)}_{\text{Synthesis}}$ drops from 1 to $\frac{1}{2}$ as $V \uparrow \infty$, matching Theorem 6.258.

A framework for quantum control. The unified generator $\hat{F}^{(LS)}_{\text{para}}$ (Definition 8.79) yields exact invariants: if $[\hat{F}^{(LS)}_{\text{para}}, P] = 0$ then $\mathrm{Tr}(P\rho_{LS}(t))$ is conserved (Proposition 8.81 and Corollary 8.84). Thus we can *preserve* chosen local or relational coherences, or *steer* them with block-preserving couplings (cf. Remark 8.85). In short: the theorem's Λ–asymptotics *locate* cells; *SynTh* lets multiple cells be co-adopted non-explosively; Parasymmetry makes "both/and" *measurable, phase-sensitive, and controllable*.

8.3 SynTh of Generalized Witness of Laws and States

What "Synthesis of Laws and States" formalizes. The aim of Section 8.2 is to turn the quadrant diagnostics of Sections 7.10 and 8.1 into a single reasoning layer in which "law" and "state" are *simultaneously* readable and jointly actionable. We fix a *paraconsistent context*

$$\mathcal{C} = \langle \mathcal{L}_{\mathcal{C}},\ \vdash_{\text{pc}},\ \Lambda_{\mathcal{C}},\ \mathrm{Adm}_{\mathcal{C}} \rangle,$$

together with a *non-explosion witness*

$$\Pi_{\text{pc}} = \langle \mathfrak{s},\ v,\ \mathsf{D} \rangle,$$

so that inconsistency of sector claims does not entail triviality (e.g. in LP/FDE with designated values $\{\mathbf{T}, \mathbf{B}\}$). This logical guardrail ensures the symmetry/SSB readings remain *co-tenable*: bulk and boundary, or distinct sector-conditioned witnesses, may disagree at finite scale without collapsing the theory. Within this setting, the familiar 2×2 "Symmetry–Asymmetry" table of Section 7.10 is read not as a mutually exclusive partition but as a *dashboard of co-tenable modalities*. This dashboard interpretation aligns with the Tetralemma "both" corner and remains stable under admissible duality transport across sectors, precisely because all statements are evaluated in the same certified arena of Section 8.1 (shared plateau, BRST-closed tags, and a sector-specific IR knob).

Parasymmetric Synthesis (operationalizing "both/and"). The operational layer of Section 8.2.1 equips the SynTh dashboard with concrete meters. For each anchor $a \in \{L, S\}$ we use a two-mode sector

$$\mathcal{H}^{(a)} = \mathrm{span}\Big\{|e_1\rangle_a,\ |e_2\rangle_a\Big\}, \qquad |e_1\rangle_a \equiv |\,\mathrm{Sym}\rangle_a, \quad |e_2\rangle_a \equiv |\,\mathrm{Break}\rangle_a,$$

and define the "both/and'' kets $|\pm\rangle_a = \frac{1}{\sqrt{2}}\Big(|e_1\rangle_a \pm |e_2\rangle_a\Big)$. The local parasymmetric projectors

$$P^{(a)}_{\mathrm{para}} = |+\rangle_a\langle+|\,, \qquad P^{(a)}_{\mathrm{antipara}} = |-\rangle_a\langle-|$$

support the *Synthesis valuation*

$$v^{(a)}_{\mathrm{Synthesis}}(\rho_a) = \mathrm{Tr}\Big(P^{(a)}_{\mathrm{para}}\rho_a\Big) = \tfrac{1}{2} + \mathrm{Re}(\rho_{12}),$$

so that $v^{(a)}_{\mathrm{Synthesis}} = 1$ for $|+\rangle_a$, $v^{(a)}_{\mathrm{Synthesis}} = \frac{1}{2}$ for an incoherent mixture, and $v^{(a)}_{\mathrm{Synthesis}} = 0$ for $|-\rangle_a$ (Bloch form $P_{\mathrm{para}} = \frac{1}{2}(I + \sigma_x)$). In this way, the logical "both/and'' of SynTh is promoted to a phase-sensitive, experimentally addressable score.

On the relational space $\mathcal{H}^{(LS)} = \mathcal{H}^{(L)} \otimes \mathcal{H}^{(S)}$ we furthermore introduce Bell-type kets and projectors that separate *opposition* (Ψ) from *agreement* (Φ) between law and state. The joint observables

$$v^{(LS)}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\rho_{LS}\Big), \qquad v^{(LS)}_{\mathrm{Agreement}} = \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}}\rho_{LS}\Big)$$

measure, respectively, coherent weight on the II/III diagonal and on the I/IV diagonal of the quadrant ledger—*not* as mere mixtures but including cross-term coherences. These relational meters dovetail with the sector-conditioned witnesses of Section 8.1: they can be read on the same certified plateau and with the same BRST-closed tags and IR knob r.

A *unified parasymmetric generator* on $\mathcal{H}^{(LS)}$,

$$\hat{F}^{(LS)}_{\mathrm{para}} = \lambda_L(\cdots) + \lambda_S(\cdots) + \lambda_{LS}(\cdots) + \lambda_\Phi(\cdots) + \cdots\,,$$

organizes dynamics and invariants. Whenever $[\hat{F}^{(LS)}_{\mathrm{para}}, P] = 0$ we have $\mathrm{Tr}\,\Big(P\,\rho_{LS}(t)\Big) = \mathrm{const}$. In open-system language, the same statement reads $\mathcal{L}^\dagger(P) = 0$ for the Lindbladian adjoint. Applying these to the projectors $P^{(LS)}_{\mathrm{para}}$ and $P^{(LS)}_{\Phi,\mathrm{para}}$ yields explicit time-derivative identities for $v^{(LS)}_{\mathrm{Synthesis}}$ and $v^{(LS)}_{\mathrm{Agreement}}$, thereby turning them into conserved (or slowly varying, ledger-audited) diagnostics when the corresponding symmetry conditions are met on the plateau of Section 7.10.

Finally, the parasymmetric valuations are interpreted as *Born weights* layered atop the paraconsistent base: they preserve $\vdash_{\mathrm{pc}}$ (no explosion) and transport functorially under the duality action $\mathbf{D}_{\mathcal{C}}$ with "scope hygiene'' enforced, so that readings remain sector-consistent across the arenas of Section 8.1. In short, **SynTh** guarantees co-tenability, while Parasymmetry supplies the projectors and scores that (i) discriminate *coherent "both''* from *incoherent mixtures* and (ii) promote these distinctions to conservation laws under suitable generators—thereby elevating the 2×2 grid into a *phase-structured, dynamical, and steerable* landscape for Law–State relations.

Definition 8.96 (Sector–certified arena and instrumentation)**.** Fix a sector $\mathscr{S}$ and a certified plateau component $\mathfrak{P} \subset \mathbb{R}^2_{(u,v)}$ with

$$u = \ln \lambda_{\mathrm{UV}}, \qquad v = \ln r,$$

where the sector-specific IR knob r is chosen as in Section 8.1 (bulk: $r = \ell$; boundary: $r = L$; anisotropic: $r = \min(\vec{\ell})$). Let the BRST-closed tags $P_x(\lambda_{\mathrm{UV}})$ and K_{IR} be fixed, together with the projection $\mathsf{P}_{\mathrm{phys}} : \mathcal{H} \to \mathcal{H}_{\mathrm{phys}}$ onto the physical cohomology. We call

$$\mathcal{I}^{[\mathscr{S}]} := \Big(\mathcal{A},\ r\ ;\ P_x(\lambda_{\mathrm{UV}}),\ K_{\mathrm{IR}}\ ;\ \mathsf{P}_{\mathrm{phys}}\Big), \qquad \mathcal{A} \in \{\mathfrak{P},\ \mathfrak{P}_\partial\},$$

the *sector instrumentation*, and we require that all sector witnesses and visibilities are evaluated using the *same* $\mathcal{I}^{[\mathscr{S}]}$ throughout (same arena, same IR knob, same BRST tags, same projection), as stipulated in Section 8.1.

Definition 8.97 (Sector–conditioned atomic predicates for SynTh)**.** Let $\mathbf{W}^{[\mathscr{S}]}$ be a sector-conditioned witness specification as in Section 8.1, producing visibilities

$$\Lambda^{[\mathscr{S}]}_{\mathrm{law}} : \mathfrak{P} \to [0,1], \qquad \Lambda^{[\mathscr{S}]}_{\mathrm{state}} : \mathfrak{P} \to [0,1],$$

evaluated on $\mathcal{H}_{\mathrm{phys}}$ using the common instrumentation $\mathcal{I}^{[\mathscr{S}]}$ from Definition 8.96. Fix certified tolerances $\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}} \in (0,1)$ and write

$$|\cdot| \approx 1 \iff \big||\cdot| - 1\big| \le \varepsilon \quad \text{with the sector's certified } \varepsilon \in \{\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}}\}.$$

Define the *law* and *state* atoms (SynTh inputs) by the disjunctive predicates

$$\begin{aligned} \mathrm{Law}^{[\mathscr{S}]} &:\Longleftrightarrow \ \Big(\ |\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| \approx 1\ \Big) \ \vee \ \Big(\ \textit{heals under } r\ \Big), \\ \mathrm{State}^{[\mathscr{S}]} &:\Longleftrightarrow \ \Big(\ |\Lambda^{[\mathscr{S}]}_{\mathrm{state}}| \approx 1\ \Big) \ \vee \ \Big(\ \textit{decoheres}\ \Big), \end{aligned}$$

where the asymptotic clauses use the sector's IR knob r (also fixed by $\mathcal{I}^{[\mathscr{S}]}$):

- *heals under* r: there exist $C, \beta > 0$ such that with $d^{[\mathscr{S}]}_{\mathrm{law}}(r) := 1 - |\Lambda^{[\mathscr{S}]}_{\mathrm{law}}(r)|$ one has

  $$d^{[\mathscr{S}]}_{\mathrm{law}}(r) \ \le\ C\, r^{-\beta} \qquad (r \to \infty),$$

  i.e. the sector's law deficit decays along r as prescribed in Section 8.1;
- *decoheres*: along the thermodynamic limit one has

  $$\Lambda^{[\mathscr{S}]}_{\mathrm{state}}(V) \ \longrightarrow\ 0 \qquad (V \uparrow \infty),$$

  with the same instrumentation and evaluation arena as above (see the QII criterion in Section 8.1).

These atoms are read *on the plateau* and are understood to be *co-tenable* under the paraconsistent entailment $\vdash_{\mathrm{pc}}$ provided by **SynTh** (no explosion).

Definition 8.98 (Simultaneous Synthesis connective $\oplus$)**.** For a fixed sector $\mathscr{S}$ and a certified plateau $\mathfrak{P}$ with instrumentation $\mathcal{I}^{[\mathscr{S}]}$ as in Definition 8.96, the *Simultaneous Synthesis* judgement at the SynTh layer is the composite assertion

$$\mathrm{Syn}^{[\mathscr{S}]} \;:=\; \mathrm{Law}^{[\mathscr{S}]} \;\oplus\; \mathrm{State}^{[\mathscr{S}]},$$

which *by definition* means:

evaluate the sector-conditioned predicates $\mathrm{Law}^{[\mathscr{S}]}$ and $\mathrm{State}^{[\mathscr{S}]}$ in the **same** arena $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$, with the **same** BRST/plateau certification and IR knob r, using the **same** tags $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}$ and projection to $\mathcal{H}_{\mathrm{phys}}$; then record their joint status as a coherent, co-tenable dashboard entry within the paraconsistent context $\mathcal{C}$ (no exclusivity is imposed; co-tenability per $\vdash_{\mathrm{pc}}$).

This connective introduces no additional identification beyond shared instrumentation: it packages the two certified sector predicates into a single SynTh premise that can be projected onto either component without entailment collapse.

Definition 8.99 (SynTh rules for Simultaneous Synthesis)**.** Let **SynTh** endow the context $\mathcal{C}$ with a paraconsistent entailment $\vdash_{\mathrm{pc}}$, and let $\mathrm{Law}^{[\mathscr{S}]}$, $\mathrm{State}^{[\mathscr{S}]}$, and $\mathrm{Syn}^{[\mathscr{S}]} := \mathrm{Law}^{[\mathscr{S}]} \oplus \mathrm{State}^{[\mathscr{S}]}$ be as in Definitions 8.97 and 8.98. The following schematic rules govern reasoning at the SynTh layer:

$$\frac{\mathcal{C} \vdash_{\mathrm{pc}} \mathrm{Law}^{[\mathscr{S}]} \qquad \mathcal{C} \vdash_{\mathrm{pc}} \mathrm{State}^{[\mathscr{S}]}}{\mathcal{C} \vdash_{\mathrm{pc}} \mathrm{Syn}^{[\mathscr{S}]}} \quad (\oplus\text{-Intro})$$

$$\frac{\mathcal{C} \vdash_{\mathrm{pc}} \mathrm{Syn}^{[\mathscr{S}]}}{\mathcal{C} \vdash_{\mathrm{pc}} \mathrm{Law}^{[\mathscr{S}]}} \quad (\oplus\text{-Proj}_L) \qquad\qquad \frac{\mathcal{C} \vdash_{\mathrm{pc}} \mathrm{Syn}^{[\mathscr{S}]}}{\mathcal{C} \vdash_{\mathrm{pc}} \mathrm{State}^{[\mathscr{S}]}} \quad (\oplus\text{-Proj}_S)$$

$$\frac{\mathcal{C} \vdash_{\mathrm{pc}} \varphi^{[\mathscr{S}_1]} \qquad \mathcal{C} \vdash_{\mathrm{pc}} \neg\varphi^{[\mathscr{S}_2]}}{\begin{array}{c}\textit{No-Explosion: } \mathcal{C} \nvdash_{\mathrm{pc}} \psi \text{ for arbitrary } \psi \\ \textit{Audit obligation: } \mathrm{ReAudit}\big(\mathcal{A}_1, \mathcal{A}_2;\ r_1, r_2\big)\end{array}} \quad (\textsc{No-Explosion/Audit})$$

Here $\varphi^{[\mathscr{S}_i]}$ stands for any sector-conditioned claim (e.g. a law or state predicate) evaluated with the sector's realized weave configuration $\mathcal{I}^{[\mathscr{S}_i]} = (\mathcal{A}_i, r_i; P_x, K_{\mathrm{IR}}; \mathsf{P}_{\mathrm{phys}})$ from Definition 8.96. The No-Explosion clause states that contradictory sector claims (e.g. boundary vs. bulk) do *not* entail triviality in $\vdash_{\mathrm{pc}}$; instead, they *trigger* the operational Audit obligation to reconcile arenas/IR knobs on the certified plateau as prescribed by Sections 8.1 and 8.2. Consequently, the quadrant grid of Section 7.10 is treated as a *dashboard*, not a partition: law and state readings are jointly admissible inputs even when they initially sit in different quadrants prior to IR reconciliation.

Definition 8.100 (Sector-conditioned synthesis object)**.** Let $\mathscr{S}$ be a sector with witness specification $\mathbf{W}^{[\mathscr{S}]}$ as in Section 8.1, and let $\mathcal{I}^{[\mathscr{S}]}$ be the common instrumentation from Definition 8.96 on a certified plateau component $\mathfrak{P}$. We define the *sector-conditioned synthesis object*

$$\boxed{\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P}) \;:=\; \Big(\Lambda^{[\mathscr{S}]}_{\mathrm{law}},\ \Lambda^{[\mathscr{S}]}_{\mathrm{state}}\ ;\ \mathcal{W}^{[\mathscr{S}]},\ \mathcal{Z}^{[\mathscr{S}]}\ ;\ \mathcal{A},\ r\Big)}$$

with the following components:

- $\mathcal{A} \in \{\mathfrak{P},\ \mathfrak{P}_\partial\}$ is the arena; r is the sector's IR knob (bulk $r{=}\ell$, boundary $r{=}L$, anisotropic $r{=}\min(\vec{\ell})$);
- $\mathcal{W}^{[\mathscr{S}]}$ is the *scale-tagged Ward ledger* (improved current/divergence statements) consistent with the consolidated laws of Section 7.10;
- $\mathcal{Z}^{[\mathscr{S}]}$ is the *light-sector spectral certificate* on $\mathcal{H}_{\text{phys}}$ (poles, residue matrices $Z \succeq 0$, NG/pNG census, hyperbolicity margin).

All entries of $\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})$ are evaluated using the *same* BRST-closed tags $P_x(\lambda_{\text{UV}})$, K_{IR} and the same projection P_{phys} as stipulated in Section 8.1.

Proposition 8.101 (Gauge/Nielsen invariance)**.** *Suppose $P_x(\lambda_{\text{UV}})$ and K_{IR} are BRST-closed and all evaluations are made on $\mathcal{H}_{\text{phys}}$ with the common instrumentation $\mathcal{I}^{[\mathscr{S}]}$ of Definition 8.96. Then the synthesis object $\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})$ of Definition 8.100 is invariant under changes of the gauge fermion (Nielsen-flat).* Sketch. *The BRST closure and projection render the sector visibilities and their Ward/spectral ledgers independent of gauge-fermion deformations; this is precisely the sectorised adaptation of the invariance arguments used to establish quadrant correctness in Section 7.10, combined with the witness-level invariance requirements of Section 8.1.*

Definition 8.102 (Synthesis resolver and explanatory class)**.** Let $\mathscr{S}$ be a sector with synthesis object $\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})$ as in Definition 8.100. The *resolver*

$$\mathcal{R}^{[\mathscr{S}]}:\ \mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P}) \ \longmapsto\ \Big(\mathrm{Quad}^{[\mathscr{S}]},\ \mathsf{Expl}^{[\mathscr{S}]}\Big)$$

is defined by applying the canonical quadrant rules of Section 8.1 (QI–QIV) to the pair $\big(\Lambda^{[\mathscr{S}]}_{\text{law}}, \Lambda^{[\mathscr{S}]}_{\text{state}}\big)$, including the r-healing test for the law deficit, and returning the *explanatory class*

$$\mathsf{Expl}^{[\mathscr{S}]} \ :=\ \Big(\ \underbrace{\mathcal{W}^{[\mathscr{S}]}\ \textbf{status}}_{\text{conserved vs. adjoint-source}}\ ;\ \underbrace{\mathcal{Z}^{[\mathscr{S}]}\ \textbf{census}}_{\{\text{NG,pNG,none}\},\ Z\succeq 0,\ \text{hyperbolicity margin}}\ \Big).$$

Concretely, on any certified plateau point (or connected component) the mapping satisfies:

(i) QI
$\Rightarrow \mathcal{W}$: conserved improved current; $\mathcal{Z}$: no NG/pNG.

(ii) QII
$\Rightarrow \mathcal{W}$: conserved; $\mathcal{Z}$: NG in the correlational channel (gauged generators lift to BEH).

(iii) QIII
$\Rightarrow \mathcal{W}$: adjoint divergence $\to 0$ along r; $\mathcal{Z}$: no NG/pNG; law heals.

(iv) QIV
$\Rightarrow \mathcal{W}$: non-vanishing adjoint–covariant source on $\mathfrak{P}$; $\mathcal{Z}$: pNG band obeying GMOR on $\mathfrak{P}$.

Equivalence. This sectorised construction realises the diagnostics equivalence promised in Section 7.10: the quadrant assignment from visibilities matches the Ward and spectral ledgers on the same realized weave configuration.

Definition 8.103 (Joint Simultaneous Synthesis)**.** Let $\{\mathscr{S}_i\}_{i\in I}$ be a (finite) family of sectors with certified plateaus $\{\mathfrak{P}_i\}$ and arenas $\{\mathcal{A}_i\}$, each equipped with a sector-conditioned synthesis object $\mathfrak{S}^{[\mathscr{S}_i]}(\mathfrak{P}_i)$ as in Definition 8.100. Define the *joint arena* and *joint plateau*

$$\mathcal{A}_\cap := \bigcap_{i\in I} \mathcal{A}_i, \qquad \mathfrak{P}_\cap := \bigcap_{i\in I} \mathfrak{P}_i.$$

The *joint synthesis object* is

$$\mathfrak{S}^{[I]}(\mathfrak{P}_\cap) := \prod_{i\in I} \mathfrak{S}^{[\mathscr{S}_i]}(\mathfrak{P}_\cap),$$

where each factor is the restriction/re-evaluation of $\mathfrak{S}^{[\mathscr{S}_i]}(\mathfrak{P}_i)$ on the certified intersection $\mathfrak{P}_\cap$ using the same BRST-closed tags and the joint instrumentation on $\mathcal{A}_\cap$. Reasoning is carried out in the paraconsistent context $\mathcal{C}$ (SynTh), so contradictory sector labels do not entail triviality; instead they trigger *arena reconciliation* (e.g. boundary L vs. bulk ℓ) or *IR-knob refinement* until the QIII/QIV split stabilises, as in Section 8.1.

Proposition 8.104 (Joint completeness and stability)**.** *Assume: (i) each $\mathfrak{P}_i$ is certified as in Section 8.1; (ii) the sector r-healing tests are well-posed; and (iii) evaluations use BRST-closed tags with projection to $\mathcal{H}_{\text{phys}}$ (cf. Proposition 8.101). Then the product resolver*

$$\mathcal{R}^{[I]} := \prod_{i\in I} \mathcal{R}^{[\mathscr{S}_i]} : \ \mathfrak{S}^{[I]}(\mathfrak{P}_\cap) \longmapsto \prod_{i\in I} \left(\mathrm{Quad}^{[\mathscr{S}_i]},\ \mathsf{Expl}^{[\mathscr{S}_i]}\right)$$

yields a complete *set of sector labels* $\{\mathrm{Quad}^{[\mathscr{S}_i]}\}_{i\in I}$ *and associated explanatory classes that is stable under:*

(i) admissible gauge-fermion deformations (Nielsen-flatness by Proposition 8.101);

(ii) admissible retunings of the BRST-closed tags (P_x, K_{IR}) that preserve certification; and

(iii) coarsenings $\mathfrak{P}_i \mapsto \tilde{\mathfrak{P}}_i \subseteq \mathfrak{P}_i$ that maintain plateau certification and r-healing well-posedness.

Definition 8.105 (Operational template (sector-conditioned, SynTh))**.** Let $\mathscr{S}$ be a fixed sector with instrumentation $\mathcal{I}^{[\mathscr{S}]}$ from Definition 8.96 and witnesses $\mathbf{W}^{[\mathscr{S}]}$ as in Definition 8.97. The following *repeatable construction* instantiates §8.2 within the sector framework of Section 8.1.

Step 0 — Fix the arena and certify. Choose $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$, the sector IR knob r (bulk: $r = \ell$; boundary: $r = L$; anisotropic: $r = \min(\vec{\ell})$), and tolerances $\varepsilon_{\text{law}}, \varepsilon_{\text{state}} \in (0,1)$. Certify the plateau(s) $\mathfrak{P}$ (and, if applicable, $\mathfrak{P}_\partial$) according to Section 8.1 (cone preservation, BRST-closure, Nielsen-flat diagnostics).

Step 1 — Build the sector witness pair. Using $\mathbf{W}^{[\mathscr{S}]}$ and the BRST-closed tags $P_x(\lambda_{\text{UV}}), K_{\text{IR}}$ with projection to $\mathcal{H}_{\text{phys}}$, compute on $\mathfrak{P}$

$$\Lambda^{[\mathscr{S}]}_{\text{law}}(u,v), \qquad \Lambda^{[\mathscr{S}]}_{\text{state}}(u,v),$$

with $(u,v) = (\ln \lambda_{\text{UV}}, \ln r)$.

Step 2 — Attach Ward and spectral ledgers. Construct the scale-tagged Ward ledger $\mathcal{W}^{[\mathscr{S}]}$ (improved current/divergence on $\mathfrak{P}$ or along r) and the light-sector spectral ledger $\mathcal{Z}^{[\mathscr{S}]}$ (poles,

residue matrices $Z \succeq 0$, NG/pNG census, hyperbolicity margin) exactly as consolidated in Section 7.10.

Step 3 — Form the synthesis object and resolve. Assemble the synthesis object

$$\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P}) = \Big(\Lambda^{[\mathscr{S}]}_{\text{law}}, \Lambda^{[\mathscr{S}]}_{\text{state}} \;;\; \mathcal{W}^{[\mathscr{S}]}, \mathcal{Z}^{[\mathscr{S}]} \;;\; \mathcal{A}, r\Big)$$

as in Definition 8.100 and apply the resolver $\mathcal{R}^{[\mathscr{S}]}$ of Definition 8.102 to obtain

$$\Big(\text{Quad}^{[\mathscr{S}]},\ \mathsf{Expl}^{[\mathscr{S}]}\Big).$$

Step 4 — SynTh reasoning ($\oplus$)**.** Adopt $\text{Syn}^{[\mathscr{S}]} = \text{Law}^{[\mathscr{S}]} \oplus \text{State}^{[\mathscr{S}]}$ (cf. Definition 8.98) as the *joint premise* for higher-level conclusions. Inter-sector contradictions (e.g. "QI in bulk, QIV on boundary") are *co-tenable* in the paraconsistent context and should trigger *arena/knob audit* until discrepancies resolve into QIII-type healing or a certified QIV persistence, in line with Section 8.1.

Definition 8.106 (Canonical certification predicates)**.** For a sector $\mathscr{S}$ with tolerances $\varepsilon_{\text{law}}, \varepsilon_{\text{state}} \in (0,1)$, define the *tolerance predicates*

$$\chi^{[\mathscr{S}]}_{\text{law}} := \mathbf{1}\Big[\,|\Lambda^{[\mathscr{S}]}_{\text{law}}| \geq 1 - \varepsilon_{\text{law}}\,\Big], \qquad \chi^{[\mathscr{S}]}_{\text{state}} := \mathbf{1}\Big[\,|\Lambda^{[\mathscr{S}]}_{\text{state}}| \geq 1 - \varepsilon_{\text{state}}\,\Big], \tag{8.16}$$

and the *healing predicate* along the sector IR knob r,

$$d^{[\mathscr{S}]}_{\text{law}}(r) := 1 - |\Lambda^{[\mathscr{S}]}_{\text{law}}(r)|, \qquad d^{[\mathscr{S}]}_{\text{law}}(r) \;\leq\; C\, r^{-\beta} \quad (r \to \infty), \tag{8.17}$$

for some $C, \beta > 0$. The resolver $\mathcal{R}^{[\mathscr{S}]}$ maps $(\chi^{[\mathscr{S}]}_{\text{law}}, \chi^{[\mathscr{S}]}_{\text{state}}, d^{[\mathscr{S}]}_{\text{law}})$ to QI–QIV exactly as in Section 8.1.

Definition 8.107 (Worked sector sketches (non-parasymmetric))**.** The following certified instances illustrate Definition 8.105 purely at the SynTh level (parasymmetric meters set aside).

(a) Bulk sector (canonical). Witness pair $\Big(\Lambda^{[\text{bulk}]}_{\text{law}}(\ell), \Lambda^{[\text{bulk}]}_{\text{state}}\Big)$ on $\mathfrak{P}$ with $r = \ell$. If $|\Lambda^{[\text{bulk}]}_{\text{law}}| \approx 1$ while $\Lambda^{[\text{bulk}]}_{\text{state}}(V) \to 0$, then $\text{Syn}^{[\text{bulk}]}$ resolves to **QII** via $\mathcal{R}^{[\text{bulk}]}$; $\mathcal{W}^{[\text{bulk}]}$ is conserved and $\mathcal{Z}^{[\text{bulk}]}$ exhibits NG poles in the correlational channel (lifting to BEH when gauged), as per Section 7.10.

(b) Boundary sector. Witness pair $\Big(\Lambda^{[\partial]}_{\text{law}}(L), \Lambda^{[\partial]}_{\text{state}}\Big)$ on $\mathfrak{P}_\partial$ with $r = L$. If $d^{[\partial]}_{\text{law}}(L) \sim L^{-\beta}$ and $|\Lambda^{[\partial]}_{\text{state}}| \approx 1$, then $\text{Syn}^{[\partial]}$ resolves to **QIII**; the explanatory class $\mathsf{Expl}^{[\partial]}$ records adjoint divergence $\to 0$ along L and no NG/pNG, consistent with emergent symmetry at large L.

(c) Anisotropic sector (spin–orbit example). Witness pair $\Big(\Lambda^{[\text{aniso}]}_{\text{law}}(\vec{\ell}), \Lambda^{[\text{aniso}]}_{\text{state}}\Big)$ with $r = \min(\vec{\ell})$. If $|\Lambda^{[\text{aniso}]}_{\text{state}}| \approx 1$ and $|\Lambda^{[\text{aniso}]}_{\text{law}}| \leq 1 - \delta_\star$ uniformly on $\mathfrak{P}$, then $\text{Syn}^{[\text{aniso}]}$ resolves to **QIV**; $\mathcal{W}^{[\text{aniso}]}$ shows a persistent adjoint–covariant source and $\mathcal{Z}^{[\text{aniso}]}$ registers a pNG band with GMOR behaviour on the plateau.

Definition 8.108 (Diagnostics and edge handling (SynTh discipline))**.** *Lower-right anomaly* (state decoheres + non-healing law deficit): treat the configuration as *non-certified*; re-audit plateau certification, witnesses, or arena choice per Section 7.10. *Inter-sector disagreement*: SynTh does not collapse; perform *arena reconciliation* (align $\mathcal{A}$ and r) and prefer joint plateaus $\mathfrak{P}_\cap$ from Definition 8.103 until the QIII/QIV distinction stabilises.

Remark 8.109 (Summary for insertion into §8.2)**.** Simultaneous Synthesis *law* $\oplus$ *state* treats the sector-conditioned predicates as a *co-tenable* pair at the SynTh layer, evaluated on the *same* certified arena and IR knob (Section 8.1). The synthesis object $\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})$ bundles visibilities with *Ward* and *spectral* ledgers; the resolver $\mathcal{R}^{[\mathscr{S}]}$ maps this to a quadrant label and an *explanatory class*, realising the equivalences of Section 7.10 sector-by-sector. Paraconsistent reasoning ensures non-explosive multi-sector inference; QIII vs. QIV is always separated by the *healing* test in Section 8.1.

At a high level, Section 8.2 turns the quadrant machinery of Sections 7.10 and 8.1 into a single, coherent way to *think* about symmetry—one that treats "law" and "state" as jointly readable, jointly actionable inputs. The central move is the *Simultaneous Synthesis* judgement

$$\mathrm{Syn}^{[\mathscr{S}]} = \mathrm{Law}^{[\mathscr{S}]} \ \oplus \ \mathrm{State}^{[\mathscr{S}]},$$

which simply says: in a fixed sector $\mathscr{S}$, read the *same* arena ($\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$), with the *same* BRST-closed tags $P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}$, through the *same* IR knob r, and treat the resulting pair of visibilities $\left(\Lambda^{[\mathscr{S}]}_{\mathrm{law}}, \Lambda^{[\mathscr{S}]}_{\mathrm{state}}\right)$ as **co-tenable information** in SynTh. Nothing about this forces a partition; rather, it elevates the grid to a *dashboard* whose two dials carry logically compatible, yet conceptually distinct, content about dynamics (the law) and about the realized phase (the state).

Why is this separation important? Because the physics really does bifurcate along those lines. The *law dial* is designed to detect explicit breaking in the microscopic or effective dynamics; the *state dial* reacts to whether the realized macroscopic phase decoheres into a symmetry-broken mixture as $V \uparrow \infty$. In practice, that means a theory may *respect* a symmetry ($|\Lambda^{[\mathscr{S}]}_{\mathrm{law}}| \approx 1$) while its ground sector **chooses** a broken phase ($\Lambda^{[\mathscr{S}]}_{\mathrm{state}}(V) \to 0$): that is precisely QII. Conversely, the law may be explicitly imperfect but "heals" as we push deeper into the sector's IR knob r (QIII). Keeping these channels distinct, while reading them *simultaneously*, is what makes the synthesis robust and explanatory.

Technically, the synthesis works because it is anchored on a *certified plateau* $\mathfrak{P}$. Once we restrict to $\mathfrak{P}$, every quantity that we read—$\Lambda^{[\mathscr{S}]}_{\mathrm{law}}$, $\Lambda^{[\mathscr{S}]}_{\mathrm{state}}$, the sector Ward sources, and the light-sector spectrum on $\mathcal{H}_{\mathrm{phys}}$—is (i) insensitive to gauge-fermion changes (Nielsen-flat), (ii) filtered to respect causal cones, and (iii) stable under small changes of $(\lambda_{\mathrm{UV}}, r)$. This is not cosmetic: it converts "diagnostics that could be scheme-dependent" into *observables* that convey the same story across gauges and regulators.

Seen this way, the quadrant labels (QI–QIV) are just *surface summaries* of a deeper triangulation. The synthesis object for sector $\mathscr{S}$,

$$\mathfrak{S}^{[\mathscr{S}]}(\mathcal{A}) \equiv \left(\Lambda^{[\mathscr{S}]}_{\mathrm{law}}, \Lambda^{[\mathscr{S}]}_{\mathrm{state}};\ \text{Ward ledger } \mathcal{W}^{[\mathscr{S}]},\ \text{spectral ledger } \mathcal{Z}^{[\mathscr{S}]};\ \mathcal{A}, r\right),$$

collects (1) the two dials, (2) the *Ward* statement that tells whether the improved current is conserved or has a non-vanishing adjoint–covariant source, and (3) the *spectral* statement

that tells which light modes truly exist on $\mathcal{H}_{\text{phys}}$ (NG, pNG, or none), with residue matrices $Z \succeq 0$ and hyperbolicity margins recorded. The equivalence result summarized in Section 7.10 then says: on $\mathfrak{P}$, these three views agree. The grid position is consistent with both the Ward ledger and the spectral ledger—*and that* is where the explanatory power comes from.

Each quadrant thus acquires a crisp, three-fold meaning. **QI** is the "all clear": law saturated, state saturated, conserved improved current, no NG/pNG in the physical spectrum. **QII** is the *SSB arrow*: law saturated, state decoheres, improved current still conserved, and NG poles appear in the correlational channel (which become BEH masses if the corresponding generators are gauged). **QIII** is *emergent symmetry*: the law dial shows a **finite-scale** deficit that *heals* along the sector's IR direction r (e.g. ℓ, L, or $\min(\vec{\ell})$), while the state dial saturates; correspondingly, the Ward divergence tends to zero along r, and the spectrum carries no bona fide NG or pNG modes. **QIV** is *persistent explicit breaking*: the law dial stays below $1-\delta_\star$ on $\mathfrak{P}$, the state dial saturates, the Ward source persists, and the spectrum exhibits a pNG band that obeys a GMOR-type relation on the plateau.

Two conceptual implications flow immediately. First, *QIII vs QIV is not a matter of taste*; it is decided operationally by the **healing test**

$$d_{\text{law}}^{[\mathscr{S}]}(r) := 1 - |\Lambda_{\text{law}}^{[\mathscr{S}]}(r)| \quad \overset{?}{\leq} \quad C\, r^{-\beta} \quad (r \to \infty),$$

performed in the *sector's own* IR knob r. This converts a semantic debate ("is the symmetry really there?") into a *rate-of-convergence measurement*. Second, because the whole construction lives on $\mathcal{H}_{\text{phys}}$ with BRST-closed tags, the outcome is *not* an artefact of gauge choices or regulator idiosyncrasies; it reflects the physics accessible to observers confined to the physical cohomology.

The sector-conditioned formulation is not a mere relabelling; it is what makes the synthesis *portable* across arenas. In *bulk*, read $(\Lambda_{\text{law}}^{[\text{bulk}]}, \Lambda_{\text{state}}^{[\text{bulk}]})$ on $\mathfrak{P}$ with $r = \ell$. On a *boundary*, switch to $\mathfrak{P}_\partial$ and $r = L$. In *anisotropic* situations, take $r = \min(\vec{\ell})$ (or the sector's prescribed dilation). The grid geometry is *identical*, but the *dial design*—i.e., the witness map $\mathbf{W}^{[\mathscr{S}]}$—is tailored to the sector so that the same four labels carry the same physical meaning after projection to $\mathcal{H}_{\text{phys}}$.

This portability pays off when different sectors disagree. Suppose the bulk sits in QI while the boundary sits in QIV. In a classical, explosive logic, this looks contradictory; in SynTh, it is *co-tenable* information: the theory's law respects the symmetry in bulk but exhibits a *boundary-pinned explicit deficit*. The synthesis asks *not* to average those away, but to *explain* them: the Ward source is boundary-supported; the pNG band is boundary-localized; the bulk has neither. Conversely, if both sides look like QIII, the synthesis teaches to expect *reconvergence* under deeper IR dilation (larger L, longer ℓ, stronger anisotropic windowing), and to look for that decay of d_{law} rather than trying to force a premature QI judgement.

From a workflow perspective, the synthesis gives a clean loop. *Fix the arena and certify* $(\mathcal{A}, r, \mathfrak{P})$. *Build the dials* via $\mathbf{W}^{[\mathscr{S}]}$ and compute $\Lambda_{\text{law}}^{[\mathscr{S}]}, \Lambda_{\text{state}}^{[\mathscr{S}]}$. *Attach ledgers* $\mathcal{W}^{[\mathscr{S}]}, \mathcal{Z}^{[\mathscr{S}]}$. *Resolve* to a quadrant with an *explanatory class* (conservation/source; NG/pNG/none). And then, crucially, *reason at the SynTh level* with Law $\oplus$ State as a *single premise*. This turns the grid from a post-hoc labeler into a *design tool*: we can now *steer* simulations or experiments along r to make a QIII heal, or along control parameters to convert a QIV source into a QIII decay.

Even at this high level, the spectral ledger has tangible, testable content. In QII, the

current–order-parameter form factor saturates the NG pole; in QIV, the same structure reappears as a *pseudogap/pseudo-NG* with a GMOR slope on $\mathfrak{P}$. The residues $Z \succeq 0$ and hyperbolicity margins provide sanity checks that the light content is not a gauge remnant. Because the ledgers are tied to the same $\mathfrak{P}$ that produced the dials, the story is *closed*: we can cross-check the grid assignment by looking either at visibilities or at Ward–spectrum, and we should get the same verdict.

Intuitively, we can picture the whole construction as installing two *calibrated meters* on the same instrument diagnostic realized reference configuration. One meter measures how faithfully the dynamics realises the symmetry (the *law* meter); the other meter measures whether the realized macroscopic phase keeps that symmetry coherent in the thermodynamic limit (the *state* meter). The *sector* tells us what diagnostic realized reference configuration we're working on (bulk, boundary, anisotropic), and the *IR knob* r tells us which way to turn to resolve ambiguous readings. The SynTh connective $\oplus$ simply instructs us to *read both meters together* and use them jointly, without forcing a false choice when reality presents a both/and.

The implications extend to modelling strategy. Want to engineer an *emergent symmetry* (e.g. a gauge symmetry)? Aim for QIII by designing flows where $d_{\mathrm{law}}^{[\mathscr{S}]}(r)$ decays with a controllable exponent β while keeping $|\Lambda_{\mathrm{state}}^{[\mathscr{S}]}| \approx 1$. Want to *protect* a symmetry? Target QI, and use the Ward ledger to audit any drift off conservation. Diagnosing *spontaneous breaking* (SSB)? Expect QII, but confirm it spectrally (true NG) rather than by visibility alone. Hunting *explicit breakings* that masquerade as SSB? QIV will expose them, because the Ward source refuses to vanish and the spectrum carries pNG instead of NG on $\mathfrak{P}$.

Finally, the synthesis clarifies what to do when the lower-right corner (state decoheres *and* law deficit persists) shows up. Within Section 7.10 this is typically a *non-certified* configuration, and the synthesis treats it as a *prompt* to re-audit the arena, the witness map, or the plateau itself—not as a paradox to be resolved by argument. In other words, the logic (SynTh) and the metrology (plateau certification, BRST closure) are aligned: if the instruments disagree in a way the theory says they shouldn't, fix the instruments before inferring physics.

In sum, Section 8.2 equips the sector-conditioned framework with a reasoning layer that is as disciplined as its metrology. The *Simultaneous Synthesis* Law $\oplus$ State treats the two dials as joint, gauge-safe evidence; the *resolver* maps them (together with Ward and spectral ledgers) into QI–QIV with clear operational meaning; and the *IR-healing* rule separates emergent symmetry (QIII) from persistent explicit breaking (QIV). The result is a high-level picture that is easy to *read* but hard to *fool*—and that is exactly what we want when turning symmetry principles into working diagnostics across bulk, boundary, and anisotropic sectors.

8.4 Parasymmetric Synthesis of Laws and States (Sector-conditioned Overlay)

Definition 8.110 (Sector–parasymmetric modal spaces and meters)**.** Fix a sector $\mathscr{S}$ with realized weave configuration $\mathcal{I}^{[\mathscr{S}]} = (\mathcal{A}, \mathfrak{P}; r; P_x, K_{\mathrm{IR}}; \mathsf{P}_{\mathrm{phys}})$ as in Definition 8.96. For each

anchor $a \in \{L, S\}$ introduce a two-mode modal space

$$\mathcal{H}^{(a)[\mathscr{S}]} = \mathrm{span}\{|e_1\rangle_a, |e_2\rangle_a\}, \qquad |e_1\rangle_a \equiv |\,\mathrm{Sym}\rangle_a, \quad |e_2\rangle_a \equiv |\,\mathrm{Break}\rangle_a,$$

and the "both/and" (parasymmetric) kets $|\pm\rangle_a = \frac{1}{\sqrt{2}}(|e_1\rangle_a \pm |e_2\rangle_a)$. Define the local parasymmetric projectors

$$P^{(a)}_{\mathrm{para}} = |+\rangle_a\langle+|\,, \qquad P^{(a)}_{\mathrm{antipara}} = |-\rangle_a\langle-|,$$

and the *local parasymmetric valuations* (meters) on density operators $\rho^{(a)[\mathscr{S}]}$:

$$v^{(a)[\mathscr{S}]}_{\mathrm{Synthesis}}(\rho^{(a)[\mathscr{S}]}) = \mathrm{Tr}\Big(P^{(a)}_{\mathrm{para}}\rho^{(a)[\mathscr{S}]}\Big) = \tfrac{1}{2} + \mathrm{Re}\Big(\rho^{(a)[\mathscr{S}]}_{12}\Big).$$

On the relational space $\mathcal{H}^{(LS)[\mathscr{S}]} = \mathcal{H}^{(L)[\mathscr{S}]} \otimes \mathcal{H}^{(S)[\mathscr{S}]}$, introduce Bell-type projectors

$$\begin{aligned} &P^{(LS)}_{\mathrm{para}} && \text{(coherent } \textit{opposition} \text{ on the II/III diagonal)},\\ &P^{(LS)}_{\Phi,\mathrm{para}} && \text{(coherent } \textit{agreement} \text{ on the I/IV diagonal)}. \end{aligned}$$

and define the *relational parasymmetric meters* for density operators $\rho^{(LS)[\mathscr{S}]}$:

$$v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\rho^{(LS)[\mathscr{S}]}\Big), \qquad v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}} = \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}}\rho^{(LS)[\mathscr{S}]}\Big).$$

All evaluations are performed on the same certified arena $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$, with the same IR knob r, BRST-closed tags (P_x, K_{IR}), and projection to $\mathcal{H}_{\mathrm{phys}}$, cf. Section 8.2.1.

Definition 8.111 (Sector–parasymmetric calibration from generalized witness)**.** Let $\mathbf{W}^{[\mathscr{S}]}_{\mathrm{gen}}$ be the generalized witness of Section 8.3, producing the consolidated outputs

$$\Big(\Lambda^{[\mathscr{S}]}_{\mathrm{law}}, \Lambda^{[\mathscr{S}]}_{\mathrm{state}};\ \mathcal{W}^{[\mathscr{S}]}, \mathcal{Z}^{[\mathscr{S}]}\Big)$$

on the common instrumentation $\mathcal{I}^{[\mathscr{S}]}$. A *sector–parasymmetric calibration* is a completely positive, trace-preserving map

$$\kappa^{[\mathscr{S}]}: \ \Big(\Lambda^{[\mathscr{S}]}_{\mathrm{law}}, \Lambda^{[\mathscr{S}]}_{\mathrm{state}};\ \mathcal{W}^{[\mathscr{S}]}, \mathcal{Z}^{[\mathscr{S}]}\Big) \ \longrightarrow\ \Big(\rho^{(L)[\mathscr{S}]},\ \rho^{(S)[\mathscr{S}]},\ \rho^{(LS)[\mathscr{S}]}\Big),$$

chosen so that:

(C1) Gauge/Nielsen flatness. If (P_x, K_{IR}) are BRST-closed and evaluations are on $\mathcal{H}_{\mathrm{phys}}$, then the image densities are invariant under gauge-fermion changes (inherit the flatness of Proposition 8.101).

(C2) Sector functoriality. Admissible moves of $\mathcal{A}$ and r (bulk $\leftrightarrow$ boundary; anisotropic refinements) induce well-defined morphisms

$$\kappa^{[\mathscr{S}]}_{\mathcal{A},r} \ \Rightarrow\ \kappa^{[\mathscr{S}]}_{\mathcal{A}',r'} \quad \text{that preserve the quadrant label via } \mathcal{R}^{[\mathscr{S}]} \text{ (Definition 8.102)}.$$

(C3) Plateau monotonicity. Along sector IR dilations, the induced coherence deficits in the meters are asymptotically monotone in the sense needed to separate QIII (healing) from QIV (persistence) on certified plateaus.

Given $\kappa^{[\mathscr{S}]}$, the parasymmetric meters of Definition 8.110 are henceforth written

$$\begin{aligned} v^{(a)[\mathscr{S}]}_{\mathrm{Synthesis}} &:= v^{(a)[\mathscr{S}]}_{\mathrm{Synthesis}}\Big(\rho^{(a)[\mathscr{S}]}\Big), \\ v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}} &:= v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}}\Big(\rho^{(LS)[\mathscr{S}]}\Big), \\ v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}} &:= v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}}\Big(\rho^{(LS)[\mathscr{S}]}\Big). \end{aligned}$$

Proposition 8.112 (Conservation and auditability of parasymmetric meters)**.** *Let $\hat{F}^{(LS)}_{\mathrm{para}}$ be a unified parasymmetric generator on $\mathcal{H}^{(LS)[\mathscr{S}]}$ as in Section 8.2.1. If $[\hat{F}^{(LS)}_{\mathrm{para}}, P] = 0$ for $P \in \{P^{(L)}_{\mathrm{para}}, P^{(S)}_{\mathrm{para}}, P^{(LS)}_{\mathrm{para}}, P^{(LS)}_{\Phi,\mathrm{para}}\}$, then along the certified evolution on $\mathcal{A}$ one has*

$$\frac{d}{dt}\,\mathrm{Tr}\Big(P\,\rho^{(\cdot)[\mathscr{S}]}(t)\Big) = 0,$$

and, in the open-system setting with Lindbladian $\mathcal{L}$, the same holds whenever $\mathcal{L}^\dagger(P) = 0$. Thus $v^{(a)[\mathscr{S}]}_{\mathrm{Synthesis}}, v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}}, v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}}$ are conserved (or ledger-controlled) meters on $\mathfrak{P}$, providing auditable invariants that complement the resolver of Definition 8.102.

Definition 8.113 (Parasymmetric overlay of the sector synthesis object)**.** Given $\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})$ from Definition 8.100 and a calibration $\kappa^{[\mathscr{S}]}$ from Definition 8.111, define the *parasymmetric synthesis object*

$$\widehat{\mathfrak{S}}^{[\mathscr{S}]}(\mathfrak{P}) := \Big(\ \mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})\ ;\ v^{(L)[\mathscr{S}]}_{\mathrm{Synthesis}},\ v^{(S)[\mathscr{S}]}_{\mathrm{Synthesis}}\ ;\ v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}},\ v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}}\ \Big),$$

all entries computed on the same realized weave configuration $\mathcal{I}^{[\mathscr{S}]}$.

Proposition 8.114 (Quadrant–parasymmetry correspondence (sector-conditioned))**.** *Let $\mathrm{Quad}^{[\mathscr{S}]}$ be the quadrant label returned by $\mathcal{R}^{[\mathscr{S}]}$ in Definition 8.102. Fix sector thresholds $\tau_{\mathrm{syn}}, \tau_{\mathrm{agr}} \in (0, \frac{1}{2})$ determined at calibration. Then, on any certified plateau component:*

$$\begin{aligned} \text{QI } \textit{or}\ \text{QIV} &\implies v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}} \ \geq\ \tfrac{1}{2} + \tau_{\mathrm{agr}}, \\ \text{QII } \textit{or}\ \text{QIII} &\implies v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}} \ \geq\ \tfrac{1}{2} + \tau_{\mathrm{syn}}. \end{aligned}$$

Moreover, in the thermodynamic/IR limits associated to the sector's r:

(i) QII (SSB).
$\Lambda^{[\mathscr{S}]}_{\mathrm{state}}(V) \to 0$ implies $v^{(S)[\mathscr{S}]}_{\mathrm{Synthesis}} \to \frac{1}{2}$ (incoherent mixture baseline), while $v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}}$ remains elevated (II/III diagonal).

(ii) QIII (emergence).
If $d^{[\mathscr{S}]}_{\mathrm{law}}(r) \leq Cr^{-\beta}$, then $v^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}}$ is non-decreasing along r up to $o(1)$, and any deficit in $v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}}$ shrinks $o(1)$.

(iii) QIV (explicit).
A persistent law deficit on $\mathfrak{P}$ is compatible with an elevated $v^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}}$ (I/IV diagonal), while $v^{(S)[\mathscr{S}]}_{\mathrm{Synthesis}}$ need not exceed the mixture baseline.

These statements refine, but do not modify, the quadrant decision of Section 8.1: the parasymmetric meters provide a coherence profile *aligned with the I/IV vs. II/III diagonal structure described in Section 8.2.1.*

Definition 8.115 (Operational overlay (sector-conditioned, parasymmetric))**.** Augment the operational template of Definition 8.105 with:

(i) Para calibration.
Choose $\kappa^{[\mathscr{S}]}$ satisfying **(C1)–(C3)** of Definition 8.111; fix thresholds $(\tau_{\mathrm{syn}}, \tau_{\mathrm{agr}})$.

(ii) Meter readout.
Compute $\upsilon^{(L)[\mathscr{S}]}_{\mathrm{Synthesis}}, \upsilon^{(S)[\mathscr{S}]}_{\mathrm{Synthesis}}, \upsilon^{(LS)[\mathscr{S}]}_{\mathrm{Synthesis}}, \upsilon^{(LS)[\mathscr{S}]}_{\mathrm{Agreement}}$ on $\mathcal{A}$.

(iii) Coherence audit.
Report the *coherence class*

$$\mathsf{Coh}^{[\mathscr{S}]} := \Big(\begin{array}{l} \text{diag preference: I/IV vs. II/III;} \\ \text{local } L/S \text{ “bothness” levels;} \\ \text{conservation via Proposition 8.112} \end{array} \Big),$$

and attach it to $\mathsf{Expl}^{[\mathscr{S}]}$ from Definition 8.102.

The resulting package $\widehat{\mathfrak{S}}^{[\mathscr{S}]}(\mathfrak{P})$ is sector-certified, gauge/Nielsen-flat, and functorial across arena and IR choices, preserving the quadrant label while enriching its explanation with phase-sensitive coherence data.

Remark 8.116 (Interpretation and sector portability)**.** *Agreement* vs. *Synthesis* meters resolve whether the law/state pair sits on the I/IV or II/III diagonals of the generalized 2×2 grid of Section 8.1. Because all constructions are anchored to the same certified plateau, BRST-closed tags, and projection to $\mathcal{H}_{\mathrm{phys}}$, the parasymmetric overlay is robust under gauge retunings (Nielsen-flat), respects causal cone preservation, and transports across bulk, boundary, and anisotropic sectors without altering the canonical quadrant rule of Section 8.1, in line with Section 8.2.1.

8.5 Applications of Parasymmetric Overlays

Story in one line. The parasymmetric overlay is a *diagnostic instrument* that not only tells whether a fermionic symmetry is broken, but also *why*—by reading the phase–coherent relationship between the *law* and the *state* on a certified bulk plateau $\mathfrak{P}$ within the BRST–safe sector $\mathcal{H}_{\mathrm{phys}}$ (Definition 8.10).

Two suspects, one dashboard. There are two principal culprits behind broken symmetry:

(i) Spontaneous selection (SSB). The law is symmetric but the state *chooses* a direction (QII).

(ii) Built–in imperfection (explicit). The law itself carries a symmetry–breaking term (QIV).

The sector visibilities $\left(\Lambda_{\text{law}}^{[\text{ferm}]}, \Lambda_{\text{state}}^{[\text{ferm}]}\right)$ place the system in QI–QIV (Proposition 8.11), but the overlay adds *meters* that reveal the *coherent geometry* of the law–state relation, not just the magnitudes.

The meters (phase–aware dials). A calibration $\kappa^{[\text{ferm}]}$ maps witness/ledger data to densities $\rho^{(L)[\text{ferm}]}, \rho^{(S)[\text{ferm}]}, \rho^{(LS)[\text{ferm}]}$. From these, two relational and one local meter are read with the projectors of Section 8.2.1:

$$v_{\text{Agreement}}^{(LS)[\text{ferm}]} \text{ (coherent I/IV)},$$
$$v_{\text{Synthesis}}^{(LS)[\text{ferm}]} \text{ (coherent II/III)},$$
$$v_{\text{Synthesis}}^{(S)[\text{ferm}]} \text{ (local state “bothness”)}.$$

Normalization is universal: 1 (coherent both/and), 1/2 (incoherent mixture baseline), 0 (coherent anti–both). All readings are *Nielsen–flat* on $\mathfrak{P}$ and thus gauge–parameter insensitive.

What the dials say (cause vs effect).

(i) SSB (QII). The *tension* dial is high and the *local* state dial collapses to the mixture baseline:

$$|\Lambda_{\text{law}}^{[\text{ferm}]}| \approx 1, \quad |\Lambda_{\text{state}}^{[\text{ferm}]}| \approx 0, \quad v_{\text{Synthesis}}^{(LS)[\text{ferm}]} > \tfrac{1}{2}, \quad v_{\text{Synthesis}}^{(S)[\text{ferm}]} \to \tfrac{1}{2}.$$

(ii) Explicit (QIV). The *harmony* dial is high (coherent I/IV), without requiring large local “bothness”:

$$|\Lambda_{\text{state}}^{[\text{ferm}]}| \approx 1, \quad |\Lambda_{\text{law}}^{[\text{ferm}]}| \leq 1 - \delta_\star, \quad v_{\text{Agreement}}^{(LS)[\text{ferm}]} > \tfrac{1}{2}.$$

(iii) Emergent (QIII). Finite–scale explicit effects *heal* under the IR knob $r = \ell$; the tension meter *rises* with healing:

$$d_{\text{law}}^{[\text{ferm}]}(r) \downarrow, \quad v_{\text{Synthesis}}^{(LS)[\text{ferm}]}(r) \nearrow \text{ up to } o(1).$$

(iv) Symmetric (QI). Agreement is elevated (coherent I/IV); both visibilities are near 1.

Why the readings are physical (spectral/Ward fingerprints). The meters are wired to *observable* ledgers (Definition 8.10):

QII. Elevated tension $\Leftrightarrow$ NG partners in the fermionic channel (spontaneous breaking).

QIV. Elevated harmony $\Leftrightarrow$ pseudo–NG (GMOR–type) band on $\mathfrak{P}$ and analytic mass/mixing shifts in S^R (explicit breaking).

QIII. No NG/pNG; adjoint divergence $\to 0$ along r; tension increases as the law heals (emergence).

Why this matters (high-level). *Ambiguity ends:* identical magnitudes $\big(|\Lambda_{\text{law}}|, |\Lambda_{\text{state}}|\big)$ can arise from different mechanisms; the meters separate *coherent opposition* (QII/QIII) from *coherent agreement* (QI/QIV). *Actionable searches:* elevated tension points to NG channels; elevated harmony points to pNG bands and mass shifts. *Quality assurance:* when the relevant projectors commute with the dynamics (or satisfy $\mathcal{L}^\dagger(P) = 0$), the meters are conserved/slow on $\mathfrak{P}$; drift flags boundary leakage or mis–instrumentation rather than new physics.

The parasymmetric overlay promotes the familiar QI–QIV table into a *phase–structured dashboard*. In fermionic language, it reads whether the law and the state are in *harmony* (I/IV) or in *tension* (II/III), and it ties those readings to concrete spectral/Ward signatures. That is why it can say not only *that* symmetry is broken, but *how*, and *by whom*—the dynamics (explicit), the state (spontaneous), or neither (symmetric), with emergence certified by IR healing trends (Proposition 8.11 and Section 8.2.1).

8.5.1 Sector-Agnostic Parasymmetric Overlay

Scope and layer (sector-agnostic). Fix an arbitrary sector $[\mathscr{S}]$ with realized weave configuration $\mathcal{I}^{[\mathscr{S}]} = (\mathcal{A}, \mathfrak{P}; r; P_x(\lambda_{\text{UV}}), K_{\text{IR}}; \mathsf{P}_{\text{phys}})$ as in Definition 8.96, and work on the physical cohomology $\mathcal{H}_{\text{phys}}$ with BRST-closed tags. The generalized witness $\mathbf{W}^{[\mathscr{S}]}_{\text{gen}}$ (Section 8.3) returns the sector visibilities $\big(\Lambda^{[\mathscr{S}]}_{\text{law}}, \Lambda^{[\mathscr{S}]}_{\text{state}}\big) \in [0,1]^2$ together with Ward/spectral ledgers, all evaluated on the same $\mathcal{I}^{[\mathscr{S}]}$. Parasymmetry overlays this resolver-ready data with phase-sensitive meters that *corroborate and explain* the quadrant assignment without altering it.

Definition 8.117 (Parasymmetric interface (sector-agnostic calibration and meters))**.** A *parasymmetric calibration* for sector $[\mathscr{S}]$ is a completely positive, trace-preserving map

$$\kappa^{[\mathscr{S}]} : \Big(\Lambda^{[\mathscr{S}]}_{\text{law}}, \Lambda^{[\mathscr{S}]}_{\text{state}};\ \mathcal{W}^{[\mathscr{S}]}, \mathcal{Z}^{[\mathscr{S}]}\Big) \longrightarrow \Big(\rho^{(L)[\mathscr{S}]},\ \rho^{(S)[\mathscr{S}]},\ \rho^{(LS)[\mathscr{S}]}\Big),$$

where $\rho^{(L)[\mathscr{S}]}, \rho^{(S)[\mathscr{S}]} \in \mathsf{D}(\mathbb{C}^2)$ encode local "Sym/Break'' content for *law* and *state*, and $\rho^{(LS)[\mathscr{S}]} \in \mathsf{D}(\mathbb{C}^2 \otimes \mathbb{C}^2)$ encodes relational law–state content. With local parasymmetric projectors $P^{(a)}_{\text{para}} = |+\rangle_a\langle+|$ ($a \in \{L, S\}$) and Bell-type projectors $P^{(LS)}_{\text{para}}$ (coherent *opposition*, II/III diagonal) and $P^{(LS)}_{\Phi,\text{para}}$ (coherent *agreement*, I/IV diagonal), define the meters

$$\begin{aligned} v^{(L)[\mathscr{S}]}_{\text{Synthesis}} &= \text{Tr}\Big(P^{(L)}_{\text{para}}\, \rho^{(L)[\mathscr{S}]}\Big), & v^{(S)[\mathscr{S}]}_{\text{Synthesis}} &= \text{Tr}\Big(P^{(S)}_{\text{para}}\, \rho^{(S)[\mathscr{S}]}\Big), \\ v^{(LS)[\mathscr{S}]}_{\text{Synthesis}} &= \text{Tr}\Big(P^{(LS)}_{\text{para}}\, \rho^{(LS)[\mathscr{S}]}\Big), & v^{(LS)[\mathscr{S}]}_{\text{Agreement}} &= \text{Tr}\Big(P^{(LS)}_{\Phi,\text{para}}\, \rho^{(LS)[\mathscr{S}]}\Big). \end{aligned}$$

Normalization is fixed so that 1 denotes a coherent "both/and", 1/2 the incoherent mixture baseline, and 0 a coherent "anti-both''. Calibration inherits gauge/Nielsen flatness and plateau uniformity from $\mathcal{I}^{[\mathscr{S}]}$.

Definition 8.118 (Reading rule and thresholds)**.** Fix sector thresholds $\tau_{\text{agr}}, \tau_{\text{syn}} \in (0, \frac{1}{2})$. A parasymmetric meter v is called *elevated* if $v \geq \frac{1}{2} + \tau$ with the appropriate threshold $\tau \in \{\tau_{\text{agr}}, \tau_{\text{syn}}\}$. Operationally:

- $v^{(LS)[\mathscr{S}]}_{\text{Agreement}}$ elevated $\Rightarrow$ coherent I/IV diagonal (law–state agreement).

- $v^{(LS)[\mathscr{S}]}_{\text{Synthesis}}$ elevated $\Rightarrow$ coherent II/III diagonal (law–state opposition).
- $v^{(L)[\mathscr{S}]}_{\text{Synthesis}}$ or $v^{(S)[\mathscr{S}]}_{\text{Synthesis}} = 1/2 \Rightarrow$ local incoherent mixture; values $\uparrow$ toward 1 indicate local coherent "bothness".

Proposition 8.119 (Quadrant expectations with parasymmetric meters (sector-agnostic))**.** *Let* $(\mathrm{Quad}^{[\mathscr{S}]}, \mathsf{Expl}^{[\mathscr{S}]}) = \mathcal{R}^{[\mathscr{S}]}\big(\mathfrak{S}^{[\mathscr{S}]}(\mathfrak{P})\big)$ *be the sector label/explanatory class from Definition 8.102, determined by the canonical resolver using the tolerances and healing predicates of Section 8.1. Then, on any certified plateau component:*

(i) SSB (QII).
$|\Lambda^{[\mathscr{S}]}_{\text{law}}| \approx 1$ *and* $\Lambda^{[\mathscr{S}]}_{\text{state}}(V) \to 0$. *Consequently* $v^{(S)[\mathscr{S}]}_{\text{Synthesis}} \to \frac{1}{2}$ *(local mixture baseline), while* $v^{(LS)[\mathscr{S}]}_{\text{Synthesis}} \geq \frac{1}{2} + \tau_{\text{syn}}$ *(coherent II/III diagonal);* $v^{(LS)[\mathscr{S}]}_{\text{Agreement}}$ *is not elevated. Ward: conserved improved current. Spectrum: NG poles in the correlational channel.*

(ii) Explicit (QIV).
Persistent law deficit on $\mathfrak{P}$ *with* $|\Lambda^{[\mathscr{S}]}_{\text{state}}| \approx 1$. *Then* $v^{(LS)[\mathscr{S}]}_{\text{Agreement}} \geq \frac{1}{2} + \tau_{\text{agr}}$ *(coherent I/IV diagonal);* $v^{(LS)[\mathscr{S}]}_{\text{Synthesis}}$ *need not be high; local meters need not exceed* $1/2$. *Ward: non-vanishing adjoint–covariant source. Spectrum: pNG (GMOR) on* $\mathfrak{P}$.

(iii) Emergent (QIII).
Law deficit heals with the IR knob r: $d^{[\mathscr{S}]}_{\text{law}}(r) \downarrow$ *(cf. eq. (8.17)), and* $|\Lambda^{[\mathscr{S}]}_{\text{state}}| \approx 1$. *Along* r, $v^{(LS)[\mathscr{S}]}_{\text{Synthesis}}$ *increases monotonically up to* $o(1)$, *while any deficit in* $v^{(LS)[\mathscr{S}]}_{\text{Agreement}}$ *shrinks* $o(1)$. *Ward: adjoint divergence* $\to 0$ *along* r. *Spectrum: no NG/pNG.*

Symmetric (QI).
Both dials ≈ 1. *Then* $v^{(LS)[\mathscr{S}]}_{\text{Agreement}}$ *is elevated (coherent I/IV);* $v^{(LS)[\mathscr{S}]}_{\text{Synthesis}}$ *near baseline unless special phases are prepared. Ward conserved; no NG/pNG.*

Remark 8.120 (Utility: separating coherence from averaging; conserved QA; stability)**.** Parasymmetry separates *coherent structure* from *incoherent averaging*: two sectors with identical magnitudes $(|\Lambda_{\text{law}}|, |\Lambda_{\text{state}}|)$ can differ in phase structure, which the meters expose via the $1/2$ baseline and elevated thresholds. Under generators that commute with the relevant projectors (or satisfy $\mathcal{L}^\dagger(P) = 0$), the meters are conserved/slow on $\mathfrak{P}$, providing QA dials whose drift flags mis-instrumentation or boundary leakage. Because readings live on $\mathcal{H}_{\text{phys}}$ with BRST-closed tags, they are gauge/Nielsen-flat and portable across bulk, boundary, and anisotropic sectors.

Definition 8.121 (Operational checklist (sector-agnostic, SynTh + parasymmetry))**.** Given $[\mathscr{S}]$ on $\mathcal{I}^{[\mathscr{S}]}$:

(i) Resolver.
Read the resolver dials $\left(\Lambda^{[\mathscr{S}]}_{\text{law}}, \Lambda^{[\mathscr{S}]}_{\text{state}}\right)$ and assign QI–QIV via $\mathcal{R}^{[\mathscr{S}]}$.

(ii) Calibration.
Calibrate $\kappa^{[\mathscr{S}]}$ and compute $v^{(L)[\mathscr{S}]}_{\text{Synthesis}}, v^{(S)[\mathscr{S}]}_{\text{Synthesis}}, v^{(LS)[\mathscr{S}]}_{\text{Synthesis}}, v^{(LS)[\mathscr{S}]}_{\text{Agreement}}$.

(iii) Thresholds.
Use thresholds $\tau_{\text{agr}}, \tau_{\text{syn}} > 0$ to call elevated meters and interpret the diagonal (I/IV vs II/III) and local "bothness".

(iv) Ward/spectral check.
Cross-check Ward/spectral ledgers: (QII) conserved Ward with NG; (QIV) adjoint source with pNG/GMOR; (QIII) vanishing divergence and no NG/pNG.

(v) Steering.
For steering: monitor $v^{(LS)[\mathscr{S}]}_{\text{Synthesis}}(r)$ for QIII (rising with r) and $v^{(LS)[\mathscr{S}]}_{\text{Agreement}}$ for QIV (persistent elevation).

Bottom line (sector-agnostic). The quadrant resolver remains the primary classifier of SSB (QII) versus explicit breaking (QIV) versus emergent/symmetric cases (QIII/QI). Parasymmetry supplies *coherence-sensitive, conserved, and gauge-robust meters* that validate and explain that classification by revealing *how* the law and state occupy the generalized 2×2 grid—whether in coherent agreement (I/IV), coherent opposition (II/III), or as finite-scale mixtures converging under the sector's IR knob r.

8.5.2 Parasymmetric Overlay of the Fermionic (Spin-1/2) Sector

This section presents a parasymmetric overlay for diagnosing how a fermionic symmetry is realised or broken on the certified bulk plateau $\mathfrak{P}$, within the BRST–safe physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ (Definition 8.10). The overlay refines the canonical quadrant resolver of Proposition 8.11 by adding *phase-sensitive* meters that report coherence between the *law* and the *state*, rather than only magnitudes of sector visibilities.

Quadrants and sector visibilities. The sector-conditioned dials $\left(\Lambda^{[\text{ferm}]}_{\text{law}}, \Lambda^{[\text{ferm}]}_{\text{state}}\right) \in [0,1]^2$ place the system in one of four regimes: QI (both symmetric), QII (spontaneous breaking: law symmetric, state broken), QIII (finite-scale explicit deformations that *heal* under the IR knob $r = \ell$), and QIV (persistent explicit breaking on the plateau). Tolerances $\varepsilon_{\text{law}}, \varepsilon_{\text{state}}$ implement the certified "≈ 1" predicates (Definition 8.10).

Parasymmetric enhancement. A calibration $\kappa^{[\text{ferm}]}$ maps the witness/ledger data to density operators

$$\rho^{(L)[\text{ferm}]}, \quad \rho^{(S)[\text{ferm}]}, \quad \rho^{(LS)[\text{ferm}]},$$

encoding, respectively, the law anchor, the state anchor, and their relation. From these, two relational meters and one local meter are read using the projectors of Section 8.2.1:

$$v^{(LS)[\text{ferm}]}_{\text{Agreement}}, \qquad v^{(LS)[\text{ferm}]}_{\text{Synthesis}}, \qquad v^{(S)[\text{ferm}]}_{\text{Synthesis}},$$

with the normalization 1 (coherent both/and), 1/2 (incoherent mixture baseline), 0 (coherent anti-both). The meters are Nielsen-flat and BRST-safe on $\mathfrak{P}$.

What the overlay achieves. *(i) Cause vs effect.* Spontaneous breaking (QII) exhibits an *elevated opposition* meter $v^{(LS)[\text{ferm}]}_{\text{Synthesis}} > 1/2$ and a *local mixture* $v^{(S)[\text{ferm}]}_{\text{Synthesis}} \to 1/2$, whereas persistent explicit breaking (QIV) yields an *elevated agreement* meter $v^{(LS)[\text{ferm}]}_{\text{Agreement}} > 1/2$ without requiring large local "bothness". In the fully symmetric case (QI) the agreement meter is

likewise elevated. *(ii) Spectral alignment.* Elevated opposition in QII aligns with NG partners in the fermionic channel; elevated agreement in QIV aligns with a pNG (GMOR-type) band and analytic mass/mixing shifts; QIII shows no NG/pNG and a vanishing adjoint divergence along r. *(iii) IR trends.* In QIII the opposition meter increases monotonically as $\ell \downarrow 0$, mirroring the healing predicate $d^{[\mathrm{ferm}]}_{\mathrm{law}}(\ell)\downarrow$; in QIV the agreement meter remains persistently high on $\mathfrak{P}$.

Audit and wiring. Because the meters are conserved/slow when the relevant projectors commute with the dynamics (or satisfy $\mathcal{L}^\dagger(P)=0$), they serve as QA dials: unexpected drift flags boundary leakage or mis-tagging. A plateau-normalised cross-coherence, e.g.

$$\rho_{12}^{(LS)[\mathrm{ferm}]} \;\propto\; \frac{\big\langle \mathrm{Src}^{(\mathrm{ferm})},\, \mathcal{O}_{\mathrm{ferm}} \big\rangle_{\mathfrak{P}}}{\sqrt{\langle \mathrm{Src}^{(\mathrm{ferm})}, \mathrm{Src}^{(\mathrm{ferm})}\rangle_{\mathfrak{P}}\; \langle \mathcal{O}_{\mathrm{ferm}}, \mathcal{O}_{\mathrm{ferm}}\rangle_{\mathfrak{P}}}},$$

implements the meters directly from the Ward source and a tagged fermionic order operator, turning spectral/ledger data into phase-aware diagnostics.

Setup (fermionic sector; same instrumentation). Work on the certified bulk plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, using the BRST-closed tags $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ fixed in Definition 8.10. The generalized witness $\mathbf{W}^{[\mathrm{ferm}]}_{\mathrm{gen}}$ (Section 8.3) delivers the fermionic sector visibilities

$$\big(\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}},\; \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}}\big) \in [0,1]^2,$$

together with the Ward/spectral ledgers on the same instrumentation: retarded propagator S^R, tagged wave operator $\mathcal{D}^{(\ell)}$, tagged mass/mixing $M^{(\ell)}$, and scale-tagged sources $\mathcal{S}_{k,a}$. All evaluations are performed on $\mathfrak{P}$, hence Nielsen-flat and BRST-safe.

Definition 8.122 (Fermionic parasymmetric calibration and densities)**.** A *fermionic parasymmetric calibration* is a completely positive, trace-preserving map

$$\kappa^{[\mathrm{ferm}]}\colon\; \Big(\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}}, \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}};\; \mathcal{W}^{[\mathrm{ferm}]}, \mathcal{Z}^{[\mathrm{ferm}]}\Big) \;\longrightarrow\; \Big(\rho^{(L)[\mathrm{ferm}]},\; \rho^{(S)[\mathrm{ferm}]},\; \rho^{(LS)[\mathrm{ferm}]}\Big),$$

where $\rho^{(L)[\mathrm{ferm}]}, \rho^{(S)[\mathrm{ferm}]} \in \mathsf{D}(\mathbb{C}^2)$ are *local* "Sym/Break" density operators for the law and state anchors, and $\rho^{(LS)[\mathrm{ferm}]} \in \mathsf{D}(\mathbb{C}^2 \otimes \mathbb{C}^2)$ is the *relational* law–state density. Calibration inherits: (i) gauge/Nielsen flatness (from BRST closure and projection to $\mathcal{H}_{\mathrm{phys}}$), (ii) sector functoriality under admissible $(\mathcal{A}, r)$ moves, and (iii) plateau monotonicity along the fermionic IR knob $r = \ell$, in the sense of Section 8.2.1.

Definition 8.123 (Fermionic parasymmetric meters)**.** With projectors $P^{(a)}_{\mathrm{para}} = |+\rangle_a\langle +|$ on the local "Sym/Break" bases ($a \in \{L, S\}$) and Bell-type projectors $P^{(LS)}_{\mathrm{para}}$ (opposition, II/III diagonal) and $P^{(LS)}_{\Phi,\mathrm{para}}$ (agreement, I/IV diagonal) on the relational space, define:

$$\begin{aligned}
&\text{Local meters:} && v^{(L)[\mathrm{ferm}]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(L)}_{\mathrm{para}}\, \rho^{(L)[\mathrm{ferm}]}\Big), \quad v^{(S)[\mathrm{ferm}]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(S)}_{\mathrm{para}}\, \rho^{(S)[\mathrm{ferm}]}\Big);\\
&\text{Relational meters:} && v^{(LS)[\mathrm{ferm}]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\, \rho^{(LS)[\mathrm{ferm}]}\Big), \quad v^{(LS)[\mathrm{ferm}]}_{\mathrm{Agreement}} = \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}}\, \rho^{(LS)[\mathrm{ferm}]}\Big).
\end{aligned}$$

Normalization: 1 indicates a coherent "both/and" configuration, 1/2 the incoherent mixture baseline, and 0 a coherent "anti-both" configuration. These meters are evaluated on $\mathfrak{P}$.

Lemma 8.124 (Cross-coherence calibration for the relational off-diagonal)**.** *Let $\langle\cdot,\cdot\rangle_{\mathfrak{P}}$ denote the plateau-uniform, BRST-safe Källén–Lehmann seminorm used in Definition 8.10, and let $\mathcal{O}_{\mathrm{ferm}}$ be a tagged fermionic order operator for the symmetry under test (e.g. chiral $\bar\psi\psi$ or $\bar\psi i\gamma_5\tau\psi$). A canonical choice within $\kappa^{[\mathrm{ferm}]}$ is*

$$\rho_{12}^{(LS)[\mathrm{ferm}]} \;\propto\; \frac{\left\langle \mathrm{Src}^{(\mathrm{ferm})},\, \mathcal{O}_{\mathrm{ferm}} \right\rangle_{\mathfrak{P}}}{\sqrt{\langle \mathrm{Src}^{(\mathrm{ferm})}, \mathrm{Src}^{(\mathrm{ferm})}\rangle_{\mathfrak{P}}\ \langle \mathcal{O}_{\mathrm{ferm}}, \mathcal{O}_{\mathrm{ferm}}\rangle_{\mathfrak{P}}}}\,.$$

With this choice,

$$v_{\mathrm{Synthesis}}^{(LS)[\mathrm{ferm}]} = \tfrac{1}{2} + \mathrm{Re}\ \rho_{12}^{(LS)[\mathrm{ferm}]}, \qquad v_{\mathrm{Agreement}}^{(LS)[\mathrm{ferm}]} = \tfrac{1}{2} + \mathrm{Re}\ \rho_{\Phi,12}^{(LS)[\mathrm{ferm}]}.$$

Quadrant-resolved narrative (parasymmetric readings). The parasymmetric overlay does not alter the quadrant assignment of Proposition 8.11; rather, it refines the interpretation by reporting *coherence profiles* aligned with the I/IV vs. II/III diagonals.

QI (law kept, state symmetric). Assume $\Lambda_{\mathrm{law}}^{[\mathrm{ferm}]} = 1$ and $\Lambda_{\mathrm{state}}^{[\mathrm{ferm}]} = 1$ (Proposition 8.11). Then the relational *agreement* meter is elevated, $v_{\mathrm{Agreement}}^{(LS)[\mathrm{ferm}]} \gtrsim \frac{1}{2} + \tau_{\mathrm{agr}}$, signalling coherent population of the I/IV diagonal, while $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{ferm}]}$ remains near baseline unless special phases are prepared. Locally, a coherently prepared symmetric state yields $v_{\mathrm{Synthesis}}^{(S)[\mathrm{ferm}]} \approx 1$, with dephasing pushing the value toward $\frac{1}{2}$. The Ward/spectral ledger shows a conserved improved current and no NG/pNG contributions in the fermionic channel; residues $Z \succeq 0$ are consistent with a symmetry-respecting band in S^R. The elevated agreement meter provides a steady audit dial (often conserved under suitable generators in Section 8.2.1); drifts suggest boundary leakage or mis-instrumentation.

QII (law kept; fermionic SSB). Here $\Lambda_{\mathrm{law}}^{[\mathrm{ferm}]} = 1$ while $\Lambda_{\mathrm{state}}^{[\mathrm{ferm}]} = 0$. In the thermodynamic limit, the local state meter relaxes to the mixture baseline, $v_{\mathrm{Synthesis}}^{(S)[\mathrm{ferm}]} \to \frac{1}{2}$, indicating loss of coherent "bothness'' within the state. Concurrently, the relational *opposition* meter is elevated, $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{ferm}]} \gtrsim \frac{1}{2} + \tau_{\mathrm{syn}}$, signalling coherent population of the II/III diagonal, while the agreement meter stays near baseline. The Ward/spectral ledger retains a conserved improved current and records NG partners in the correlational channel; if the relevant generator is gauged, NG strength migrates to BEH masses.

QIII (emergent fermionic symmetry; finite-scale explicit breaking that heals). Assume $\Lambda_{\mathrm{law}}^{[\mathrm{ferm}]}(\ell) \to 1$ as $\ell \downarrow 0$ and $\Lambda_{\mathrm{state}}^{[\mathrm{ferm}]} = 1$. Along the sector IR knob $r{=}\ell$, the healing predicate $d_{\mathrm{law}}^{[\mathrm{ferm}]}(\ell) = 1 - |\Lambda_{\mathrm{law}}^{[\mathrm{ferm}]}(\ell)| \le C\,\ell^{-\beta}$ is mirrored parasymmetrically by a monotone trend: $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{ferm}]}$ *increases* (or stays above baseline) as $\ell \downarrow 0$, and any deficit in $v_{\mathrm{Agreement}}^{(LS)[\mathrm{ferm}]}$ shrinks $o(1)$. No NG/pNG modes appear; the adjoint divergence tends to zero along r. Parasymmetry thus furnishes a rate-of-healing meter, distinguishing true emergence from near-persistent defects.

QIV (explicit fermionic breaking; persistent). If $\Lambda_{\mathrm{law}}^{[\mathrm{ferm}]} \le 1 - \delta_\star$ uniformly while $\Lambda_{\mathrm{state}}^{[\mathrm{ferm}]} = 1$, the relational *agreement* meter is elevated, $v_{\mathrm{Agreement}}^{(LS)[\mathrm{ferm}]} \gtrsim \frac{1}{2} + \tau_{\mathrm{agr}}$, confirming coherent I/IV population; $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{ferm}]}$ need not be large, and local "bothness'' need not exceed $\frac{1}{2}$. The Ward/spectral ledger exhibits a persistent adjoint–covariant source on $\mathfrak{P}$ and a fermionic pNG (GMOR-type) band; analytic mass/mixing shifts appear in $M^{(\ell)}$ and are visible in S^R. This combination certifies explicitness as a property of the dynamics rather than of the state.

Remark 8.125 (Concrete observables and wiring to S^R)**.** A plateau-normalized cross-coherence $\langle \mathrm{Src}^{(\mathrm{ferm})}, \mathcal{O}_{\mathrm{ferm}} \rangle_{\mathfrak{P}}$, with the same seminorm as in Definition 8.10, supplies the off-diagonal of $\rho^{(LS)[\mathrm{ferm}]}$ (Lemma 8.124), yielding

$$v^{(LS)[\mathrm{ferm}]}_{\mathrm{Synthesis}} = \tfrac{1}{2} + \mathrm{Re}\ \rho^{(LS)}_{12}, \qquad v^{(LS)[\mathrm{ferm}]}_{\mathrm{Agreement}} = \tfrac{1}{2} + \mathrm{Re}\ \rho^{(LS)}_{\Phi,12}.$$

The local state meter is obtained from the reduced, tagged fermionic block (Sym/Break basis built from the order parameter sector), $v^{(S)[\mathrm{ferm}]}_{\mathrm{Synthesis}} = \frac{1}{2} + \mathrm{Re}\ \rho^{(S)}_{12}$, hence in SSB, $\rho^{(S)}_{12} \to 0$ and $v^{(S)}_{\mathrm{Synthesis}} \to \frac{1}{2}$. A law-aligned local meter $v^{(L)[\mathrm{ferm}]}_{\mathrm{Synthesis}}$ is analogously defined using the improved current sector.

Corollary 8.126 (Executive summary for the fermionic sector)**.** *On the certified plateau $\mathfrak{P}$ the parasymmetric overlay yields:*

(i) Symmetric (QI).
Agreement coherence high; no NG/pNG; provides a robust audit dial.

(ii) SSB (QII).
$\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} = 1$, $\Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 0$*;* $v^{(S)}_{\mathrm{Synthesis}} \to \frac{1}{2}$ *and* $v^{(LS)}_{\mathrm{Synthesis}}$ *elevated (coherent II/III); NG partners present.*

(iii) Emergent (QIII).
Law heals with ℓ; $v^{(LS)}_{\mathrm{Synthesis}}$ *grows monotonically along r; Ward divergence $\to 0$; no NG/pNG.*

(iv) Explicit (QIV).
Persistent law deficit; $v^{(LS)}_{\mathrm{Agreement}}$ *elevated (coherent I/IV); pNG/GMOR on $\mathfrak{P}$; analytic shifts in $S^R/M^{(\ell)}$.*

These meters are phase-sensitive, gauge-robust (Nielsen-flat), and provide conserved/slow invariants under the conditions of Section 8.2.1, thereby refining the quadrant interpretation of Proposition 8.11 without altering the canonical sector-conditioned decision rules.

The parasymmetric overlay augments the sector-conditioned fermionic diagnostics of Definition 8.10 with phase-sensitive meters, while preserving the canonical quadrant resolver of Proposition 8.11. All readings are taken on the certified bulk plateau $\mathfrak{P}$, within the physical cohomology $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$, using the same BRST-closed tags $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$. The generalized witness $\mathbf{W}^{[\mathrm{ferm}]}_{\mathrm{gen}}$ (Section 8.3) supplies the fermionic visibilities $\left(\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}}, \Lambda^{[\mathrm{ferm}]}_{\mathrm{state}}\right)$ together with Ward and spectral ledgers (retarded propagator S^R, tagged wave operator $\mathcal{D}^{(\ell)}$, tagged mass/mixing $M^{(\ell)}$, sources $\mathcal{S}_{k,a}$). A fermionic calibration $\kappa^{[\mathrm{ferm}]}$ (the sector instance of Section 8.2.1) maps these data to local and relational "Sym/Break" density operators, from which the parasymmetric valuations are read; by construction they are Nielsen-flat and plateau-uniform.

A first payoff is the disentangling of *cause* versus *effect* in fermionic symmetry breaking. When the law is intact while the state selects a broken phase (QII: $\Lambda^{[\mathrm{ferm}]}_{\mathrm{law}} = 1$, $\Lambda^{[\mathrm{ferm}]}_{\mathrm{state}} = 0$), the parasymmetric state meter relaxes to the mixture baseline, $v^{(S)[\mathrm{ferm}]}_{\mathrm{Synthesis}} \to \frac{1}{2}$, reflecting incoherent occupation of broken sectors by the state, whereas the relational "opposition" meter is elevated, $v^{(LS)[\mathrm{ferm}]}_{\mathrm{Synthesis}} \gtrsim \frac{1}{2} + \tau_{\mathrm{syn}}$, indicating coherent population of the II/III diagonal

(law–state tension). In contrast, under explicit breaking (QIV: a plateau-stable law deficit with $\Lambda_{\text{state}}^{[\text{ferm}]} = 1$), the "agreement'' meter is elevated, $v_{\text{Agreement}}^{(LS)[\text{ferm}]} \gtrsim \frac{1}{2} + \tau_{\text{agr}}$, diagnosing coherent occupation of the I/IV diagonal without requiring enhanced local "bothness". Thus, parasymmetry discriminates *coherent opposition* (SSB) from *coherent agreement* (explicit breaking) even when finite-scale visibilities alone could be ambiguous.

The overlay aligns the quadrant labels with *mechanism-specific spectral fingerprints* in the fermionic ledgers. In QII, the improved current remains conserved while S^R exhibits Nambu–Goldstone partners in the correlational channel; upon gauging, this strength migrates to BEH masses, preserving the diagnosis. In QIV, the Ward source persists on $\mathfrak{P}$ and the spectrum presents a pseudo–Nambu–Goldstone (GMOR-type) band together with analytic shifts in $M^{(\ell)}$, directly visible in the pole structure and residues of S^R. In the emergent case QIII (finite-scale explicit breaking that heals), no NG/pNG modes appear and the adjoint divergence vanishes along the fermionic IR knob $r = \ell$, matching a coherent rise of the relational synthesis meter. Parasymmetry does not replace spectral analysis; rather, it renders the QI–QIV labels *explainable* in fermionic terms by tying coherence patterns to Ward/spectral content.

A further advantage is the ability to *track IR healing versus persistence* with a phase-aware dial. Along $r = \ell$, the healing predicate $d_{\text{law}}^{[\text{ferm}]}(\ell) \downarrow$ that defines QIII is mirrored by a monotone increase of $v_{\text{Synthesis}}^{(LS)[\text{ferm}]}$, signalling coherent reconvergence of law and state as the IR window widens; any deficit in $v_{\text{Agreement}}^{(LS)[\text{ferm}]}$ shrinks to $o(1)$. Conversely, in QIV the agreement meter remains persistently high on $\mathfrak{P}$, commensurate with a plateau-stable law deficit. This differential behavior provides a direct, quantitative separation between "nearly explicit but heals'' (QIII) and "truly explicit'' (QIV).

The parasymmetric meters also supply *quality-control invariants* that are robust under admissible retunings. When the relevant projectors commute with the unified parasymmetric generator (or satisfy $\mathcal{L}^\dagger(P) = 0$ in an open-system description), both local and relational meters are conserved or evolve slowly on $\mathfrak{P}$. Any unexpected drift thus functions as an audit signal for boundary leakage, numerical artefacts, or mis-tagged witnesses. Because all readings are taken on $\mathcal{H}_{\text{phys}}$ with BRST-closed tags, they inherit gauge-fermion independence and respect cone preservation, ensuring portability across bulk, boundary, and anisotropic implementations (Section 8.1).

Operationally, the construction furnishes a *practical wiring diagram* for fermions. A plateau-normalized law–state cross-coherence,

$$\rho_{12}^{(LS)[\text{ferm}]} \propto \frac{\left\langle \text{Src}^{(\text{ferm})},\ \mathcal{O}_{\text{ferm}} \right\rangle_{\mathfrak{P}}}{\sqrt{\langle \text{Src}^{(\text{ferm})}, \text{Src}^{(\text{ferm})} \rangle_{\mathfrak{P}}\ \langle \mathcal{O}_{\text{ferm}}, \mathcal{O}_{\text{ferm}} \rangle_{\mathfrak{P}}}},$$

with $\mathcal{O}_{\text{ferm}}$ a tagged order operator (e.g. chiral), populates the relational off-diagonal used by

$$v_{\text{Synthesis}}^{(LS)[\text{ferm}]} = \tfrac{1}{2} + \text{Re}\ \rho_{12}^{(LS)[\text{ferm}]}, \qquad v_{\text{Agreement}}^{(LS)[\text{ferm}]} = \tfrac{1}{2} + \text{Re}\ \rho_{\Phi,12}^{(LS)[\text{ferm}]}.$$

The local state meter follows from the reduced, tagged fermionic block, $v_{\text{Synthesis}}^{(S)[\text{ferm}]} = \frac{1}{2} + \text{Re}\ \rho_{12}^{(S)}$, approaching $\frac{1}{2}$ in SSB; a law-aligned local meter is defined analogously from the improved current sector. This recipe is reproducible, tag-compatible, and consistent with the generalized witness interface of Section 8.3.

In summary, the parasymmetric overlay turns the fermionic visibilities and spectral data into *reliable, phase-aware diagnostics*. It cleanly separates state-driven (QII) from dynamics-driven (QIV) breaking, quantifies coherence at finite scale via the baseline $v = \frac{1}{2}$, reveals IR emergence (QIII) through monotone coherence growth, and provides conserved or slow meters suitable for ongoing audits on $\mathfrak{P}$. All of these enhancements refine, but do not alter, the quadrant rules and sector-conditioned decision procedures of Proposition 8.11 and Section 8.1.

8.5.3 Parasymmetric Overlay of Supersymmetry (SUSY)

Idea in one sentence. Think of supersymmetry (SUSY) diagnostics as a mechanic's dashboard for the cosmos. The parasymmetric overlay adds two phase–aware dials that show whether the *law* and the *state* are moving in *harmony* or in *tension*, and thereby reveal *how* SUSY is broken.

Setting (where the dashboard is read). Readouts are taken on a certified plateau $\mathfrak{P}$ (or boundary $\mathfrak{P}_\partial$) with the IR knob r (bulk: $r{=}\ell$, boundary: $r{=}L$), in the BRST–safe physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$; see Section 8.1 and Definition 8.12. This makes the numbers *Nielsen–flat* (insensitive to gauge-fermion retunings) and thus trustworthy.

Two suspects behind broken symmetry. *Spontaneous* SUSY breaking: the law is symmetric, the state *chooses* a direction (like a generalized eigen-operator pair falling). *Explicit* SUSY breaking: the law itself carries an asymmetry (fine print in the rule).

The basic dials (visibilities) and the overlay. SUSY supplies two visibilities $\Lambda_{\text{law}}^{[\text{SUSY}]}$ and $\Lambda_{\text{state}}^{[\text{SUSY}]}$ (both in $[0,1]$). These dials place the situation in the QI–QIV table (Proposition 8.14). The parasymmetric overlay (Section 8.2.1) then adds two *coherence* meters, built from density operators $\rho^{(L/S/LS)[\text{SUSY}]}$ via a calibration $\kappa^{[\text{SUSY}]}$:

$$\underbrace{v_{\text{Agreement}}^{(LS)[\text{SUSY}]}}_{\text{Harmony}} \text{ (coherent I/IV)}, \qquad \underbrace{v_{\text{Synthesis}}^{(LS)[\text{SUSY}]}}_{\text{Tension}} \text{ (coherent II/III)}.$$

Normalization is universal: 1 = coherent "both/and", 1/2 = incoherent mixture baseline, 0 = coherent "anti–both".

How to read the dashboard (high-level map).

Why the dials track real physics. The meters are wired to SUSY's Ward and spectral ledgers (Definition 8.12): *Tension high (QII/QIII)* lines up with NG channels (global) or the super–Higgs pattern (local, massive gravitino), and with vanishing adjoint divergence as emergence sets in (QIII). *Harmony high (QI/QIV)* lines up with conserved/improved currents (QI) or persistent adjoint–covariant sources and pseudo–NG scaling when breaking is explicit (QIV).

Figure 8.1: The parasymmetric diagnostic map, correlating visibilities (Λ) with coherence meter readings and their physical fingerprints across the four quadrants of symmetry realization.

Quadrant	**What visibilities say**	**What the meters confirm**
QI (symmetric)	$\lvert\Lambda_{\text{law}}\rvert \approx 1$, $\lvert\Lambda_{\text{state}}\rvert \approx 1$	*Harmony* is high, indicating coherent agreement. The associated supercurrent is conserved and no Nambu–Goldstone (NG) or pseudo-NG (pNG) modes appear.
QII (spontaneous)	$\lvert\Lambda_{\text{law}}\rvert \approx 1$, $\lvert\Lambda_{\text{state}}\rvert \approx 0$	*Tension* is high, indicating coherent opposition. The local state "bothness" collapses to the mixture baseline ($\to \frac{1}{2}$). The physical signature is a goldstino or the super-Higgs mechanism (Lemma 8.13).
QIII (emergent)	The law deficit heals along the IR knob r.	*Tension* meter *rises* monotonically as the symmetry heals with r. The Ward divergence vanishes, and no NG/pNG modes are present.
QIV (explicit)	The law deficit persists on the certified plateau $\mathfrak{P}$.	*Harmony* is high. A persistent boundary or source term is present in the Ward identity, and a pseudo-goldstino is possible.

IR knob intuition (seeing healing vs persistence). Turning the IR knob r widens the view from short to long distances. If the law deficit *heals* (QIII), the *tension* meter $v^{(LS)}_{\text{Synthesis}}(r)$ climbs monotonically up to $o(1)$, showing the law and state coherently re–align. If the deficit *persists* (QIV), the *harmony* meter stays high on $\mathfrak{P}$—the law and state coherently agree on the breaking.

Operational recipe. (1) Place the point in QI–QIV with $\left(\Lambda^{[\text{SUSY}]}_{\text{law}}, \Lambda^{[\text{SUSY}]}_{\text{state}}\right)$ (Proposition 8.14). (2) Compute $v^{(LS)}_{\text{Agreement}}$, $v^{(LS)}_{\text{Synthesis}}$ (and the local state dial if needed). (3) Match the elevated meter to the expected spectral channel (goldstino vs super–Higgs vs pseudo–goldstino). (4) Vary r to confirm *healing* (QIII: tension $\nearrow$) vs *persistence* (QIV: harmony $\uparrow$ steady); cf. Definition 8.131.

The overlay turns "Is SUSY broken?" into "*How* is it broken—and *who* is responsible?" *Harmony* (I/IV) signals explicit or intact laws; *tension* (II/III) signals spontaneous selection or emergent reconvergence. Because the dials are read on a certified plateau and are Nielsen–flat, they serve as stable, audit–ready guides from abstract symmetry talk to concrete, searchable signatures (goldstino, super–Higgs, pseudo–NG).

Setup (SUSY sector; same instrumentation). Work on a certified plateau $\mathfrak{P}$ and in the physical sector $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ with BRST-closed tags $P_x(\lambda_{\text{UV}})$, $K^{(\ell)}_{\text{IR}}$, as in Definition 8.12. The SUSY witness delivers the sector visibilities $\left(\Lambda^{[\text{SUSY}]}_{\text{law}}, \Lambda^{[\text{SUSY}]}_{\text{state}}\right) \in [0,1]^2$ together with a SUSY Ward ledger (improved supercurrent S^{μ}_{α}, tagged sources $Y_{j,\alpha}$) and spectral diagnostics (global: goldstino channel; local: gravitino/super-Higgs channel). Parasymmetry adds phase-sensitive meters that corroborate the quadrant assignment of Proposition 8.14 and explain it in terms of coherent *agreement* (I/IV diagonal) or coherent *opposition* (II/III diagonal) between law and state.

Definition 8.127 (SUSY parasymmetric calibration and densities)**.** A *SUSY parasymmetric calibration* is a completely positive, trace-preserving map

$$\kappa^{[\text{SUSY}]}: \left(\Lambda^{[\text{SUSY}]}_{\text{law}}, \Lambda^{[\text{SUSY}]}_{\text{state}};\ \mathcal{W}^{[\text{SUSY}]}, \mathcal{Z}^{[\text{SUSY}]}\right) \longrightarrow \left(\rho^{(L)[\text{SUSY}]},\ \rho^{(S)[\text{SUSY}]},\ \rho^{(LS)[\text{SUSY}]}\right),$$

where $\rho^{(L)[\text{SUSY}]}, \rho^{(S)[\text{SUSY}]} \in \mathsf{D}(\mathbb{C}^2)$ are local "Sym/Break" densities for the *law* and *state* anchors, and $\rho^{(LS)[\text{SUSY}]} \in \mathsf{D}(\mathbb{C}^2 \otimes \mathbb{C}^2)$ encodes the relational law–state sector. Calibration is performed on the same realized weave configuration $(\mathcal{A}, \mathfrak{P}; r; P_x, K_{\text{IR}}; \mathsf{P}_{\text{phys}})$ and inherits Nielsen flatness.

Definition 8.128 (SUSY parasymmetric meters)**.** Let $P^{(a)}_{\text{para}} = |+\rangle_a\langle+|$ $(a \in \{L, S\})$ be local parasymmetric projectors and $P^{(LS)}_{\text{para}}$ (opposition, II/III diagonal), $P^{(LS)}_{\Phi,\text{para}}$ (agreement, I/IV diagonal) be relational Bell-type projectors. Define

$$v^{(L)[\text{SUSY}]}_{\text{Synthesis}} = \text{Tr}\left(P^{(L)}_{\text{para}}\rho^{(L)[\text{SUSY}]}\right), \quad v^{(S)[\text{SUSY}]}_{\text{Synthesis}} = \text{Tr}\left(P^{(S)}_{\text{para}}\rho^{(S)[\text{SUSY}]}\right),$$

$$v^{(LS)[\text{SUSY}]}_{\text{Synthesis}} = \text{Tr}\left(P^{(LS)}_{\text{para}}\rho^{(LS)[\text{SUSY}]}\right), \qquad v^{(LS)[\text{SUSY}]}_{\text{Agreement}} = \text{Tr}\left(P^{(LS)}_{\Phi,\text{para}}\rho^{(LS)[\text{SUSY}]}\right).$$

Normalization: 1 indicates a coherent "both/and", 1/2 the incoherent mixture baseline, and 0 a coherent "anti-both".

Lemma 8.129 (Cross-coherence choices: global vs local SUSY)**.** *Let $\langle\cdot,\cdot\rangle_{\mathfrak{P}}$ be the plateau-uniform, BRST-safe seminorm. A canonical choice for the relational off-diagonal is*

$$\rho_{12}^{(LS)[\mathrm{SUSY}]} \;\propto\; \frac{\Big\langle \sum_j \epsilon_j(\ell) Y_j,\ \mathcal{O}_{\mathrm{SUSY}} \Big\rangle_{\mathfrak{P}}}{\sqrt{\Big\langle \sum_j \epsilon_j Y_j, \sum_k \epsilon_k Y_k \Big\rangle_{\mathfrak{P}}\ \langle \mathcal{O}_{\mathrm{SUSY}}, \mathcal{O}_{\mathrm{SUSY}} \rangle_{\mathfrak{P}}}},$$

with $\mathcal{O}_{\mathrm{SUSY}}$ chosen by sector:

(i) Global SUSY.
$\mathcal{O}_{\mathrm{SUSY}} = \eta_\alpha$ *(goldstino interpolating operator extracted from the supercurrent multiplet).*

(ii) Local SUSY (SUGRA).
$\mathcal{O}_{\mathrm{SUSY}} = \psi_\mu^{\parallel}$ *(longitudinal gravitino/super-Higgs channel on the background admitting a Killing spinor when unbroken).*

Then

$$v_{\mathrm{Synthesis}}^{(LS)[\mathrm{SUSY}]} = \tfrac{1}{2} + \mathrm{Re}\ \rho_{12}^{(LS)[\mathrm{SUSY}]}, \qquad v_{\mathrm{Agreement}}^{(LS)[\mathrm{SUSY}]} = \tfrac{1}{2} + \mathrm{Re}\ \rho_{\Phi,12}^{(LS)[\mathrm{SUSY}]}.$$

Quadrant-resolved narrative (parasymmetric readings for SUSY). The parasymmetric overlay refines the tolerance-form quadrants of Proposition 8.14 by reporting coherence along the I/IV vs. II/III diagonals and by aligning these with goldstino/super-Higgs diagnostics (Lemma 8.13).

QI (law intact, state unbroken). If $|\Lambda_{\mathrm{law}}^{[\mathrm{SUSY}]}| \geq 1-\varepsilon_{\mathrm{law}}$ and $|\Lambda_{\mathrm{state}}^{[\mathrm{SUSY}]}| \geq 1-\varepsilon_{\mathrm{state}}$, the agreement meter is elevated, $v_{\mathrm{Agreement}}^{(LS)[\mathrm{SUSY}]} \gtrsim \frac{1}{2} + \tau_{\mathrm{agr}}$, indicating coherent I/IV occupation. The opposition meter is near baseline unless special phases are prepared. Ward: improved supercurrent conserved; Spectrum: no goldstino/pNG; for local SUSY, a Killing spinor exists and the gravitino is massless as dictated by the background.

QII (spontaneous SUSY breaking). Assume $|\Lambda_{\mathrm{law}}^{[\mathrm{SUSY}]}| \geq 1-\varepsilon_{\mathrm{law}}$ while $|\Lambda_{\mathrm{state}}^{[\mathrm{SUSY}]}| \leq \varepsilon_{\mathrm{state}}$. Then $v_{\mathrm{Synthesis}}^{(S)[\mathrm{SUSY}]} \to \frac{1}{2}$ (the state becomes an incoherent mixture across broken SUSY sectors), and the relational *opposition* meter is elevated, $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{SUSY}]} \gtrsim \frac{1}{2} + \tau_{\mathrm{syn}}$ (coherent II/III diagonal). Global SUSY: a massless goldstino appears (NG of SUSY). Local SUSY: the super-Higgs mechanism eats the goldstino and renders the gravitino massive; no physical massless goldstino remains (Lemma 8.13).

QIII (emergent SUSY). If the explicit SUSY-breaking source heals with the IR knob r (e.g. $1-|\Lambda_{\mathrm{law}}^{[\mathrm{SUSY}]}(\ell)| \leq C\,\ell^{\Delta-(d+z)}$ as $\ell \downarrow 0$) while $|\Lambda_{\mathrm{state}}^{[\mathrm{SUSY}]}| \geq 1-\varepsilon_{\mathrm{state}}$, then $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{SUSY}]}$ increases monotonically along r up to $o(1)$, reflecting coherent reconvergence of law and state; any deficit in $v_{\mathrm{Agreement}}^{(LS)[\mathrm{SUSY}]}$ shrinks. Ward: adjoint divergence $\to 0$ along r; Spectrum: no NG/pNG.

QIV (explicit SUSY breaking; persistent). If there exists $\delta_\star > \varepsilon_{\mathrm{law}}$ with $|\Lambda_{\mathrm{law}}^{[\mathrm{SUSY}]}| \leq 1-\delta_\star$ uniformly on $\mathfrak{P}$ and $|\Lambda_{\mathrm{state}}^{[\mathrm{SUSY}]}| \geq 1-\varepsilon_{\mathrm{state}}$, the agreement meter is elevated, $v_{\mathrm{Agreement}}^{(LS)[\mathrm{SUSY}]} \gtrsim \frac{1}{2} + \tau_{\mathrm{agr}}$ (coherent I/IV diagonal), while $v_{\mathrm{Synthesis}}^{(LS)[\mathrm{SUSY}]}$ need not be large. Ward: adjoint–covariant source persists on $\mathfrak{P}$; Spectrum: no true goldstino; in global models with small explicit breaking, a pseudo-goldstino band may appear (GMOR-type scaling on $\mathfrak{P}$); in local SUSY, the super-Higgs pattern remains controlled by the background and couplings.

Proposition 8.130 (SUSY quadrant–parasymmetry correspondence)**.** *Let* $\tau_{\mathrm{agr}}, \tau_{\mathrm{syn}} \in (0, \frac{1}{2})$ *be fixed sector thresholds. On any certified plateau component:*

$$\begin{aligned} \text{QI } \textit{or } \text{QIV} &\implies v^{(LS)[\mathrm{SUSY}]}_{\mathrm{Agreement}} \geq \tfrac{1}{2} + \tau_{\mathrm{agr}}, \\ \text{QII } \textit{or } \text{QIII} &\implies v^{(LS)[\mathrm{SUSY}]}_{\mathrm{Synthesis}} \geq \tfrac{1}{2} + \tau_{\mathrm{syn}}. \end{aligned}$$

In QII the local state meter satisfies $v^{(S)[\mathrm{SUSY}]}_{\mathrm{Synthesis}} \to \frac{1}{2}$ *as the volume grows, while in QIII the relational synthesis meter increases along* r *in tandem with the healing of* $\Lambda^{[\mathrm{SUSY}]}_{\mathrm{law}} \to 1$*. These coherence statements refine, but do not alter, Proposition 8.14.*

Definition 8.131 (Operational overlay (SUSY, SynTh + parasymmetry))**.** Given [SUSY] on $(\mathcal{A}, \mathfrak{P}; r)$, proceed as follows:

(i) Quadrant assignment.
Assign QI–QIV by $\mathcal{R}^{[\mathrm{SUSY}]}$ using Definition 8.12 and Proposition 8.14.

(ii) Calibration and meters.
Calibrate $\kappa^{[\mathrm{SUSY}]}$ and compute $v^{(L)}_{\mathrm{Synthesis}}$, $v^{(S)}_{\mathrm{Synthesis}}$, $v^{(LS)}_{\mathrm{Synthesis}}$, and $v^{(LS)}_{\mathrm{Agreement}}$ on $\mathfrak{P}$.

(iii) Coherence interpretation.
Interpret elevated meters using Proposition 8.130: I/IV (agreement) versus II/III (opposition); detect local mixture baselines at 1/2.

(iv) Ward/spectral cross-checks.
Cross-check ledgers: (QII global) goldstino; (QII local) super-Higgs with massive gravitino; (QIV) persistent adjoint source and possible pseudo-goldstino scaling; (QIII) vanishing divergence, no NG/pNG.

(v) Steering via meter trends.
Use meter trends for steering: monitor $v^{(LS)}_{\mathrm{Synthesis}}(r)$ for emergent SUSY (QIII) and persistent $v^{(LS)}_{\mathrm{Agreement}}$ for explicitness (QIV).

Remark 8.132 (Consequences and advantages.)**.** Parasymmetry renders SUSY-breaking diagnostics *phase-aware*: it separates coherent opposition (SSB) from coherent agreement (explicit), quantifies finite-scale coherence via the 1/2 baseline, and provides conserved/slow meters under suitable generators on $\mathfrak{P}$. Because all constructions are BRST-safe and Nielsen-flat, the meters are stable under benign retunings and portable across backgrounds (global vs local SUSY), while remaining fully compatible with the sector-conditioned resolver of Proposition 8.14.

The parasymmetric overlay for supersymmetry complements the sector-conditioned witnesses of Definition 8.12 by adding phase-sensitive meters that certify how the "law" and the "state" co-occupy the generalized 2×2 grid on a certified plateau $\mathfrak{P}$, after projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ [52, 82, 91]. The canonical resolver of Proposition 8.14 still determines the quadrant (QI–QIV) from the SUSY visibilities $\left(\Lambda^{[\mathrm{SUSY}]}_{\mathrm{law}}, \Lambda^{[\mathrm{SUSY}]}_{\mathrm{state}}\right)$, but the parasymmetric meters—local "bothness" and relational agreement/opposition as in Section 8.2.1—explain *why* a given point sits where it does by revealing coherent *agreement* (I/IV diagonal) versus coherent *opposition* (II/III diagonal) and by distinguishing coherent structure from mere statistical mixtures (baseline 1/2).

A first conceptual dividend is a clean separation of *cause* and *effect* in SUSY breaking. In the spontaneously broken case (QII), the law is intact while the state fails the tolerance test; correspondingly the local state "bothness'' meter relaxes to the mixture baseline $v^{(S)[\mathrm{SUSY}]}_{\mathrm{Synthesis}} \to \frac{1}{2}$, indicating that the state populates broken sectors incoherently, whereas the relational opposition meter is elevated $v^{(LS)[\mathrm{SUSY}]}_{\mathrm{Synthesis}} \geq \frac{1}{2} + \tau_{\mathrm{syn}}$, signaling coherent occupancy of the II/III diagonal. This coherence pattern matches the mechanism: a goldstino appears in global SUSY, while in local SUSY the super-Higgs effect eats the goldstino and renders the gravitino massive (Lemma 8.13) [92, 94, 91, 52]. In the explicitly broken case (QIV), a plateau-stable law deficit coexists with a symmetric state; the elevated agreement meter $v^{(LS)[\mathrm{SUSY}]}_{\mathrm{Agreement}} \geq \frac{1}{2} + \tau_{\mathrm{agr}}$ then certifies coherent I/IV occupancy without requiring large local "bothness". In global models with small explicit breaking, a pseudo-goldstino (GMOR-type) band may appear on $\mathfrak{P}$ [112, 102]. Thus, identical magnitudes $\big(|\Lambda_{\mathrm{law}}|, |\Lambda_{\mathrm{state}}|\big)$ at finite scale can conceal different phase structures that parasymmetry makes explicit: coherent opposition for QII versus coherent agreement for QIV.

The overlay also aligns quadrant labels with mechanism-specific spectral diagnostics. In QII the improved supercurrent is conserved and the spectrum exhibits either a massless goldstino (global) or, in the local case, a massive gravitino produced by the super-Higgs mechanism; in QIV the SUSY Ward source persists on $\mathfrak{P}$ and the spectrum may show pseudo–NG scaling in the SUSY channel; in QIII no NG/pNG modes occur and the adjoint divergence tends to zero along the sector IR knob, consistent with emergent symmetry [52, 91, 112]. Parasymmetry does not replace spectral analysis; rather, it renders the QI–QIV labels *explainable* in SUSY terms by tying an elevated coherence meter to the appropriate Ward/spectral feature.

A further advantage is a phase-aware view of *healing versus persistence*. In the emergent regime QIII, the healing predicate $1 - |\Lambda^{[\mathrm{SUSY}]}_{\mathrm{law}}(r)| \downarrow$ along the IR knob is mirrored by a monotone increase of the relational synthesis meter $v^{(LS)[\mathrm{SUSY}]}_{\mathrm{Synthesis}} \nearrow$ up to $o(1)$, while any shortfall in the agreement meter shrinks; this documents coherent reconvergence of law and state as the IR window widens, in line with the general RG picture of emergent symmetries [112, 102]. In contrast, QIV exhibits a persistently high agreement meter on $\mathfrak{P}$, matching the plateau-stable source and distinguishing truly explicit breaking from nearly explicit deformations that eventually heal.

The meters themselves serve as robust audit invariants. Under generators commuting with the parasymmetric projectors—or, in open dynamics, whenever $\mathcal{L}^\dagger(P) = 0$—both local and relational meters are conserved or slow on $\mathfrak{P}$. Any unexpected drift therefore signals boundary leakage, mis-instrumentation, or witness mis-tagging. Because all readouts are taken with BRST-closed tags on $\mathcal{H}_{\mathrm{phys}}$, the numbers are Nielsen-flat and transport across global versus local SUSY backgrounds without spurious gauge dependence, preserving the sector portability emphasized in Section 8.2.1 [82, 91, 52].

For practice, fixed sector thresholds $\tau_{\mathrm{agr}}, \tau_{\mathrm{syn}} > 0$ yield a compact rule-of-thumb. Elevated agreement ($v^{(LS)}_{\mathrm{Agreement}} \geq \frac{1}{2} + \tau_{\mathrm{agr}}$) characterizes QI/QIV (I/IV diagonal), whereas elevated opposition ($v^{(LS)}_{\mathrm{Synthesis}} \geq \frac{1}{2} + \tau_{\mathrm{syn}}$) characterizes QII/QIII (II/III diagonal). Additionally, QII displays the finite-volume signature $v^{(S)}_{\mathrm{Synthesis}} \to \frac{1}{2}$ as the state becomes an incoherent mixture, and QIII displays $v^{(LS)}_{\mathrm{Synthesis}}(r)$ increasing with the IR knob as the law heals. These signatures

refine, but do not alter, the tolerance-form quadrant assignment of Proposition 8.14.

In summary, the SUSY parasymmetric overlay cleanly separates spontaneous from explicit breaking through coherence structure (opposition versus agreement), ties these patterns to goldstino/super-Higgs or pseudo–NG spectral content, tracks emergent behavior via monotone coherence growth, and provides gauge-robust, audit-ready meters on the certified plateau [52, 91, 112, 102]. The result is a resolver-compatible, mechanism-explanatory portrait of SUSY phases that remains stable under admissible retunings while offering actionable diagnostics for analysis and control.

8.5.4 Parasymmetric Overlay of Boundary Soft/Edge Modes

We now turn to a natural and powerful extension of the *parasymmetric overlay* to a third, richer setting: boundary soft/edge modes. The central advance is methodological rather than merely topical: the framework now operates in a *multi-sector arena*, diagnosing the symmetry story of the bulk (interior) and the boundary (edge) on their respective certified plateaus, $\mathfrak{P}$ and $\mathfrak{P}_\partial$, and then *reconciling* them within a single, coherent construction [112, 102]. The result is a phase-aware, instrument-grade diagnostic that treats edges not as afterthoughts but as first-class loci of symmetry phenomena.

The dashboard readers introduced earlier carry over intact, but the physics at an edge is distinctive. Boundaries can host special modes—soft waves with long memory, chiral currents that carry protected flow, and other excitations absent in the interior [450, 102]. The question is no longer only whether an edge mode is present; it is how the governing symmetry is realised *at the edge* and how that realisation relates to the bulk. In practical terms, the framework offers a precise way to diagnose and explain the symmetry principles behind edge behaviour, rather than merely recording its existence [112, 102].

The bulk–boundary unification is achieved by analysing the two regions *simultaneously*: the Bulk Plateau $\mathfrak{P}$ with IR knob $r = \ell$, and the Boundary Plateau $\mathfrak{P}_\partial$ with tangential IR knob $r = L$. Treating them together enables questions that previously fragmented the analysis: for instance, what to conclude when a symmetry is perfectly respected in the bulk yet appears broken at the boundary. The joint resolver on the certified intersection $\mathfrak{P} \cap \mathfrak{P}_\partial$ provides a common arena for decision, converting apparent contradictions into a coherent diagnosis that localises mechanisms and prescribes which knob (e.g. L vs. ℓ) should be varied [112, 102].

On the boundary, the familiar toolkit is specialised but not reinvented. A calibration map $\kappa^{[\partial]}$ translates edge data into the same trio of density operators, $\rho^{(L)[\partial]}$, $\rho^{(S)[\partial]}$, and $\rho^{(LS)[\partial]}$, that encode the law anchor, the state anchor, and their relation, in the spirit of the general parasymmetric synthesis of law and state Section 8.2.1. Two coherence meters then read the law–state geometry at the boundary: the *harmony* dial $v^{(LS)[\partial]}_{\text{Agreement}}$ (coherent I/IV diagonal, elevated in QI and QIV) and the *tension* dial $v^{(LS)[\partial]}_{\text{Synthesis}}$ (coherent II/III diagonal, elevated in QII and QIII). The normalisation is universal—1 for a coherent both/and signal, 1/2 for an incoherent mixture baseline, 0 for a coherent anti-signal—and all readings are taken on $\mathfrak{P}_\partial$ with BRST-closed tags and projection to $\mathcal{H}_{\text{phys}}$, ensuring Nielsen-flat, audit-ready numbers [82, 91, 112].

This specialisation yields concrete payoffs for boundary physics. First, it delivers a clear,

phase-aware edge diagnosis: spontaneous breaking at the boundary (QII) appears as elevated tension, with the local state "bothness" relaxing to the mixture baseline $v^{(S)[\partial]}_{\text{Synthesis}} \to \frac{1}{2}$ as edge extent grows, and it is physically accompanied by edge Goldstone modes such as chiral currents [94, 102]. By contrast, explicit breaking at the boundary (QIV) exhibits a persistently high harmony reading and aligns with pseudo–Nambu–Goldstone (GMOR-type) bands in the boundary spectrum [112, 102]. Second, it provides a controllable dial for testing: the size L acts as a direct IR knob. Emergent edge symmetry (QIII) can be demonstrated by increasing L and observing the tension meter $v^{(LS)[\partial]}_{\text{Synthesis}}(L)$ rise monotonically while the boundary Ward source heals, $1 - |\Lambda^{[\partial]}_{\text{law}}(L)| \downarrow\sim L^{-\beta}$, in line with the general emergent-symmetry picture in effective field theory [112]. When breaking is explicit (QIV), the harmony dial remains stably high as L grows, tracking a plateau-persistent source.

Perhaps most importantly, bulk–boundary puzzles become solvable rather than vexing. With the joint resolver, situations like "bulk QI but boundary QII/QIV" are recognised not as inconsistencies but as *localised edge mechanisms*. The coherence profile—harmony versus tension—certifies whether an observed split is a genuine physical effect confined to the boundary or a transient artefact of mismatched arenas, and it guides the necessary reconciliation of knobs until a stable QIII/QIV distinction is reached [112, 102].

In summary, bringing boundary modes into the parasymmetric dashboard advances the framework from single-sector checks to a *multi-sector diagnostic* capable of seeing a whole physical system holistically. It independently diagnoses bulk and boundary symmetry structure with the same, sector-conditioned dials; it connects those diagnoses to observable edge phenomena such as currents, soft modes, and memory effects [450, 102]; and it reconciles apparent contradictions through a unified, phase-aware reading. In doing so, it shows that the parasymmetric overlay scales from the heart of a system to its very edges, turning subtle boundary lore into a coherent, testable story told by harmony, tension, and the single, tangible knob L.

Setup (boundary sector; same instrumentation). Work on the certified boundary plateau $\mathfrak{P}_\partial$ with tangential IR window $K^{(L)}_{\text{IR},\partial}$ and IR knob $r{=}L$, evaluate in $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ with BRST–closed tags $P_x(\lambda_{\text{UV}})$, and adopt the boundary witnesses of Definition 8.31. Thus the edge dials are $\left(\Lambda^{[\partial]}_{\text{law}}(L), \Lambda^{[\partial]}_{\text{state}}\right) \in [0,1]^2$, and the ledgers consist of the *edge Ward ledger* (large–gauge/asymptotic charges, improved boundary current $J^{(\partial)}_{\parallel}$) and the *edge spectral ledger* (soft/edge poles, residues $Z \succeq 0$, memory signals). Parasymmetry overlays these inputs with phase–sensitive meters while preserving the quadrant resolver of Proposition 8.32.

Definition 8.133 (Boundary parasymmetric calibration and densities)**.** A *boundary parasymmetric calibration* is a completely positive, trace–preserving map

$$\kappa^{[\partial]} : \left(\Lambda^{[\partial]}_{\text{law}}(L), \Lambda^{[\partial]}_{\text{state}};\ \mathcal{W}^{[\partial]}, \mathcal{Z}^{[\partial]}\right) \longrightarrow \left(\rho^{(L)[\partial]},\ \rho^{(S)[\partial]},\ \rho^{(LS)[\partial]}\right),$$

where $\rho^{(L)[\partial]}, \rho^{(S)[\partial]} \in \mathsf{D}(\mathbb{C}^2)$ encode local "Sym/Break" content for the *law* and *state* anchors at the boundary, and $\rho^{(LS)[\partial]} \in \mathsf{D}(\mathbb{C}^2 \otimes \mathbb{C}^2)$ encodes relational law–state boundary content. Calibration is performed on $(\mathfrak{P}_\partial; L; P_x, K^{(L)}_{\text{IR},\partial}; \mathsf{P}_{\text{phys}})$ and is Nielsen–flat by BRST closure.

Definition 8.134 (Boundary parasymmetric meters)**.** Let $P^{(a)}_{\mathrm{para}} = |+\rangle_a\langle+|$ $(a \in \{L, S\})$ be local parasymmetric projectors, and $P^{(LS)}_{\mathrm{para}}$ (coherent *opposition*, II/III diagonal) and $P^{(LS)}_{\Phi,\mathrm{para}}$ (coherent *agreement*, I/IV diagonal) be Bell–type projectors on the relational space. Define:

$$v^{(L)[\partial]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(L)}_{\mathrm{para}}\rho^{(L)[\partial]}\Big), \quad v^{(S)[\partial]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(S)}_{\mathrm{para}}\rho^{(S)[\partial]}\Big),$$

$$v^{(LS)[\partial]}_{\mathrm{Synthesis}} = \mathrm{Tr}\Big(P^{(LS)}_{\mathrm{para}}\rho^{(LS)[\partial]}\Big), \qquad v^{(LS)[\partial]}_{\mathrm{Agreement}} = \mathrm{Tr}\Big(P^{(LS)}_{\Phi,\mathrm{para}}\rho^{(LS)[\partial]}\Big).$$

Normalization: 1 indicates a coherent "both/and", 1/2 the incoherent mixture baseline, and 0 a coherent "anti–both''.

Lemma 8.135 (Boundary cross–coherence (soft/edge channels))**.** *Let $\langle\cdot,\cdot\rangle_{\mathfrak{P}_\partial}$ be a plateau–uniform, BRST–safe seminorm. A canonical relational off–diagonal is*

$$\rho^{(LS)[\partial]}_{12} \;\propto\; \frac{\big\langle S_\partial,\ \mathcal{O}_\partial\big\rangle_{\mathfrak{P}_\partial}}{\sqrt{\langle S_\partial, S_\partial\rangle_{\mathfrak{P}_\partial}\ \langle \mathcal{O}_\partial, \mathcal{O}_\partial\rangle_{\mathfrak{P}_\partial}}},$$

where $\mathcal{O}_\partial$ is an edge operator matched to the Ward/spectral ledger (e.g. chiral edge current, soft charge density, or memory/vertex operator). Then

$$v^{(LS)[\partial]}_{\mathrm{Synthesis}} = \tfrac{1}{2} + \mathrm{Re}\ \rho^{(LS)[\partial]}_{12}, \qquad v^{(LS)[\partial]}_{\mathrm{Agreement}} = \tfrac{1}{2} + \mathrm{Re}\ \rho^{(LS)[\partial]}_{\Phi,12}.$$

Proposition 8.136 (Boundary quadrant–parasymmetry correspondence)**.** *Fix thresholds $\tau_{\mathrm{agr}}, \tau_{\mathrm{syn}} \in (0, \frac{1}{2})$. On any certified boundary plateau component:*

$$\begin{aligned} \mathrm{QI}\ \textit{or}\ \mathrm{QIV} &\implies v^{(LS)[\partial]}_{\mathrm{Agreement}} \ \geq\ \tfrac{1}{2} + \tau_{\mathrm{agr}} \quad (\textit{coherent I/IV diagonal}),\\ \mathrm{QII}\ \textit{or}\ \mathrm{QIII} &\implies v^{(LS)[\partial]}_{\mathrm{Synthesis}} \ \geq\ \tfrac{1}{2} + \tau_{\mathrm{syn}} \quad (\textit{coherent II/III diagonal}). \end{aligned}$$

Moreover: (i) in boundary–QII, $v^{(S)[\partial]}_{\mathrm{Synthesis}} \to \frac{1}{2}$ with increasing boundary extent (local mixture baseline; edge Goldstone present); (ii) in boundary–QIII, $v^{(LS)[\partial]}_{\mathrm{Synthesis}}(L)$ increases monotonically up to $o(1)$ as $d^{[\partial]}_{\mathrm{law}}(L)\downarrow$; (iii) in boundary–QIV, $v^{(LS)[\partial]}_{\mathrm{Agreement}}$ remains persistently elevated and the edge spectral ledger exhibits a pNG band on $\mathfrak{P}_\partial$.

Definition 8.137 (Operational overlay (boundary, SynTh + parasymmetry))**.** Given $\mathfrak{P}_\partial$ and L, proceed as follows:

(i) Quadrant assignment.
Assign QI–QIV via $\mathcal{R}^{[\partial]}$ using Definition 8.31 and Proposition 8.32.

(ii) Calibration and meters.
Calibrate $\kappa^{[\partial]}$ and compute $v^{(L)[\partial]}_{\mathrm{Synthesis}}$, $v^{(S)[\partial]}_{\mathrm{Synthesis}}$, $v^{(LS)[\partial]}_{\mathrm{Synthesis}}$, and $v^{(LS)[\partial]}_{\mathrm{Agreement}}$.

(iii) Coherence interpretation.
Use $\tau_{\mathrm{agr}}, \tau_{\mathrm{syn}}$ to call elevated meters and identify the occupied diagonal (I/IV vs II/III); detect local "bothness'' via the 1/2 baseline.

(iv) Ward/spectral cross-checks.
Cross–check ledgers: (QII) edge Goldstone and conserved improved edge current; (QIV) persistent boundary source with pNG band; (QIII) vanishing adjoint divergence along L and no NG/pNG.

(v) Steering via L and boundary conditions.
For steering: vary L and boundary conditions to test healing vs persistence; monitor meter conservation where the relevant projectors commute (or satisfy $\mathcal{L}^\dagger(P) = 0$).

Narrative and intuition (boundary punchline). The boundary parasymmetric overlay turns the tolerance–form witnesses of Definition 8.31 into *instrument–grade* coherence diagnostics. Explicit edge breaking (QIV) manifests as coherent *agreement* between law and state—elevated $v^{(LS)[\partial]}_{\text{Agreement}}$ on $\mathfrak{P}_\partial$—and aligns with a persistent boundary source and a pNG band in the edge spectrum. Emergent edge symmetry (QIII) is visible as a monotone rise of $v^{(LS)[\partial]}_{\text{Synthesis}}$ with L in tandem with the healing of the boundary law deficit $d^{[\partial]}_{\text{law}}(L)\downarrow$. Spontaneous edge selection (boundary–QII) presents the finite–extent signature $v^{(S)[\partial]}_{\text{Synthesis}} \to \frac{1}{2}$ with an elevated opposition meter, certifying an edge Goldstone under an intact boundary law. All meters are BRST–safe and Nielsen–flat, and therefore stable under admissible retunings of the boundary instrumentation. In multi–sector settings (bulk & boundary), the joint resolver pairs these boundary coherence profiles with the bulk ones to distinguish benign arena mismatches from genuine boundary–localized symmetry mechanisms.

8.6 Parasymmetric Diagnostics of Type, Location, and Onset (TLO)

All statements below are made on the BRST–physical sector $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$ with realized weave configuration $(P_x(\lambda_{\text{UV}}), K^{(\ell)}_{\text{IR}}; \mathsf{P}_{\text{phys}})$ on a plateau $\mathfrak{P}$ (or boundary plateau $\mathfrak{P}_\partial$), as in Sections 8.1, 8.2 and 8.2.1. Gauge/Nielsen safety and regulator robustness follow from the bandwise identities and algebraic–renormalisation arguments cited earlier. [117, 442, 114, 91]

8.6.1 Parasymmetric Meters and Laws-States Quadrant Readings

We use the local parasymmetric projectors $P^{(a)}_{\text{para}}$ and valuations $v^{(a)}_{\text{Synthesis}}(\rho_a) = \text{Tr}\big(P^{(a)}_{\text{para}}\rho_a\big) \in [0,1]$ for each anchor $a \in \{L, S\}$, together with the relational meter $v^{(LS)}_{\text{Synthesis}}$, as fixed in Section 8.2.1. In the two-mode basis $|e_1\rangle_a \equiv |\,\text{Sym}\rangle_a$, $|e_2\rangle_a \equiv |\,\text{Break}\rangle_a$, the explicit form $v^{(a)}_{\text{Synthesis}} = \frac{1}{2} + \text{Re}(\rho^{(a)}_{12})$ will be used for diagnostics.

Quadrant II (State–SSB; law $\simeq 1$)

Finite-window elevation of the *state meter*,

$$v^{(S)}_{\text{Synthesis}}(\rho_S) = \tfrac{1}{2} + \text{Re}(\rho^{(S)}_{12}) > \tfrac{1}{2},$$

with *decay to baseline* 1/2 under IR/volume dilation $r \uparrow$ (no persistent coherence), identifies state–SSB. Concomitant spectral NG content and the resolver conditions $\Lambda_{\text{law}} \simeq 1$, $\Lambda_{\text{state}}(V) \to 0$ complete the QII certification; see Section 7.10 and Lemma 8.87. [82, 91]

Quadrant IV (explicit breaking; persistent law deficit)

A *non-healing* law deficit $d_{\text{law}}^{[\mathscr{S}]}(r) \geq \delta_\star$ for all large r, together with a *baseline* state meter $v_{\text{Synthesis}}^{(S)} \approx \frac{1}{2}$ (no "cat'' coherence), and a pNG band obeying the plateau GMOR slope (eq. (7.747)), identifies explicit breaking. The parasymmetric meters record *persistence* (no decay toward the QIII baseline), in agreement with the canonical resolver of Definition 7.685.

Quadrant III (law–healing; emergent symmetry)

When the law asymmetry is *irrelevant*, cross-terms and law–state parasymmetric valuations *decay* to 1/2 with the IR knob according to the power law $d_{\text{law}}^{[\mathscr{S}]}(r) \leq Cr^{-\beta}$ (eq. (7.746)); no NG/pNG survive in the strict IR. The meters thus diagnose *healing* rather than SSB or explicit persistence.

Quadrant I (fully symmetric)

Both anchors register *baseline* values $v_{\text{Synthesis}}^{(L,S)} \approx \frac{1}{2}$, consistent with $|\Lambda_{\text{law}}| \approx |\Lambda_{\text{state}}| \approx 1$ and the symmetry-respecting census.

8.6.2 Locator Sets: "Where" the Patterns Occur

Let $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$ denote the arena (bulk/boundary) and r the IR window ($r = \ell$ in bulk, $r = L$ on the boundary). Using the sector tag $[\mathscr{S}]$ from Section 8.1, define *window-resolved loci*:

$$\mathcal{L}_{\text{SSB}}^{[\mathscr{S}]} = \Big\{(x,r) : \ |\Lambda_{\text{law}}^{[\mathscr{S}]}| \geq 1 - \varepsilon_{\text{law}},\ v_{\text{Synthesis}}^{(S)}(x;r) > \tfrac{1}{2},\ v_{\text{Synthesis}}^{(LS)}(x;r) \xrightarrow{r\uparrow} \tfrac{1}{2}\Big\},$$

$$\mathcal{L}_{\text{QIV}}^{[\mathscr{S}]} = \Big\{(x,r) : \ d_{\text{law}}^{[\mathscr{S}]}(r) \geq \delta_\star,\ v_{\text{Synthesis}}^{(S)}(x;r) \approx \tfrac{1}{2},\ v_{\text{Synthesis}}^{(LS)}(x;r) \text{ non-healing}\Big\},$$

$$\mathcal{L}_{\text{QIII}}^{[\mathscr{S}]} = \Big\{(x,r) : \ d_{\text{law}}^{[\mathscr{S}]}(r) \leq Cr^{-\beta},\ v_{\text{Synthesis}}^{(L)}(x;r) \to \tfrac{1}{2},\ v_{\text{Synthesis}}^{(LS)}(x;r) \to \tfrac{1}{2}\Big\},$$

and analogously $\mathcal{L}_{\text{QI}}^{[\mathscr{S}]}$ for the symmetric case. Because $P_x(\lambda_{\text{UV}})$ is centered at x and $K_{\text{IR}}^{(\ell)}$ sets r, scans $x \mapsto P_x$ and $r \mapsto \ell$ (or L) produce *maps* of these loci across space and scale, per sector $[\mathscr{S}]$.

8.6.3 Onset Scales and Times: "When" the Patterns Occur

Define *scale onsets* by certified tolerances $(\varepsilon_{\mathrm{law}}, \varepsilon_{\mathrm{state}})$:

$$r^\star_{\mathrm{SSB}} = \inf\{r : \ v^{(S)}_{\mathrm{Synthesis}}(r) > \tfrac{1}{2} \text{ and } v^{(LS)}_{\mathrm{Synthesis}}(r) \downarrow \tfrac{1}{2}\},$$

$$r^\star_{\mathrm{QIV}} = \inf\{r : \ d^{[\mathscr{S}]}_{\mathrm{law}}(r) \geq \delta_\star\}, \qquad r^\star_{\mathrm{QIII}} = \inf\{r : \ d^{[\mathscr{S}]}_{\mathrm{law}}(r) \leq Cr^{-\beta}\}.$$

If a dynamics generator for the relational sector is provided (e.g. $\hat{F}^{(LS)}_{\mathrm{para}}$), one may likewise define *onset times* $t^\star$ from $t \mapsto v^{(a)}_{\mathrm{Synthesis}}(t; r)$ under the same inequalities.

8.6.4 Boundary/Edge Arenas and Sector Checks

On $\mathfrak{P}_\partial$, elevated *tangential or chiral* parasymmetric valuations certify *edge Goldstones* (QII) or *edge pseudo-modes* (QIV) with small gaps; decay to baseline corroborates QIII healing. The construction is *functorial* under admissible dualities and *cone-preserving*, so it *refines* but does not alter the quadrant assignments fixed by SynTh (Section 8.2).

Proposition 8.138 (Parasymmetric resolver is quadrant-sound and gauge-safe)**.** *On the certified arena, with meters* $v^{(a)}_{\mathrm{Synthesis}}$ *and* $v^{(LS)}_{\mathrm{Synthesis}}$ *of Section 8.2.1 evaluated in* $\mathcal{H}_{\mathrm{phys}}$*, the following implications hold:*

(i) QI.
Baseline meters equal to $\frac{1}{2}$ *and symmetric visibilities imply the unbroken regime.*

(ii) QIII.
Power-law decay $d^{[\mathscr{S}]}_{\mathrm{law}}(r) \leq Cr^{-\beta}$ *and meters tending to* $\frac{1}{2}$ *imply IR healing (no NG/pNG in the strict IR).*

(iii) QII.
Elevated $v^{(S)}_{\mathrm{Synthesis}}$ *at finite* r and *decay to* $1/2$ *as* $r \uparrow$*, together with NG poles, implies state–SSB with symmetric law.*

(iv) QIV.
A non-healing law deficit and pNG gaps obeying eq. (7.747), with $v^{(S)}_{\mathrm{Synthesis}} \approx \frac{1}{2}$*, imply persistent explicit breaking.*

Moreover, all valuations are Nielsen-flat (gauge-parameter independent) on the band, and stable under admissible regulator changes within $\varepsilon_{\mathrm{reg}}$*.* □

Parasymmetry provides *meters* whose *magnitudes and large-window behavior* distinguish the four quadrants while localising *where* (bulk/boundary, sector, position) and *when* (onset scale—and, if applicable, onset time) the pattern holds:

SSB (QII)	$\Rightarrow$	elevated then decaying $v^{(S)}_{\mathrm{Synthesis}}$ (NG present),
explicit (QIV)	$\Rightarrow$	persistent law deficit with GMOR pNG gaps,
healing (QIII)	$\Rightarrow$	decay to baseline without NG/pNG,
symmetric (QI)	$\Rightarrow$	baseline throughout.

These diagnostics are *BRST/Nielsen-safe*, *cone-preserving*, and compatible with the SynTh resolver, thereby turning the conceptual 2×2 into a *workable cartography* across sectors $[\mathscr{S}]$, arenas $\mathcal{A}$, and scales r.

8.6.5 Typed Sector Witnesses and Parasymmetric Meters (Spin/Helicity/Polarization–conditioned)

All constructions in this subsection are evaluated on the BRST–physical sector $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ with realized weave configuration $(\mathcal{A}, \mathfrak{P}; r; P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}; \mathsf{P}_{\mathrm{phys}})$ as in Sections 8.1, 8.2 and 8.2.1. They preserve BRST/Nielsen safety and plateau stability by Proposition 7.644 and Theorem 7.646.

Definition 8.139 (Typed sector witness and typed state)**.** Let $[\mathscr{S}]$ be a sector with witness $\mathbf{W}^{[\mathscr{S}]}$. For a BRST–closed projector ("filter") $\Pi^{[\chi]}$ selecting a kinematic/spectral class χ (spin, helicity, polarization, chirality, or an isolated species), define

$$\mathbf{W}^{[\mathscr{S};\chi]} \;:=\; \Pi^{[\chi]}\,\mathbf{W}^{[\mathscr{S}]}\,\Pi^{[\chi]}, \qquad \rho^{[\chi]} \;:=\; \frac{\Pi^{[\chi]}\,\rho\,\Pi^{[\chi]}}{\mathrm{Tr}\big(\Pi^{[\chi]}\rho\big)} \quad (\text{on } \mathcal{H}_{\mathrm{phys}}). \tag{8.18}$$

Definition 8.140 (Typed visibilities and typed parasymmetric meters)**.** Using Definition 7.35 with $\mathbf{W}^{[\mathscr{S};\chi]}$ and $\rho^{[\chi]}$, set

$$\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}, \qquad \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}. \tag{8.19}$$

With $a \in \{L, S\}$ and $P_{\mathrm{para}}^{(a)}$ as in Section 8.2.1, define the typed parasymmetric valuations

$$v_{\mathrm{Synthesis}}^{(a);\,[\chi]}(\rho_a) \;:=\; \mathrm{Tr}\Big(P_{\mathrm{para}}^{(a)}\,\rho_a^{[\chi]}\Big) \in [0,1], \qquad v_{\mathrm{Synthesis}}^{(LS);\,[\chi]} \;\text{ analogously.} \tag{8.20}$$

Canonical filters $\Pi^{[\chi]}$ (on $\mathcal{H}_{\mathrm{phys}}$). All items below are BRST–closed and commute with $\mathsf{P}_{\mathrm{phys}}$.

(i) Spin filters. $\Pi^{[s=2]} := \Pi_{\mathrm{TT}}$ (transverse–traceless tensor), $\Pi^{[s=1]} := P_T$ (transverse vector), $\Pi^{[s=0]} := \mathbf{1}_{\mathrm{scalar}}$. These are the polarization blocks $X \in \{h_{\mathrm{TT}}, A^T, \pi\}$ used in the pole analysis.

(ii) Helicity filters (momentum–resolved). For spin–1, $\Pi^{[1,\lambda=\pm1]}(\hat{\mathbf{k}}) := |e_\pm(\hat{\mathbf{k}})\rangle\langle e_\pm(\hat{\mathbf{k}})| \subset \mathrm{Im}\,P_T$. For spin–2, $\Pi^{[2,\lambda=\pm2]}(\hat{\mathbf{k}}) := |e_{\pm2}(\hat{\mathbf{k}})\rangle\langle e_{\pm2}(\hat{\mathbf{k}})| \subset \mathrm{Im}\,\Pi_{\mathrm{TT}}$. (Implemented as covariant little–group projectors, averaged on the IR window.)

(iii) Polarization filters (hydrodynamics/elasticity). $P_L^{ij}(\hat{\mathbf{k}}) = \hat{k}^i\hat{k}^j$, $P_T^{ij}(\hat{\mathbf{k}}) = \delta^{ij} - \hat{k}^i\hat{k}^j$; shear vs. sound sub-blocks are obtained by composing $\Pi^{[\chi]}$ with the hydrodynamic witness.

(iv) Boundary tangential/chiral filters. Tangential $\Pi^{[\|]}$ on $\partial\mathcal{X}$ and chiral $\Pi^{[\chi=\pm]}$ for edge modes; compose with $\mathbf{W}^{[\partial]}$ on $\mathfrak{P}_\partial$.

(v) Isolated–pole (species) filters. For a species $\mathfrak{m}$ with an isolated pole of $\mathcal{K}_{\mathrm{phys}}$ (or $\mathcal{D}_{\mathrm{phys}}$), the Riesz projector

$$\mathcal{P}_{\mathfrak{m}} := \frac{1}{2\pi i}\oint_{C_{\mathfrak{m}}} dz\,\big(z-\mathcal{K}_{\mathrm{phys}}\big)^{-1} \tag{8.21}$$

selects that mode (mass eigenstate or narrow band). Put $\Pi^{[\chi=\mathfrak{m}]} := \mathcal{P}_{\mathfrak{m}}$ to obtain a "particle meter".

Proposition 8.141 (Gauge/Nielsen safety and analytic transport (typed))**.** *Let $\Pi^{[\chi]}$ be a BRST–closed filter as in Definition 8.139. Then the typed visibilities $\Lambda_{\bullet}^{[\mathscr{S};\chi]}$ and the typed parasymmetric valuations $v_{\mathrm{Synthesis}}^{(\cdot),[\chi]}$ are gauge–parameter independent on certified plateaux. Moreover, under small explicit deformations the corresponding spectral projectors and residue matrices vary analytically on $\mathfrak{P}$, hence these quantities transport analytically.*

Proof sketch. $\Pi^{[\chi]}$ can be written as $\mathsf{P}_{\mathrm{phys}}\, f(\mathcal{K}_{\mathrm{phys}})\,\mathsf{P}_{\mathrm{phys}}$ (bounded functional calculus) or as a little–group projector inside a physical block; gauge–parameter variations are ζ-exact and cancel on $\mathcal{H}_{\mathrm{phys}}$, giving Nielsen flatness by Proposition 7.644. Analytic transport of isolated spectral projectors and residues on $\mathfrak{P}$ follows from the band/BRST analyticity theorem Theorem 7.646. □ □

Reading rules (per χ). For each χ, apply the canonical quadrant decision rule to $\big(\Lambda_{\mathrm{law}}^{[\mathscr{S};\chi]}, \Lambda_{\mathrm{state}}^{[\mathscr{S};\chi]}\big)$ (cf. Definition 7.685). The typed parasymmetric meters $v_{\mathrm{Synthesis}}^{(a);[\chi]}$ and $v_{\mathrm{Synthesis}}^{(LS);[\chi]}$ then *localize* and *resolve in scale/time* where and when the χ–filtered content occurs (SSB vs. explicit vs. healing vs. symmetric), exactly as in the untyped case but confined to the chosen spin/helicity/polarization subspace.

Examples.

(i) Spin meter. With $\Pi^{[s]}$, record $r \mapsto v_{\mathrm{Synthesis}}^{(S);[s]}(r)$ alongside $\Lambda_{\mathrm{law}}^{[\mathscr{S};s]}(r)$. QII for $s=0$: finite–window elevation of $v_{\mathrm{Synthesis}}^{(S);[0]}$ with decay to $1/2$ and NG poles in $\mathcal{Z}^{[\mathscr{S};0]}$. QIV for $s=0$: persistent departure aligned with GMOR gaps in $\mathcal{Z}^{[\mathscr{S};0]}$. QI/QIII for $s=1,2$: unbroken massless carriers and IR healing.

(ii) Helicity meter (spin–1). $\Pi^{[1,\lambda=\pm1]}(\hat{\mathbf{k}})$ yields $v_{\mathrm{Synthesis}}^{(L);[1,\lambda]}(r)$, distinguishing helicity–selective edge transport or anisotropic media on $\mathfrak{P}_{\partial}$.

(iii) Polarization meter (hydrodynamics). With $P_{L/T}$, obtain longitudinal–sound vs. transverse–shear diagnostics, enabling QII (sound NG) vs. QIV (pseudo–sound) discrimination inside the hydrodynamic sector.

(iv) Species ("particle") meter. For $\Pi^{[\chi=\mathfrak{m}]} = \mathcal{P}_{\mathfrak{m}}$ (e.g. a specific pNG, a radial scalar, a massive vector eigenstate), the typed meters report *where/when* that mode is realized and *which breaking* accounts for it.

Typing the sector witness by BRST–closed filters $\Pi^{[\chi]}$ integrates spectral/polarization selection into parasymmetry. The resulting spin/helicity/polarization/particle meters retain the spin labels fixed by the spectral certificate $\mathcal{Z}^{[\mathscr{S}]}$ and deliver *type* (QI–QIV), *location* (bulk/boundary, sector, position), and *onset* (scale/time) diagnostics on the same BRST–clean, plateau–stable footing as the untyped SynTh/parasymmetry framework.

Complete identification stack. *Qualified yes.* Within the realized weave configuration on the BRST–physical sector $\mathcal{H}_{\rm phys}$—namely the band tags $(P_x(\lambda_{\rm UV}), K_{\rm IR}^{(\ell)})$ on a plateau $\mathfrak{P}$ (or boundary plateau $\mathfrak{P}_\partial$)—the Simultaneous Synthesis (**SynTh**) supplies the logical resolver of quadrant labels, while the parasymmetric layer furnishes phase–sensitive meters that *realize* that logic operationally (Sections 8.2 and 8.2.1). The result is a gauge/Nielsen–safe stack that, from the same sector–conditioned witnesses, returns: the *type* of symmetry status (QI–QIV), the *quadrant* itself (Section 7.10), the *where* (arena/sector/position), the *when* (onset scale/time), and—via typed witnesses—the *what* (spin/helicity/polarization/species).

Type and quadrant. Given sector–conditioned visibilities $(\Lambda_{\rm law}^{[\mathscr{S}]}, \Lambda_{\rm state}^{[\mathscr{S}]})$ and parasymmetric valuations $v_{\rm Synthesis}^{(L)}, v_{\rm Synthesis}^{(S)}, v_{\rm Synthesis}^{(LS)}$, the canonical decision rule (Section 7.10) returns the quadrant: QI (symmetric), QII (state–SSB: elevated then decaying coherence), QIII (law–healing with power–law decay), or QIV (explicit breaking: persistent law deficit with GMOR–controlled pNGs). Parasymmetric meters provide the phase–coherence corroborants that distinguish "elevated–then–decaying" (QII) from "persistent" (QIV) behavior on the same diagnostic realized reference configuration (Section 8.2.1).

Where (arena/sector/position). The arena $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$ resolves bulk versus boundary; the sector tag $[\mathscr{S}]$ (hydrodynamic, boundary/edge, p-forms via duality, higher–spin, fermions/SUSY, *etc.*) is provided by the sector–conditioned witnesses of Section 8.1; spatial localization follows from the centered projector $P_x(\lambda_{\rm UV})$, and the IR knob sets the scale ($r = \ell$ in bulk, $r = L$ on ∂). Window–resolved *maps* are obtained by scanning x and r. Typical locator sets are

$$\mathcal{L}_{\rm SSB}^{[\mathscr{S}]} = \Big\{(x,r):\ v_{\rm Synthesis}^{(S)}(x;r) > \tfrac{1}{2},\quad v_{\rm Synthesis}^{(LS)}(x;r) \xrightarrow{r\uparrow} \tfrac{1}{2}\Big\}, \tag{8.22}$$

$$\mathcal{L}_{\rm QIV}^{[\mathscr{S}]} = \Big\{(x,r):\ d_{\rm law}^{[\mathscr{S}]}(r) \geq \delta_\star,\quad \text{non-healing}\Big\}, \tag{8.23}$$

with analogous sets for QIII (healing) and QI (symmetric).

When (onset scale/time). Onset scales are defined by the first window $r^\star$ at which the quadrant inequalities hold within chosen tolerances $(\varepsilon_{\rm law}, \varepsilon_{\rm state})$:

$$r_{\rm SSB}^\star = \inf\{r:\ v_{\rm Synthesis}^{(S)}(r) > \tfrac{1}{2}\ \wedge\ v_{\rm Synthesis}^{(LS)}(r) \downarrow \tfrac{1}{2}\}, \tag{8.24}$$

$$r_{\rm QIV}^\star = \inf\{r:\ d_{\rm law}^{[\mathscr{S}]}(r) \geq \delta_\star\}, \tag{8.25}$$

$$r_{\rm QIII}^\star = \inf\{r:\ d_{\rm law}^{[\mathscr{S}]}(r) \leq C r^{-\beta}\}. \tag{8.26}$$

If a relational generator $\hat{F}_{\rm para}^{(LS)}$ is provided (Section 8.2.1), one likewise defines onset times $t^\star$ from $t \mapsto v_{\rm Synthesis}^{(\cdot)}(t;r)$.

Spins, helicities, polarizations, and species. These are supplied by *typed witnesses* $\mathbf{W}^{[\mathscr{S};\chi]}$ that compose the sector witness with a BRST–closed filter $\Pi^{[\chi]}$ (Section 8.6.5). Canonical choices include spin filters $\Pi^{[s=2]} = \Pi_{\rm TT}$, $\Pi^{[s=1]} = P_T$, $\Pi^{[s=0]} = \mathbf{1}_{\rm scalar}$; helicity filters $\Pi^{[1,\lambda=\pm1]}(\hat{\mathbf{k}})$, $\Pi^{[2,\lambda=\pm2]}(\hat{\mathbf{k}})$ within the physical blocks; polarization filters such as P_L vs P_T in hydrodynamics and tangential/chiral projectors on $\mathfrak{P}_\partial$; and species ("particle") filters given by Riesz projectors $\mathcal{P}_{\mathfrak{m}}$ onto isolated poles/bands of $\mathcal{K}_{\rm phys}$ (or $\mathcal{D}_{\rm phys}$). The typed visibilities $\big(\Lambda_{\rm law}^{[\mathscr{S};\chi]}, \Lambda_{\rm state}^{[\mathscr{S};\chi]}\big)$ and typed parasymmetric valuations $v_{\rm Synthesis}^{(\cdot);[\chi]}$ then localize *where/when* a chosen χ (spin/helicity/polarization/species) is realized and *why* (SSB vs

explicit vs healing vs symmetric), without modifying the spin labels already fixed by the physical–sector pole analysis.

Scope and caveats. All identifications are exact up to the *window resolution* determined by P_x and K_{IR}; species–level meters require isolated poles or sufficiently narrow bands, else the output is a controlled coarse–graining over the selected block. Functoriality and cone–preservation ensure that refining the instrumentation sharpens readout *without changing* quadrant membership.

With SynTh delivering the paraconsistent resolver and parasymmetry providing phase–sensitive (typed) meters on $\mathcal{H}_{\mathrm{phys}}$, the combined instrument identifies, on certified plateaux, the *type* and *quadrant* of symmetry status, *where* it holds (arena/sector/position), *when* it onsets (scale/time), and—via typed filters—the *spin*, *helicity*, *polarization*, and *species* content of the light sector (Sections 7.10, 8.1, 8.2, 8.2.1 and 8.6.5).

8.6.6 Spectral–Only Parasymmetric Protocol

All statements in this section are evaluated on the BRST–physical sector $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ with realized weave configuration $(P_x(\lambda_{\mathrm{UV}}), K_{\mathrm{IR}}^{(\ell)}; \mathsf{P}_{\mathrm{phys}})$. The protocol uses spectra alone—without the Ward ledger—to reconstruct spin/helicity/polarization content and to diagnose *what* breaks, *where*, and *when*, consistently with the quadrant resolver of Section 7.10 and the meters of Section 8.2.1.

Definition 8.142 (Spectral certificate on $\mathcal{H}_{\mathrm{phys}}$)**.** From the band/BRST–reduced quadratic kernel build the physical propagator $\mathcal{D}_{\mathrm{phys}}^{(\lambda_{\mathrm{UV}},\ell)}$. Decompose into polarization blocks

$$X \in \{h_{\mathrm{TT}},\, A^T,\, \pi\} \qquad \Rightarrow \qquad s(X) = 2, 1, 0,$$

using Π_{TT} (transverse–traceless), P_T (transverse) and the scalar block (cf. tables 7.5 and 7.6). The *spectral certificate* is the blockwise list

$$\mathcal{Z} \;:=\; \Big\{(\omega_n(\mathbf{k}),\, Z_n)\Big\}_{n,X},$$

collecting pole locations $\omega_n(\mathbf{k})$ and residues Z_n in each physical block X.

Spin/helicity/polarization identification (from $\mathcal{Z}$). Spins are assigned by block: $h_{\mathrm{TT}} \to s{=}2$, $A^T \to s{=}1$, $\pi \to s{=}0$. Massless helicities are resolved by little–group projectors (e.g. $\lambda = \pm 2$ in $\mathrm{Im}\,\Pi_{\mathrm{TT}}$, $\lambda = \pm 1$ in $\mathrm{Im}\,P_T$). Sectoral polarizations (hydro/elastic/edge) are read with P_L/P_T or tangential/chiral filters on $\mathfrak{P}_\partial$ (cf. table 7.6).

Lemma 8.143 (Spectral quadrant signatures)**.** *Using only $\mathcal{Z}$, the quadrant labels are diagnosed spectrally as follows:*

(i) QI (law ≈ 1, state ≈ 1).
No NG/pNG; unbroken massless $s = 2$ and $s = 1$ carriers present where allowed; radial gaps analytic.

(ii) QII (state SSB).
Presence of NG scalars *(gapless $s = 0$); for gauged broken directions,* massive $s = 1$ *with a restored longitudinal polarization (BEH).*

(iii) QIII (healing).
No persistent NG/pNG*; spectra reconverge to the QI census under IR dilation (*$\mathbf{k} \to 0$ *or* $\ell \uparrow$*) in accordance with eq. (7.746).*

(iv) QIV (explicit).
pNG band *with GMOR scaling* $m_{\pi_b}^2 = \mathcal{O}(\epsilon)$*; pseudo–phonons on* $\mathfrak{P}_\partial$ *share L/T structure but are gapped (cf. eq. (7.747)).*

Hence spectra alone determine what *breaks (SSB vs. explicit) and* which *quadrant is indicated, consistent with Section 7.10.*

Definition 8.144 (Spectral locator sets and onset scales)**.** For a sector tag $[\mathscr{S}]$ (cf. Section 8.1), define window–resolved loci using $\mathcal{Z}$:

$$\mathcal{L}_{\mathrm{SSB}}^{[\mathscr{S}]}(\mathcal{Z}) := \left\{ \begin{array}{l} (x,r) : \text{NG poles present;} \\ \qquad v_{\mathrm{Synthesis}}^{(S)}(x;r) > \tfrac{1}{2},\ v_{\mathrm{Synthesis}}^{(LS)}(x;r) \xrightarrow{r\uparrow} \tfrac{1}{2} \end{array} \right\}, \tag{8.27}$$

$$\mathcal{L}_{\mathrm{QIV}}^{[\mathscr{S}]}(\mathcal{Z}) := \left\{ \begin{array}{l} (x,r) : \text{pNG band with GMOR slope;} \\ \qquad \text{non-healing parasymmetric cross–terms} \end{array} \right\}, \tag{8.28}$$

with analogous $\mathcal{L}_{\mathrm{QI}}^{[\mathscr{S}]}(\mathcal{Z})$ and $\mathcal{L}_{\mathrm{QIII}}^{[\mathscr{S}]}(\mathcal{Z})$. The *arena* is fixed by $\mathcal{A} \in \{\mathfrak{P}, \mathfrak{P}_\partial\}$ (bulk $r = \ell$, boundary $r = L$). Onset scales are

$$\begin{aligned} r_{\mathrm{SSB}}^\star &= \inf\{r :\ \text{NG present and } v_{\mathrm{Synthesis}}^{(LS)}(r) \downarrow \tfrac{1}{2}\}, \\ r_{\mathrm{QIV}}^\star &= \inf\{r :\ \text{pNG with GMOR slope}\}, \\ r_{\mathrm{QIII}}^\star &= \inf\{r :\ \text{healing per eq. (7.746)}\}. \end{aligned}$$

Spectral sweeps ("where" and "when"). Arena classification follows dispersion geometry (bulk isotropic vs. tangential/chiral along $\partial\mathcal{X}$); edge Goldstones vs. pseudo–edge modes discriminate boundary QII/QIV. Spatial localization uses $x \mapsto P_x(\lambda_{\mathrm{UV}})$ and the IR knob r to map the loci of Definition 8.144. Even with a single spectrum, the low–$|\mathbf{k}|$ tail acts as an IR sweep: NG/pNG vs. healing is read from pole behavior as $|\mathbf{k}| \to 0$.

Typed meters from spectral filters (optional but powerful). Compose the sector witness with a BRST–closed filter $\Pi^{[\chi]}$ (spin/helicity/polarization/species) to obtain typed meters, as in Section 8.6.5:

$$\mathbf{W}^{[\mathscr{S};\chi]} = \Pi^{[\chi]}\, \mathbf{W}^{[\mathscr{S}]}\, \Pi^{[\chi]}, \qquad v_{\mathrm{Synthesis}}^{(\cdot);[\chi]} = \mathrm{Tr}\Big(P_{\mathrm{para}}^{(\cdot)}\, \rho^{[\chi]}\Big).$$

Riesz projectors around isolated poles yield *particle meters* for specific modes $\mathfrak{m}$, whose elevation/decay across r separates QII (elevated then decaying), QIV (persistent), QIII (healing), and QI (baseline).

Limitations. Exact law–channel visibilities (and Ward sources) require the Ward ledger; with spectra only, classification uses the spectral side of the equivalences in Section 7.10. Gauge/Nielsen safety is guaranteed provided spectra are read after the BRST projection to $\mathcal{H}_{\text{phys}}$; if given in a fixed gauge without projection, a certification step is required before applying the resolver.

Net outcome. With spectra alone, the parasymmetric framework identifies (i) the *species* and *spins/helicities/polarizations* (from block projectors and Riesz projectors), (ii) the *type of breaking* and the *quadrant* (via NG/pNG/BEH content and IR scaling), and (iii) the *arena/location* and *onset scales* $r^\star$ (and onset times if a time series is available), all on $\mathcal{H}_{\text{phys}}$ within certified plateaux/masks, consistent with Sections 8.1, 8.2 and 8.2.1.

8.6.7 Application Arenas for SynTh ⊕ Parasymmetry (Typed Witnesses)

The SynTh resolver together with parasymmetric meters on the BRST–physical sector $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$, equipped with instrumentation $(P_x(\lambda_{\text{UV}}), K_{\text{IR}}^{(\ell)}; \mathsf{P}_{\text{phys}})$ on certified plateaux $\mathfrak{P}$ (and $\mathfrak{P}_\partial$ at boundaries), yields a robust operational stack across sectors $[\mathscr{S}]$ (Sections 8.1, 8.2, 8.2.1 and 8.6.5). Gauge/Nielsen safety and analytic transport follow from the BRST/Nielsen framework and bandwise analyticity [117, 442, 114, 243]. Below are concise, ready-to-deploy application arenas.

1) Chiral/Higgs sectors and electroweak-like symmetry breaking. Use a gauge-sector witness $\mathbf{W}^{[\text{gauge}]}$ with spin/helicity filters $\Pi^{[s=1]}, \Pi^{[1,\lambda=\pm1]}$ and a species Riesz projector for massive vectors. Typed parasymmetric meters $v_{\text{Synthesis}}^{(a);\,[s=1]}$ locate *where/when* BEH longitudinal modes appear (QII/QIV) and separate pNG scalars (QIV, GMOR slope) from radial scalars (all quadrants), delivering type (SSB vs. explicit), arena (bulk/boundary), onset scale $r^\star$, and a spin/helicity census consistent with table 7.6. Standard BEH and spectral diagnostics are covered in [91, 82].

2) QCD-like chiral physics (NG π's, GMOR, anomaly filters). Adopt $\mathbf{W}^{[\chi\text{-global}]}$ with scalar/pseudoscalar filters $\Pi^{[s=0]}$ and species projectors for π_b. Read QII (exact NG) vs. QIV (pNG with GMOR slope) via $v_{\text{Synthesis}}^{(S);\,[0]}$ and typed visibilities $\left(\Lambda_{\text{law}}, \Lambda_{\text{state}}\right)^{[\chi;0]}$; boundary instantiations on $\mathfrak{P}_\partial$ capture edge pseudo-Goldstones and anomaly inflow while preserving quadrant logic; cf. chiral Ward/GMOR treatments in [91, 82].

3) Hydrodynamics / elasticity / MHD (L/T taxonomy). With $\mathbf{W}^{[\text{hydro}]}$ and polarization filters P_L, P_T, typed meters $v_{\text{Synthesis}}^{(\cdot);\,[L/T]}$ distinguish sound (QII), pseudo-sound (QIV, small gap) and healing to a diffusive T-sector (QIII). In MHD, add Alfvén/fast/slow projectors to resolve anisotropy and onset scales $r^\star$. The BRST-safe spectral reading is as in [243, 117].

4) Boundary/edge physics, SPT/CS anyonic edges. On $\mathfrak{P}_\partial$, take $\mathbf{W}^{[\partial]}$ with tangential/chiral filters $\Pi^{[\|]}, \Pi^{[\chi=\pm]}$. Parasymmetric meters locate edge Goldstones (QII), pseudo-edge modes (QIV), and certify healing (QIII). Typed helicity meters reveal chiral transport asymmetries

without altering spin labels; quadrant assignment remains SynTh-determined. Background-field and cohomological safety as in [114, 442].

5) Fractons and subsystem-symmetric phases (anisotropic IR knobs). Work with $\mathcal{A} = \mathfrak{P}$ and an *anisotropic* knob $r = \min(\vec{\ell})$. Define $\mathbf{W}^{[\text{subsys}]}$ from line/plane-conserved currents as the law witness. Parasymmetry separates persistent law deficits (QIV) from power-law healing (QIII) along selected axes; typed meters with $\Pi^{[\text{planon/lineon}]}$ localize restricted-mobility species. Robustness again follows [117, 243].

6) Higher-form and non-invertible symmetries (Wilson/'t Hooft sectors). Let $\mathbf{W}^{[\mathscr{P}_p]}$ act on p-form sectors and transport by BRST/Hodge duality to scalar/vector blocks. Typed loop/surface projectors yield "perimeter vs. area" diagnostics; parasymmetry classifies healing (QIII) vs. persistent law deficit (QIV) and maps *where* (bulk vs. boundary) loop-type excitations are realized. Cohomological control as in [442, 117].

7) Floquet/time-crystalline and driven phases (temporal anchor). Extend the IR knob to a time-window; define $\mathbf{W}^{[\text{Floquet}]}$ with frequency-block filters. Trajectories $t \mapsto \upsilon^{(S)}_{\text{Synthesis}}(t; r)$ identify discrete-time SSB (QII-like in time), explicit drive locking (QIV), and healing to symmetric dynamics (QIII), including onset times $t^\star$. Spectral gauge safety as in [243].

8) Open quantum systems / Lindbladian symmetries. With $\mathbf{W}^{[\text{open}]}$ capturing conserved quantities modulo dissipators, parasymmetry separates environment-induced explicit breaking (QIV-like persistence) from prethermal/healing regimes (QIII). Typed species meters (Riesz) still operate on narrow bands of $\mathcal{D}_{\text{phys}}$ provided isolated structures exist; algebraic consistency follows [117, 442].

9) Emergent symmetry at criticality (QIII diagnostics). Near quantum/thermal critical points, set $r \sim \xi$ and deploy $\mathbf{W}^{[\text{crit}]}$. Power-law healing of the law deficit and reconvergence of spin blocks to the symmetric census (massless $s = 1, 2$, gapped radials) are quantified by the decay of parasymmetric cross-terms—an operational test for emergent Lorentz/conformal behaviour consistent with the spectral reconvergence logic of Section 7.10 and [91].

10) Cosmological/gravitation-adjacent arenas (solid-like backgrounds). For backgrounds with broken spacetime symmetries, use $\mathbf{W}^{[\text{metric}]}$ with Π_{TT} (spin-2) and phonon filters. Parasymmetry distinguishes phonons (QII) from pseudo-phonons (QIV) and tracks cone-preserving onset scales; typed spin-2 meters verify the persistence of massless TT carriers where spacetime symmetry is unbroken. TT-filtered spectral safety follows [114, 243].

Practical note (typed meters). In each arena, *typed* witnesses

$$\mathbf{W}^{[\mathscr{S};\chi]} = \Pi^{[\chi]}\,\mathbf{W}^{[\mathscr{S}]}\,\Pi^{[\chi]}, \qquad \upsilon^{(\cdot);[\chi]}_{\text{Synthesis}} = \text{Tr}\Big(P^{(\cdot)}_{\text{para}}\,\rho^{[\chi]}\Big),$$

with BRST-closed filters $\Pi^{[\chi]}$ for *spin*, *helicity*, *polarization*, or *species* (via Riesz projectors), allow parasymmetry to report, for the chosen χ: *type* (QI/QII/QIII/QIV via SynTh's

rule), *where* (bulk/boundary, sector, spatial window P_x), *when* (onset $r^\star$, and $t^\star$ if dynamics are supplied), and *what* (spin/helicity/polarization/species realized)—all remaining gauge/Nielsen–safe on $\mathcal{H}_{\text{phys}}$ and stable on $\mathfrak{P}$ [117, 442, 243].

8.6.8 Parasymmetric Readout of Second Sound

We now apply the parasymmetric layer to the longitudinal hydrodynamic block of Section 8.1.6, retaining the same realized weave configuration $(P_x(\lambda_{\text{UV}}), K_{\text{IR}}^{(\ell)}; \mathsf{P}_{\text{phys}})$ on $\mathfrak{P}$ and working on $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$. No new definitions are introduced: we only *type* the existing hydrodynamic witness using Section 8.6.5 and read it with the meters of Section 8.2.1.

Typed witness and species (second sound). Let $\mathbf{W}^{[\text{hydro}]}$ be the hydrodynamic sector witness (Definition 8.21) and let $\Pi^{[L]}$ denote the longitudinal projector (within the hydrodynamic block). Define the typed witness and typed state by

$$\mathbf{W}^{[\text{hydro};L]} = \Pi^{[L]}\,\mathbf{W}^{[\text{hydro}]}\,\Pi^{[L]}, \qquad \rho^{[L]} = \frac{\Pi^{[L]}\,\rho\,\Pi^{[L]}}{\mathrm{Tr}(\Pi^{[L]}\rho)} \quad (\text{on } \mathcal{H}_{\text{phys}}),$$

and the corresponding typed visibilities $\Lambda_{\text{law}}^{[\text{hydro};L]}$, $\Lambda_{\text{state}}^{[\text{hydro};L]}$ as in Definition 8.140. For the *second–sound species*, let $\mathcal{P}_{2\text{nd}}$ be the Riesz projector encircling the second–sound pole of the longitudinal block (cf. $\mathcal{P}_{\mathsf{m}}$ in Section 8.6.5); set $\Pi^{[\chi=2\text{nd}]} := \mathcal{P}_{2\text{nd}}$ to obtain a species–typed witness $\mathbf{W}^{[\text{hydro};2\text{nd}]}$ and the species–typed meters $v_{\text{Synthesis}}^{(a);\,[2\text{nd}]}$.

Meters (longitudinal and species–typed). For $a \in \{L, S\}$,

$$v_{\text{Synthesis}}^{(a);\,[L]} = \mathrm{Tr}\Big(P_{\text{para}}^{(a)}\,\rho^{[L]}\Big), \qquad v_{\text{Synthesis}}^{(a);\,[2\text{nd}]} = \mathrm{Tr}\Big(P_{\text{para}}^{(a)}\,\rho^{[2\text{nd}]}\Big),$$

with the relational meter $v_{\text{Synthesis}}^{(LS);\,[\cdot]}$ defined analogously (Definition 8.140). Gauge/Nielsen safety and plateau analyticity carry over from Proposition 8.141.

Proposition 8.145 (Quadrant diagnostics for second sound (typed parasymmetry))**.** *With the longitudinal hydrodynamic block of Section 8.1.6 and typed meters as above, the following implications hold:*

(i) QI (symmetric).
$\Lambda_{\text{law}}^{[\text{hydro};L]} \approx 1$, $\Lambda_{\text{state}}^{[\text{hydro};L]} \approx 1$*; the longitudinal spectrum shows pure diffusion (no longitudinal NG/pNG). Then* $v_{\text{Synthesis}}^{(a);\,[L]} \approx \frac{1}{2}$ *and the species–typed meter satisfies* $v_{\text{Synthesis}}^{(a);\,[2\text{nd}]} \approx \frac{1}{2}$ *(baseline), consistent with the absence of a second–sound pole.*

(ii) QII (state–SSB).
Two propagating longitudinal branches exist (Definition 8.26); the second–sound species meter *elevates at finite window,*

$$v_{\text{Synthesis}}^{(S);\,[2\text{nd}]}(r) > \tfrac{1}{2}, \qquad v_{\text{Synthesis}}^{(LS);\,[2\text{nd}]}(r) \text{ elevated},$$

and both decay to $\frac{1}{2}$ *under IR/volume dilation* $r \uparrow$*, while* $\Lambda_{\text{law}}^{[\text{hydro};L]} \simeq 1$*. This is the* sound–NG *signature in the longitudinal sector, now resolved at the species level.*

(iii) QIII (healing).
Any putative second–sound signature heals *in the strict IR:*

$$v_{\mathrm{Synthesis}}^{(a);\,[2\mathrm{nd}]}(r) \xrightarrow{r\uparrow} \tfrac{1}{2}, \qquad \Lambda_{\mathrm{law}}^{[\mathrm{hydro};L]}(r) \xrightarrow{r\uparrow} 1, \qquad \textit{and the pole reconverges to diffusion,}$$

in accordance with eq. (7.746) *and Proposition 8.23.*

(iv) QIV (explicit).
The longitudinal law deficit is persistent ($\Lambda_{\mathrm{law}}^{[\mathrm{hydro};L]} \le 1-\delta_\star$)*; the second–sound pole becomes a* pseudo–sound *with a small gap* $m_{\mathrm{ph}}^2 = \mathcal{O}(\epsilon)$ *(Section 8.1.6). The species–typed meters display* non–healing *behaviour:*

$$v_{\mathrm{Synthesis}}^{(LS);\,[2\mathrm{nd}]}(r) \textit{ non–healing}, \qquad v_{\mathrm{Synthesis}}^{(S);\,[2\mathrm{nd}]} \approx \tfrac{1}{2} \textit{ (unique state, no cats)},$$

while the gap satisfies the plateau GMOR/pseudo–phonon scaling inherited from the explicit source (cf. eq. (7.747)*).*

Definition 8.146 (Locator and onset for second sound)**.** Define the *second–sound locus* and *onset scale* at window r (bulk $r=\ell$, boundary $r=L$):

$$\mathcal{L}_{2\mathrm{nd}} := \Big\{(x,r):\ v_{\mathrm{Synthesis}}^{(S);\,[2\mathrm{nd}]}(x;r) > \tfrac{1}{2},\ \text{and } \omega_{\pm}^{(2)}(k) = \pm c_2 k - i\gamma_2 k^2 + o(k^2)\Big\},$$

$$r_{2\mathrm{nd}}^{\star} := \inf\Big\{r:\ v_{\mathrm{Synthesis}}^{(S);\,[2\mathrm{nd}]}(r) > \tfrac{1}{2}\ \wedge\ v_{\mathrm{Synthesis}}^{(LS);\,[2\mathrm{nd}]}(r) \downarrow \tfrac{1}{2}\Big\},$$

with the obvious QIV/QIII variants (non–healing or healing criteria, respectively).

Boundary variant. On $\mathfrak{P}_\partial$, replace $\Pi^{[L]}$ by the tangential projector $\Pi^{[\|]}$ and read the *edge second–sound* species via $\mathcal{P}_{2\mathrm{nd},\partial}$. Quadrant diagnostics follow Proposition 8.145 verbatim (QII: gapless edge sound; QIV: pseudo–edge–sound with $\mathcal{O}(\epsilon)$ gap; QIII: healing to tangential diffusion; QI: baseline).

Operational takeaway. Applying parasymmetry to second sound *does not change its spin/polarization label* (longitudinal, spin–0). It equips the hydrodynamic block with *typed, gauge–safe meters* that: (i) certify the presence of a genuine second–sound pole (vs. diffusion), (ii) *localize* where it occurs (bulk/boundary, position, window), and (iii) determine *when* it turns on (onset scale), while assigning the *type of breaking* (QII/QIII/QIV vs. QI) in the sense of Sections 7.10, 8.2.1 and 8.6.5.

Discussion and conclusion (second sound). The matrix witness of Section 8.1.6 provides an *unambiguous spectral predicate* for second sound: the longitudinal hydrodynamic block carries two propagating roots $\omega_{\pm}^{(2)}(k) = \pm c_2 k - i\gamma_2 k^2 + \cdots$ as stated in Definition 8.26. The parameters (c_2, γ_2) are fixed kinematically and dissipatively by the generalised stiffness and dissipation matrices (Lemma 8.27), and reduce in the two–fluid limit to Landau's classic formula for second sound (Remark 8.30; [450, 451, 452]). This furnishes a *yes/no* certificate on $\mathcal{H}_{\mathrm{phys}}$, independent of model-specific fits and stable under band/BRST reduction.

Layering parasymmetry on this block equips the construction with *typed, species-level diagnostics*. A Riesz projector $\mathcal{P}_{\mathrm{2nd}}$ onto the second–sound pole produces species-typed meters $\upsilon^{(a);\,[\mathrm{2nd}]}_{\mathrm{Synthesis}}$ and $\upsilon^{(LS);\,[\mathrm{2nd}]}_{\mathrm{Synthesis}}$ that *localize* second sound across space and scale, and define an onset $r^{\star}_{\mathrm{2nd}}$ (Section 8.6.8 and Definition 8.146). Gauge/Nielsen safety of these readings follows from the typed–meter invariance and analyticity on certified plateaux (Proposition 8.141; [117, 243]), so observations become *maps* $\mathcal{L}_{\mathrm{2nd}}$ rather than global assertions.

Crucially, the same meters render the phenomenon *quadrant-resolved*. In QII (state–SSB) the species meter is elevated at finite window and decays to 1/2 under IR/volume dilation, certifying a *true NG* sound branch; in QIV (explicit breaking) the branch is a *pseudo–sound* with an $\mathcal{O}(\epsilon)$ gap obeying the GMOR/source bridge (*eq.* (7.747)) and the meter is non–healing; in QIII (healing) any would–be second–sound signature reconverges to diffusion in the strict IR per *eq.* (7.746); and QI remains at baseline (Proposition 8.145). Thus the traditional "first/second sound vs. diffusion" trichotomy is elevated to a *mechanistic* classification that says *why* the branch appears.

The boundary/tangential variant is immediate: replacing $\Pi^{[L]}$ by the tangential projector $\Pi^{[\|]}$ realizes *edge second sound* on $\mathfrak{P}_{\partial}$ with identical quadrant logic and locator/onset definitions (Section 8.6.8).

Finally, the outputs are *falsifiable and robust*: certified (c_2, γ_2) with errors tied to window resolution; a binary species meter (elevated vs. baseline) with healing/persistence trends; a gap–scaling law in QIV; and onset scales $r^{\star}_{\mathrm{2nd}}$—each directly checkable in simulation or experiment and regulator–stable on $\mathfrak{P}$ [117, 243]. Scope and limits are as usual: the analysis holds on certified plateaux, and species–level meters presume an isolated or sufficiently narrow pole; if spectra are provided in a fixed gauge, the BRST projection must be certified prior to applying the resolver [117, 243]. In sum, for second sound, SynTh + typed parasymmetry yields a *gauge-safe, quadrant-aware, mappable instrument* that states precisely *if*, *why*, *where*, and *when* second sound occurs, while reproducing the standard two–fluid limits where appropriate [450, 451, 452].

Chapter 9

The Quanta of Fields

Purpose and scope. The present introduction positions the operator–theoretic construction of fields and quanta on the emergent arena against the established BRST–physical framework and the Σ-aware symmetry diagnostics. The upstream axioms and identities of Chapters 7–8 remain unchanged—BRST charge and cohomology, gauge fixing as ζ-exact, cohomological Euler–Lagrange operators, Σ-compatible linear response, and Ward/Slavnov identities—while the upstream feed is sharpened: the pre-physical, operator-valued chronogeometry $\hat{\Sigma}_{\mu\nu} := \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ is taken as the canonical input that, after Planck-plateau upgrade and BRST projection, yields the expectation tensor $\bar{\Sigma}_{\mu\nu}$ used on the physical side (cf. §6.10 and the relational constructions surrounding $\nabla^{(\bar{\Sigma})}$, Definition 6.7). The goal is a unified and band-regular route from correlator kinematics to physical spectra, without altering the cohomological infrastructure of Chapters 7–8.

Law–state analysis at the pre-physical level. On the emergent/GNS arena, the law–state dichotomy is evaluated at band level using Σ-based, graded-covariant diagnostics. A band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is implemented via a UV projector $P_x(\lambda_{\mathrm{UV}})$ and a causal IR kernel $K_{\mathrm{IR}}^{(\ell)}$ chosen to be BRST-closed, ensuring commutation with $\hat{Q}_{\mathrm{BRST}}$ and compatibility with the physical projector $\mathsf{P}_{\mathrm{phys}}$ (§7.5, (7.143), (7.24)). With the Σ-probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$, law and state contrasts $\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}$ and $\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}$ distinguish explicit symmetry breaking of the operator law from spontaneous symmetry breaking of the Holo-State at fixed tolerance; the quadrant structure (QI–QIV) then classifies regimes and governs subsequent realization on the BRST-physical arena. In particular, QII corresponds to state-asymmetric, law-symmetric configurations that will underwrite NG/pNG content after projection, whereas QIII/QIV capture genuine (explicit) departures of the law channel, to be filtered by anomaly and BRST viability checks.

Unified chronogeometry and graded transport. The chronogeometric tensor $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ consolidates the triadic metric and temporal sector into a single operator-valued object whose coincident Hessians generate the kinematic forms that will later define $\bar{\Sigma}_{\mu\nu}$. This unification preserves gauge/frame covariance and graded selection rules while remaining finite and causal on the band (self-regularizing distances/times and their Hessians). The Fourfold Inter-Modal Correlator $\hat{\mathbf{G}}_\Lambda$ supplies the transport-covariant kernel data with $\mathbb{Z}_2 \times \mathbb{Z}_2$ grading over the modal set $\{0, 1, p, s\}$, and the relational differential structure is read through $\nabla^{(\bar{\Sigma})}$

once expectations are taken (cf. Definitions 6.4 and 6.7). The generalized field doublet $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^{\mathsf{T}}$ sits on the same operator bundle and inherits these covariances, enabling a single Σ-compatible account of geometry-like (Gaiamiti) and matter-like (Tantrakyma) sectors.

Broken directions, mode extraction, and Σ-weighted normalization. Broken symmetry directions are identified pre-physically by the graded tangent $\delta_X \hat{\mathbf{G}}_\Lambda = [X, \hat{\mathbf{G}}_\Lambda]_{\mathrm{gr}}$ for $X \in \mathfrak{g}$, evaluated blockwise and weighted by $\hat{\Sigma}$. The resulting Σ-Gram problems produce principal directions in the geometry block ($\Phi\Phi$) and the matter block ($\Theta\Theta$), defining Apeiron and Kymon creation operators with Σ-orthonormality. The phase-tangential versus amplitude-radial decomposition within the Σ-geometry separates massless versus gapped geometric excitations at the pre-physical level, while maintaining graded covariance and band regularity. These Σ-normalized mode spaces provide the inputs for linear response and spectral diagnostics, but no change is made to the physical particle criteria, which remain cohomological and pole/residue based in $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10).

Plateau certification, BRST projection, and Σ-causal response. A certified plateau in the $(\lambda_{\mathrm{UV}}, \ell)$ plane—verifying Σ-regularity, causal/hyperbolic cones, BRST nilpotency and commutation with the band map, together with Nielsen-type gauge-parameter independence—licenses the realization map that sends pre-physical operators to the BRST-physical arena. The expectation $\bar{\Sigma}_{\mu\nu} = \langle \mathsf{P}_{\mathrm{phys}} \lim_{\mathfrak{P}} \mathfrak{B}_{\lambda,\ell}[\hat{\Sigma}_{\mu\nu}] \mathsf{P}_{\mathrm{phys}} \rangle$ then serves as the background tensor for the Relational Levi–Civita connection, for Σ-causal retarded propagators, and for the cohomological Euler–Lagrange operators used in linear response (Definition 6.7). Ward/Slavnov identities, anomaly filters, and Kugo–Ojima unitarity checks are applied exactly as in Chapter 7, now with Σ-compatible currents and Green functions. The BRST-exact sector remains unphysical, and only BRST-closed, Nielsen-stable poles with positive residues are admitted as realized quanta on $\mathcal{H}_{\mathrm{phys}}$ (with the Quadrant-I spectrum at the symmetric baseline and its deformations interpreted through the Σ-fed diagnostics of Chapter 8, (7.143), (7.24)).

Organization of the construction. With these preliminaries, the subsequent sections proceed from the arena, transport, grading, and band tagging to Σ-based law/state order parameters, to Σ-weighted mode extraction in geometry and matter blocks, and finally to plateau-based realization and BRST-physical spectra. Throughout, the generalized field operator, the unified inter-modal correlator, and the operator-bundle connection are treated in their established form (Ch. 7), while the band-limited BRST checklist, acceptance rules, and quadrant logic (Ch. 8) are invoked without modification, the sole refinement being that all inputs are funneled through the chronogeometric tensor $\hat{\Sigma}_{\mu\nu}$ and its expectation $\bar{\Sigma}_{\mu\nu}$.

Overview

The Primordial Quantum Singularity (PQS) and the Quantum Holo–State. All pre–physical diagnostics are anchored at *Primordial Quantum Singularities* (PQS) as defined in

Definition 1.25, with the formal identity $\mathfrak{B}_{\vec{r}} = \hat{\mathbf{\Omega}}_{\vec{r}} = \overset{\circ}{\mathbf{\Lambda}}_{\hat{\Phi}_{\vec{r}},\hat{\Theta}_{\vec{r}}}$ (cf. (1.3)). Each PQS is intrinsically characterized by the *Quantum Holo–State* $|\overset{\circ}{\mathbf{\Psi}}\rangle$ (Definition 1.27), whose GNS realization generates the emergent arena $\mathcal{H}_{\rm em} \equiv \mathcal{H}_{\overset{\circ}{\mathbf{\Psi}}}$ used throughout (Definition 9.87). As detailed in Definitions 1.27, 6.4, 9.20 and 9.60 and eqs. (4.85) and (9.27), the causal/metric pipeline driven by the Holo–State is

$$\begin{aligned} &|\overset{\circ}{\mathbf{\Psi}}\rangle \quad (Definition\ 1.27)\\ &\rightsquigarrow\ \hat{G}_\Lambda \quad (Definition\ 6.4)\\ &\rightsquigarrow\ \langle\cdot,\cdot\rangle_x \quad (eq.\ (4.85))\\ &\rightsquigarrow\ \hat{\Sigma}_{\mu\nu}(x) \quad (Section\ 9.9)\\ &\rightsquigarrow\ \bar{\Sigma}_{\mu\nu}(x) \quad (Definition\ 9.60)\end{aligned}$$

so the fibre inner products and the operator chronogeometry are *induced* from Holo–State expectations. Moreover, Theorem 4.314 establishes that $|\overset{\circ}{\mathbf{\Psi}}\rangle$ is *globally entangled* and non–factorizable across nontrivial splits—a structural fact that remains intact in what follows.

What does it mean, here, for symmetry to be "broken"? "Broken" is precise and occurs *at the band–tagged, pre–physical level*. What can break is the G–invariance of either the *law* (band–projected, graded–covariant kernels/constraints on $\mathcal{H}_{\rm em}$) or the *state* (the Holo–State), tested by the canonical Σ–based order parameters built from the operator chronogeometry and its quadratic probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (see Section 9.9). Both channels are evaluated with the band tag $\mathfrak{B}_{\lambda_{\rm UV},\ell}[\cdot]$ and PSR functionals $\mathcal{I}[\cdot]$, and summarized by the pre–physical contrasts and their typed visibilities $\left(\Delta_\bullet^{\mathrm{pre},\Sigma},\, \Lambda_\bullet^{\Sigma;[\chi]}\right)$ (cf. Sections 9.11 and 9.12). *State breaking* here means *loss of G–invariance* of Holo–State expectations on–band; it does *not* contradict the global non–factorizability of Theorem 4.314.

What does not break: the role of the Fourfold correlator. The Fourfold inter–modal correlator $\hat{G}_\Lambda$ is an *operator object* that transforms *covariantly* under G (cf. Definition 6.4):

$$\hat{G}_\Lambda \ \longmapsto\ \mathrm{Ad}_g\, \hat{G}_\Lambda := U(g)\, \hat{G}_\Lambda\, U(g)^{-1}, \qquad g \in G.$$

At this object level, $\hat{G}_\Lambda$ *only transforms*; nothing "breaks." What the formalism calls *breaking* is detected downstream—either in the band–projected *law channel* functorially built from $\hat{G}_\Lambda$ (explicit breaking) or in the *Holo–State expectations* of G–covariant functionals of $\hat{G}_\Lambda$ (spontaneous breaking). Concretely, after band–tagging $\mathfrak{B}_{\lambda_{\rm UV},\ell}$,

$$\Delta_{\rm law}^{\mathrm{pre},\Sigma}(g;x;v) > \varepsilon \iff \mathfrak{L}\Big[\,\mathrm{Ad}_g\ \mathfrak{B}_{\lambda,\ell}(\hat{G}_\Lambda)\Big] \neq \mathfrak{L}\Big[\mathfrak{B}_{\lambda,\ell}(\hat{G}_\Lambda)\Big],$$

where $\mathfrak{L}[\cdot]$ denotes the Σ–compatible operator–law kernels/constraints (cf. Section 9.9 and Definition 9.45). By contrast, with the law invariant,

$$\Delta_{\rm law}^{\mathrm{pre},\Sigma}(g;x;v) \approx 0 \quad \text{and} \quad \Delta_{\rm state}^{\mathrm{pre},\Sigma}(g;x;v) > \varepsilon,$$

one has *spontaneous state* breaking (equivalently $H_{\rm law}(x) = G$ but $H_{\rm state}(x) \subsetneq G$; cf. Section 9.11). Thus the correlator is the *substrate*; it is the symmetry of the *law* or of the *state*—as revealed by the Σ–based contrasts—that fails.

What exactly is broken? *Explicit law breaking* means the intended symmetry G fails to leave the band–limited operator law invariant, detected as

$$\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}(g;x;v) \;>\; \varepsilon \quad (g\in G,\; v\in T_x\mathcal{X}_q),$$

equivalently, a nonzero Σ–probe difference under the graded adjoint action. *Spontaneous state breaking* preserves the law channel but not the Holo–State:

$$\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}(g;x;v) \;<\; \varepsilon \quad \text{while} \quad \Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}(g;x;v) \;>\; \varepsilon,$$

so that

$$H_{\mathrm{law}}(x) := \{g\in G : \Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}(g;x;v) < \varepsilon\ \forall v\}, \qquad H_{\mathrm{state}}(x) := \{g\in G : \Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}(g;x;v) < \varepsilon\ \forall v\},$$

and pre–physical SSB means $H_{\mathrm{law}}(x) = G$ but $H_{\mathrm{state}}(x) \subsetneq G$. The quadrant predicate (QI–QIV) encodes the four possibilities—nothing; state–only; law–only; both—driven by $\Delta_{\bullet}^{\mathrm{pre},\Sigma}$ or their typed versions $\Delta_{\bullet}^{\mathrm{pre},\Sigma;[\chi]}$ with visibilities $\Lambda_{\bullet}^{\Sigma;[\chi]}$ (see Section 9.11 and the orientation in Section 9.15.1).

Where do broken directions come from? A generator $X\in\mathfrak{g}$ is diagnosed as broken at x when its graded tangent

$$\delta_X\hat{G} \;:=\; [X,\hat{G}]_{\mathrm{gr}}$$

carries nonzero Σ–weight in a relevant block,

$$\mathcal{I}\Big[(\delta_X\hat{G}_{\bullet\bullet})^{\dagger}\,\hat{\Sigma}^{(\bullet)}\,(\delta_X\hat{G}_{\bullet\bullet})\Big] \;>\; 0, \qquad \bullet\bullet\in\{\Phi\Phi,\Theta\Theta\}.$$

These Σ–weighted variation maps seed the *block–wise* generalized eigenproblems that extract the principal pre–physical mode families (a typed, band–regular upgrade of SVD), yielding Apeiron (geometry, $\Phi\Phi$) and Kymon (matter, $\Theta\Theta$) mode spaces with Σ–orthonormality and factorizations. Their outputs feed the typed Type–Location–Onset assignments $\mathrm{TLO}^{[\chi]}(x;r)$ (cf. Sections 8.6, 9.8, 9.10 and 9.12).

What this does—and does not—claim. The QI–QIV classification and the Apeiron/Kymon construction are *pre–physical inputs*; they are not particle claims. Physical poles/residues are read only after *plateau certification* and Σ–aware *realization* with BRST projection to $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$. On certified plateaus the law channel is Nielsen–flat; BRST hygiene of the band tag guarantees our diagnostics descend functorially and remove gauge–parameter dependence before testing retarded kernels for stable, positive–residue poles (see Section 9.14 and Lemma 9.54). Only BRST–closed, Nielsen–flat features survive; BRST–exact "breakings" are projected out.

Spirit near the primordial regime (PQS). Here "singularity" means the *Primordial Quantum Singularity (PQS)* (Definition 1.25). Diagnostics are performed on finite bands $(\lambda_{\mathrm{UV}},\ell)$ in neighborhoods of the PQS on $\mathcal{H}_{\mathrm{em}}$ and continued only along certified plateaus (cf. Section 9.14).

In this regime the band map is G–covariant and BRST–closed, so the law channel remains symmetric while the Holo–State may not. Accordingly, the natural baseline is QII,

$$\Delta_{\text{law}}^{\text{pre},\Sigma} \approx 0 \quad \text{and} \quad \Delta_{\text{state}}^{\text{pre},\Sigma} > \varepsilon,$$

i.e. $H_{\text{law}}(x) = G$ but $H_{\text{state}}(x) \subsetneq G$. The broken–generator tangents with nonzero Σ–weight then seed the Apeiron/Kymon *pre–physical* mode spaces via the Σ–weighted extraction (see Section 8.6), with physical poles read only after plateau certification and BRST projection.

PQS–anchored scale principle. The pre-physical regime lies strictly between the Primordial Quantum Singularity (PQS) coherence scale and the Planck scale, and the first stage of physics ("realization") begins at the Planck scale:

$$\Big[\underbrace{\text{PQS core}}_{\text{ontic origin}} \rightsquigarrow \underbrace{\text{pre-physical band}}_{\ell_{\text{PQS}} \le \ell < \ell_P} \rightsquigarrow \underbrace{\text{stage of realization (first physics)}}_{\ell \ge \ell_P}$$
$$\rightsquigarrow \underbrace{\text{IR / classical}}_{\ell \gg \ell_P} \rightsquigarrow \underbrace{\text{cosmological}}_{\ell \sim \mathcal{L}_U}\Big]$$

This is consistent with the Chapter 6 genesis chain, where causality emanates from the PQS apex and classical chronogeometry arises only after expectation/realization steps (Section 5.4.6; cf. Table table 5.3).

Definition 9.1 (Regimes and thresholds)**.** Let ℓ_{PQS} denote the PQS coherence/patch scale (Chapter 6, Section 5.4.6) and ℓ_P the Planck length. For an IR-window parameter ℓ (from the band tag $K_{\text{IR}}^{(\ell)}$), define:

1. *PQS core*: $\ell \approx \ell_{\text{PQS}}$, with no resolvable internal distances/times (operator distances/-times are trivialized at the apex; cf. Table table 5.3).
2. *Pre-physical band*: $\ell_{\text{PQS}} \le \ell < \ell_P$.
3. *Stage of realization (first physics)*: $\ell \ge \ell_P$.

Proposition 9.2 (Operational eligibility by regime)**.** *With the operator chronogeometry $\hat{\Sigma}_{\mu\nu} := \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ (Chapter 5: $\hat{g}_{\mu\nu}$ from Definition 5.1; temporal curvature $\hat{t}_{\mu\nu}$ in the Level 2 quantum–geometric layer of Table table 5.3; cf. the unified Σ-notation in Definitions 9.20 and 9.22) and its expectation $\bar{\Sigma}_{\mu\nu} := \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (Chapter 5: Level 3 classical–geometric layer in Table table 5.3; cf. the Σ–realization map Definition 9.80 and eq. (9.35)), the admissible operations are:*

(i) PQS core
No meters or certification procedures apply; band-tagging and parasymmetry are inapplicable at the apex (Section 5.4.6).

(ii) Pre-physical band $\left[\ell_{\text{PQS}}, \ell_P\right)$
Operator-level audits only with band-tagging permiitted

$$(P_x(\lambda_{\text{UV}}), K_{\text{IR}}^{(\ell)})$$

Σ-*cone/hyperbolicity checks, BRST/Nielsen hygiene, and typed permit ledgers.* Prohibited*: plateau certification* $\mathfrak{P}$*, evaluation of holosymmetric visibilities as physical numbers, and projection to* $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$.

(iii) Realization $\ell \geq \ell_P$

First certified plateaux $\mathfrak{P}$ *may be established (tolerances as in eq. (7.28)); thereafter project to* $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$. *Physical, channelized visibilities* $(\Lambda_{\text{law}}, \Lambda_{\text{state}})$ *are evaluated; SynTh and parasymmetric meters act only on* H^0*, remaining* Σ*-causal and BRST-safe.*

Lemma 9.3 (No realization below the Planck scale)**.** *If* $\ell < \ell_P$*, then (i) plateau certification* $\mathfrak{P}$ *is not admissible, and (ii) the realization map to* $\mathcal{H}_{\text{phys}} = H^0(\hat{Q}_{\text{BRST}})$ *is not invoked. Consequently, all diagnostics in* $\left[\ell_{\text{PQS}}, \ell_P\right)$ *are pre-physical/operator-level and expectation-free, in agreement with Chapter 6.*

Remark 9.4 (Sector readings across realization)**.** At $\ell \geq \ell_P$, sector readings become physical: in the gaiamiti ($\Phi\Phi$) block, the massless spin-2 graviton (Goldstone) and gapped geometric radials are read as poles/residues on H^0; in the tantrakyma ($\Theta\Theta$) block, kymon content realizes with NG/pNG/Higgs logic resolved quadrantly (QI–QIV). For $\ell \gg \ell_P$ and $\ell \sim \mathcal{L}_U$, the same H^0 kernels govern, respectively, IR/classical and cosmological coarse-grained limits, consistent with Chapter 6.

9.1 Arena, Transport, Grading, and Band Tagging

Definition 9.5 (Emergent arena and Fourfold Inter-Modal Correlator)**.** Let $\mathcal{H}_{\text{em}}$ denote the emergent (GNS) arena. The *Fourfold Inter-Modal Correlator* is the operator-valued tensor

$$\hat{G}^{\alpha\beta}_{\Lambda}(x, x') \;:=\; \hat{\mathcal{F}}^{\dagger}_{\alpha}(x)\,\mathcal{U}(x \leftarrow x';\gamma)\,\hat{\mathcal{F}}_{\beta}(x') \;\in\; \mathcal{B}(\mathcal{H}_{\text{em}}), \qquad \alpha, \beta \in \{0, 1, p, s\},$$

as first defined in Section 4.1.5 (see eq. (4.22)). The coincident limit generates fibre inner products and organizes the four dialectical modes.

Proposition 9.6 (Hermiticity and gauge covariance of the correlator)**.** *With* $\mathcal{U}$ *the gauge–covariant transporter (cf. Definitions 6.184 and 6.192), and with the Fourfold Inter–Modal Correlator defined together with its block structure in Definition 4.9 and eq. (4.24), the Twofold block enjoys Hermitian symmetry and the full Fourfold transforms covariantly:*

$$(\hat{G}^{\alpha\beta}(x, x'))^{\dagger} = \hat{G}^{\beta\alpha}(x', x), \qquad \hat{\mathbf{G}}_{\Lambda}(x, x') \mapsto g(x)\,\hat{\mathbf{G}}_{\Lambda}(x, x')\,g(x')^{\dagger},$$

hence expectation values in a gauge–covariant state are gauge–invariant (cf. Section 4.19.1).

Definition 9.7 (Gauge-covariant transport and graded covariant derivative)**.** Let $\mathcal{A}_\mu$ be the operator–bundle connection entering the gauge–covariant transporter $\mathcal{U} = \mathcal{P}\exp\!\left(-\int_\gamma \mathcal{A}\right)$ (cf. Definitions 6.184 and 6.192). For channel components of the Fourfold Inter–Modal Correlator (cf. Definition 6.4 and eq. (4.24)), define the graded covariant derivative

$$\mathfrak{D}_\mu \hat{G}^{\alpha\beta} := \partial_\mu \hat{G}^{\alpha\beta} + [\,, \mathcal{A}_\mu, \hat{G}^{\alpha\beta},]_{\text{gr}}, \qquad (\alpha, \beta \in \{0, 1, p, s\}), \tag{9.1}$$

which transforms homogeneously under gauge changes (cf. Proposition 9.6) and preserves the $\mathbb{Z}_2 \times \mathbb{Z}_2$ degrees (cf. Definition 9.8 and the graded kinematics in Section 4.1.7).

Scale / Regime	**Apeiron & Graviton Manifestation (Gaiamiti Sector)**	**Ontological Level**	**Operational Layer (band/BRST/parasymmetry)**
$\approx \ell_{\mathbf{PQS}}$ **PQS patch (ontic origin)**	No resolvable internal relational structure; only potential excitations in the gaiamiti operator algebra; *no* SSB or particle claims.	Ontic origin; pre-geometric and pre-particle	Pre-physical: outside $H^0(\hat{Q}_{\mathrm{BRST}})$; band-tagging not applied;
$\ell_{\mathbf{PQS}} < \ell < \ell_P$ **Sub-Planckian (pre-physical band)**	Incipient geometric fluctuations $\delta\hat{\mathbf{\Phi}}(x)$; *no* physical spectra; any SSB talk is *diagnostic-only*, not realized.	Pre-physical relational layer	Operator-only: band-tagging allowed, Σ-cone/hyperbolicity audits, typed permit ledgers; *no* plateau certification, *no* projection to H^0.
$\sim \ell_P$ **Planckian (onset of realization)**	Spontaneous symmetry breaking of the geometric vacuum; massive Apeiron modes acquire intrinsic scale m_A; **massless Graviton emerges as the spin-2 Goldstone**. Physical spectra are first read here.	Emergent geometry and particle properties	*Stage of realization*: certify $\mathfrak{P}$, project to $H^0(\hat{Q}_{\mathrm{BRST}})$, use $G^{\mathrm{R}}_{\Phi\Phi,\mathrm{phys}}$ (and mixed blocks). Parasymmetry, if used, acts only on H^0.
$\gg \ell_P$ **Macroscopic (IR)**	Graviton mediates long-range classical GR; massive Apeiron modes are short-ranged.	Classical fields and stable particles	Same physical layer as Planckian: $G^{\mathrm{R}}_{\bullet,\mathrm{phys}}$ on H^0; classical limit from $\bar{\Sigma}_{\mu\nu}$; parasymmetry optional.
$\sim \mathcal{L}_U$ **Cosmological**	Collective/thermodynamic graviton effects (background; large-scale structure).	Thermodynamic/statistical limit	Coarse-grained aggregates of H^0-level kernels over cosmological domains; parasymmetry typically unnecessary.

Table 9.1: Hierarchy of emergence for quanta *(Gaiamiti → apeiron; Tantrakyma → kymon)*. The PQS patch is characterized by a *length* scale ℓ_{PQS} (PQS coherence size); use ℓ^{-1}_{PQS} only for wavenumber thresholds. **Pre-physical:** for $\ell_{\mathrm{PQS}} \leq \ell < \ell_P$, diagnostics are operator-level and expectation-free (no $\mathfrak{P}$, no projection to $H^0(\hat{Q}_{\mathrm{BRST}})$). **Realization:** at $\ell \geq \ell_P$, after plateau certification $\mathfrak{P}$ (cf. eq. (7.28)), observables are evaluated on the physical BRST cohomology $H^0(\hat{Q}_{\mathrm{BRST}})$; parasymmetric diagnostics (if used) act only on H^0.

Definition 9.8 ($\mathbb{Z}_2 \times \mathbb{Z}_2$ grading of channels)**.** Assign the channel colors $\deg(0) = (0,0)$, $\deg(1) = (1,0)$, $\deg(s) = (0,1)$, $\deg(p) = (1,1)$, and set $\deg(\hat{G}^{\alpha\beta}) = \deg(\alpha) + \deg(\beta)$. This equips the correlator components of Definition 6.4 with a minimal graded $*$–algebra structure that preserves mixing rules and sign/phase conventions under transport (cf. Definition 9.7 and Proposition 9.6); the modal basis and fibre structure are those of the Fourfold Dialectic Algebra (cf. Definition 1.5) and its operator implementation within the algebra of observables (cf. Definition 1.32).

Remark 9.9 (Modal fibres and Fourfold logic)**.** The parasymmetric and holosymmetric channels are not linear superpositions of the Twofold; they are independent basis rays in the modal fibre and are accessed by their own effects (cf. Definition 1.32). This reflects the Fourfold Dialectic Algebra (cf. Definition 1.5 and Section 1.2.5) and the emergent modal–Hilbert–space fibres with coincident–limit inner products (cf. Section 4.6); see also the generalized field doublet placed on this operator bundle (cf. Definition 6.1).

Definition 9.10 (Band tag (pre-physical window) and IR window)**.** Let $P_x(\lambda_{\mathrm{UV}})$ denote the UV spectral projector and $K_{\mathrm{IR}}^{(\ell)}$ a causal IR window kernel (mass 1), both chosen to be parallel–transport covariant (cf. Definitions 6.184 and 6.192 and Proposition 9.6) and BRST–closed on the band (cf. eq. (7.24) and Section 7.5). The *band tag* acts on any local observable $\mathfrak{O}$ by

$$\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}](x) \;:=\; \int_{\mathcal{X}_q} K_{\mathrm{IR}}^{(\ell)}(x,y)\,\mathcal{U}(x\leftarrow y)\,P_y(\lambda_{\mathrm{UV}})\,\mathfrak{O}(y)\,P_y(\lambda_{\mathrm{UV}})\,\mathcal{U}(y\leftarrow x)\,\mathrm{d}\mu_y, \tag{9.2}$$

where $\mathcal{U}$ is the gauge–covariant transporter (cf. Definitions 6.184 and 6.192) and $\mathrm{d}\mu_y$ is the integration measure on $\mathcal{X}_q$ (consistent with the relational volume conventions; cf. Definition 6.33). This definition implements the IR windowing and UV projection used in the band–limited formalism (cf. Definition 6.280 and eqs. (7.130) and (7.143)) and transforms homogeneously under gauge changes while preserving the $\mathbb{Z}_2 \times \mathbb{Z}_2$ degrees of the channel algebra (cf. Definition 9.8 and Section 4.1.7).

Lemma 9.11 (BRST-compatibility (tag hygiene))**.** *If* $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})]_\pm = [\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_\pm = 0$*, then* $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]_\pm = 0$*. Band-tagging preserves microcausality and the locality of commutators.*

Proof. By definition, the band tag acts on a local observable $\mathfrak{O}$ as (cf. Definitions 6.280 and 9.10 and eq. (9.2))

$$\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}](x) = \int_{\mathcal{X}_q} K_{\mathrm{IR}}^{(\ell)}(x,y)\,\mathcal{U}(x\leftarrow y)\,P_y(\lambda_{\mathrm{UV}})\,\mathfrak{O}(y)\,P_y(\lambda_{\mathrm{UV}})\,\mathcal{U}(y\leftarrow x)\,\mathrm{d}\mu_y,$$

where $\mathcal{U}$ is the gauge–covariant parallel transporter generated by the operator–bundle connection (cf. Definitions 6.184 and 6.192 and Proposition 9.6) and $\mathrm{d}\mu_y$ is the relational measure (cf. Definition 6.33).

Step 1 (graded derivation and BRST-covariant transport). Using that the BRST differential $\zeta(\cdot) = \{\hat{Q}_{\mathrm{BRST}}, \cdot\}$ is a graded derivation (cf. Section 6.10) and that the transporter is endpoint–covariant, one has the standard identity

$$[\hat{Q}_{\mathrm{BRST}}, \mathcal{U}(x\leftarrow y)\,X(y)\,\mathcal{U}(y\leftarrow x)]_\pm = \mathcal{U}(x\leftarrow y)\,[\hat{Q}_{\mathrm{BRST}}, X(y)]_\pm\,\mathcal{U}(y\leftarrow x),$$

for any ghost–number–zero local operator X built from the channel algebra, provided the endpoint insertions cancel by conjugation (a direct consequence of the endpoint transformation of $\mathcal{U}$ and its inverse; cf. Definition 6.192, Section 4.1.7, and Proposition 9.6).

Step 2 (commutation with the band ingredients). By hypothesis the UV projector and IR window are BRST–closed, $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})]_\pm = 0$ and $[\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_\pm = 0$ (cf. eq. (7.24) and Section 7.5), and both have ghost number zero (cf. Definition 6.280). Using linearity and the graded Leibniz rule inside the integral,

$$\begin{aligned}[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}][\mathfrak{O}](x) &= \int_{\mathcal{X}_q} K_{\mathrm{IR}}^{(\ell)}(x,y)\,\Big[\hat{Q}_{\mathrm{BRST}}, \mathcal{U}(x\leftarrow y)\,P_y\,\mathfrak{O}(y)\,P_y\,\mathcal{U}(y\leftarrow x)\Big]_\pm \,\mathrm{d}\mu_y \\ &= \int_{\mathcal{X}_q} K_{\mathrm{IR}}^{(\ell)}(x,y)\,\mathcal{U}(x\leftarrow y)\,P_y\,[\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}(y)]_\pm\,P_y\,\mathcal{U}(y\leftarrow x)\,\mathrm{d}\mu_y \\ &= \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[[\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}]_\pm\Big](x).\end{aligned}$$

Therefore $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]_\pm = 0$ as superoperators on the local algebra. This is the band–level BRST–compatibility ("tag hygiene"), consistent with the checklist used in the band–limited formalism (cf. eqs. (7.130) and (7.143)).

Step 3 (microcausality and locality of commutators). Let $\mathfrak{O}_1, \mathfrak{O}_2$ be local observables supported in regions $\mathcal{O}_1, \mathcal{O}_2 \subset \mathcal{X}_q$. By construction the IR kernel $K_{\mathrm{IR}}^{(\ell)}(x,y)$ has causal support and decays outside the lightcone (cf. Definition 6.280), and the transporter is path–ordered along γ without enlarging causal support (cf. Definition 6.184 and Proposition 9.6). If $\mathcal{O}_1$ and $\mathcal{O}_2$ are spacelike separated, microcausality of the underlying local algebra (cf. Definition 1.32) implies $[\mathfrak{O}_1(y), \mathfrak{O}_2(y')]_\pm = 0$ for $y \in \mathcal{O}_1$, $y' \in \mathcal{O}_2$. Since $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is built from causal smearing, parallel–transport conjugation, and spectral projection, none of which enlarge causal support or change graded locality, one obtains

$$\Big[\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}_1](x),\, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}_2](x')\Big]_\pm = 0 \quad \text{for spacelike } (x,x').$$

Hence band–tagging preserves microcausality and the locality of commutators.

Combining the three steps yields the claim. □

Definition 9.12 (Pre-physical observable and PSR)**.** Let $\mathcal{H}_{\mathrm{em}}$ be the emergent/GNS Hilbert space (cf. Definition 1.34 and Remark 1.36) and let $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ be the band tag defined by UV projection and IR windowing (cf. Definitions 6.280 and 9.10 and eqs. (7.130), (7.143) and (9.2)). For any local observable $\mathfrak{O}$, define the band–tagged *pre-physical observable*

$$\mathfrak{O}_{\mathrm{pre}}(x;\lambda_{\mathrm{UV}},\ell) := \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}](x).$$

Pre-physical symmetry reduction (PSR) occurs when the expectation on the emergent arena is nonvanishing *prior* to cohomological projection,

$$\Big\langle \mathfrak{O}_{\mathrm{pre}} \Big\rangle_{\mathcal{H}_{\mathrm{em}}} \neq 0,$$

where expectations are taken in the Holo-State/GNS sense (cf. Definitions 1.18 and 1.34). BRST–functoriality of the band tag is expressed as

$$[\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}_{\mathrm{pre}}]_\pm \;=\; \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big(\,[\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}]_\pm\Big),$$

which follows from the band–level BRST–compatibility ("tag hygiene") once the UV projector and IR window are BRST–closed (cf. Lemma 9.11, eq. (7.24), and Section 6.10). Subsequent physical projection to $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$ is performed only after plateau certification (cf. Section 7.5).

Proposition 9.13 (Spectral discipline and endogenous regularization)**.** *Assume the* Axiom of Spectral Smoothness *and that* $\hat{D} \in \mathfrak{D}_{\text{admissible}}$ *(cf. Definitions 4.341, 4.386, 4.392 and 4.428). Together with the* Principle of Finite Entanglement Capacity *(cf. Definitions 1.18 and 1.34), all triadic distances/times—*$d_{\text{corr}}, d_{\text{vac}}, d_{\text{spec}}$ *(cf. Definitions 4.338, 4.428 and 4.463)—and the operator fields derived from them, including* $\hat{g}_{\mu\nu}$, $\hat{t}_{\mu\nu}$, *and* $\hat{\Sigma}_{\mu\nu}$ *(cf. eq. (5.8), Definition 5.17, and Section 5.2.5) are finite on the band, without external UV cutoffs (cf. Definition 9.10 and eqs. (7.130), (7.143) and (9.2)).*

Justification of Proposition 9.13. Immediate from Definitions 4.341, 4.386, 4.392 and 4.428 (self-regularizing spectral geometry) together with bounded expectations/finite-capacity assumptions (cf. Definitions 1.18 and 1.34) and the constructions of eqs. (5.8), (7.130), (7.143) and (9.2), Definitions 5.17 and 9.10, and Section 5.2.5. No additional argument is required.

Proposition 9.14 (Bundle well-posedness and gauge/frame covariance)**.** *Under Relational and Spectral Smoothness (cf. Definitions 4.341, 4.428 and 6.7), the triads* $(\vec{d}, \vec{t})$ *vary smoothly over* $\mathcal{X}_q$ *(cf. Sections 5.1.4 and 5.2.5), local frame changes act orthogonally on the triads, and the induced connections/holonomies are intrinsic to the Holo-State and Fourfold/Spectral data (cf. Definitions 6.184 and 6.192 and Proposition 9.6).*

Justification of Proposition 9.14. Smooth variation and frame covariance follow from the Relational Levi–Civita construction (cf. Definition 6.7) together with spectral smoothness (cf. Definitions 4.341 and 4.428); gauge/frame covariance and intrinsic holonomies are inherited from the operator–bundle setup (cf. Definitions 6.184 and 6.192) and the correlator's covariance (cf. Proposition 9.6). No further proof is needed.

Remark 9.15 (IR window properties and cone preservation)**.** The windowing map $F \mapsto F^{(\ell)}$ is positivity–preserving and contractive (cf. Definition 6.280 and eq. (7.130)); with causal transport, cones defined by $\bar{\Sigma}^{(\ell)}$ are not enlarged relative to those of $\bar{\Sigma}$ (cf. Definitions 5.122 and 6.7). BRST–closure of $K_{\text{IR}}^{(\ell)}$ ensures compatibility with the physical projector on cohomology, via band–level hygiene (cf. Lemma 9.11, eq. (7.24), and Section 6.10).

Justification of Remark 9.15. Positivity/contractivity of the IR window is by construction (cf. Definition 6.280 and eq. (7.130)); cone preservation follows from causal transport and the effective light-cone definition for $\bar{\Sigma}$ (cf. Definitions 5.122 and 6.7). BRST-compatibility with P_{phys} is ensured by tag hygiene (cf. Lemma 9.11, eq. (7.24), and Section 6.10).

Corollary 9.16 (Σ-riders (no structural change))**.** *The chronogeometric operator fields* $\hat{g}_{\mu\nu}$, $\hat{t}_{\mu\nu}$ *and* $\hat{\Sigma}_{\mu\nu} := \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ *live on the same band–regulated fibres as* $\hat{\mathbf{G}}_\Lambda$*, transform covariantly under* $\mathcal{U}$*, and—by Proposition 9.13—admit SOT–Hessians at coincidence. Thus, replacing "triads only" by* Σ *introduces* no *change to the arena/transport/grade/band scaffolding; it only adds derived operator fields that are already finite and smooth on the band.*

Proof. (i) Band localisation and fibres. The Fourfold Inter–Modal Correlator and its block structure are fixed by Definition 6.4 and eq. (4.24). Band–tagging is implemented by the UV projector and IR window via Definitions 6.280 and 9.10 and eqs. (7.130), (7.143) and (9.2). Hence all objects obtained from $\hat{\mathbf{G}}_\Lambda$ by band–tagging (including distances/times and their Hessians) act on the same band–regulated fibres.

(ii) Gauge/transport covariance and graded kinematics. The transporter $\mathcal{U}$ and the operator–bundle connection are defined in Definitions 6.184 and 6.192, and graded covariant kinematics in Definition 9.7 and Section 4.1.7. Gauge covariance of the correlator (and thus of any covariant functional built from it) is given by Proposition 9.6. Therefore $\hat{g}_{\mu\nu}$ and $\hat{t}_{\mu\nu}$—being built from covariant second variations of band–regular functionals—transform by endpoint conjugation and preserve the $\mathbb{Z}_2 \times \mathbb{Z}_2$ degrees (cf. Definition 9.8).

(iii) Existence and finiteness of SOT–Hessians. The triadic distances/times $d_{\mathrm{corr}}, d_{\mathrm{vac}}, d_{\mathrm{spec}}$ are defined in Definitions 4.338, 4.428 and 4.463, with spectral generator $\hat{D}$ in Definitions 4.341 and 4.386. Under the Axiom of Spectral Smoothness and the Principle of Finite Entanglement Capacity, Proposition 9.13 ensures band–level finiteness and smoothness, so the operator–valued Hessians at coincidence defining $\hat{g}_{\mu\nu}$ and $\hat{t}_{\mu\nu}$ exist in the strong operator topology (cf. eq. (5.8), Definition 5.17, and Section 5.2.5). Hence $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ is likewise band–regular and covariant.

(iv) Structural invariance. The arena/transport/grade/band scaffolding is precisely that of Section 9.1 and Definitions 9.7, 9.8 and 9.10; replacing the separate triads by the unified Σ does not alter these structures, only the (already finite) derived operator fields used as inputs. □

Remark 9.17 (Where BRST enters later)**.** Band tags are BRST–closed by Lemma 9.11 once the checklist eq. (7.24) holds; the pre–physical observable and PSR notion are defined in Definition 9.12. These are arena–level diagnostics and not yet physical. Only after projection to the cohomology $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10) are spectra and visibilities evaluated with gauge–parameter independence ensured by the BRST/Nielsen framework (cf. Principle 6.1 and Section 7.5).

Summary of Section 9.1. The construction is placed on the emergent/GNS arena $\mathcal{H}_{\mathrm{em}}$ (cf. Definition 1.34 and Remark 1.36), where the Fourfold Inter–Modal Correlator $\hat{\mathbf{G}}_\Lambda$ is defined with its block structure (cf. Definition 6.4 and eq. (4.24)) and transported by the gauge–covariant parallel transporter $\mathcal{U}$ associated with the operator–bundle connection (cf. Definitions 6.184 and 6.192). Hermiticity of the Twofold block and covariance of the full Fourfold under gauge changes ensure that expectation values in gauge–covariant states are gauge–invariant (cf. Proposition 9.6). Channel components form a $\mathbb{Z}_2 \times \mathbb{Z}_2$ graded $*$–algebra (cf. Definition 9.8), and differentiation is performed by the graded covariant derivative $\mathfrak{D}_\mu$ (cf. Definition 9.7 and Section 4.1.7). A pre–physical window is selected by the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$, built from the UV spectral projector $P_x(\lambda_{\mathrm{UV}})$ and a causal IR window kernel $K_{\mathrm{IR}}^{(\ell)}$ (cf. Definitions 6.280 and 9.10 and eqs. (7.130), (7.143) and (9.2)). Band hygiene guarantees BRST–compatibility, namely $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]_\pm = 0$ once the checklist holds (cf. Lemma 9.11 and eq. (7.24)), and the construction preserves microcausality and locality of commutators (cf. Definition 1.32 and Lemma 9.11). Spectral discipline—combining the admissible spectral operator and self–regularizing spectral distance with the finite–capacity assumptions—yields

finiteness and smoothness on the band for the triadic distances/times $d_{\mathrm{corr}}, d_{\mathrm{vac}}, d_{\mathrm{spec}}$ and for the operator fields derived from them (cf. Definitions 1.18, 1.34, 4.338, 4.341, 4.386, 4.392, 4.428 and 4.463). In particular, the metric and temporal Hessians $\hat{g}_{\mu\nu}$ and $\hat{t}_{\mu\nu}$, and the chronogeometry $\hat{\Sigma}_{\mu\nu} := \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$, exist in the strong–operator topology and vary smoothly over $\mathcal{X}_q$ (cf. Propositions 9.13 and 9.14, eq. (5.8), Definition 5.17, and Section 5.2.5). Consequently, $\hat{\Sigma}$ "rides" on exactly the same arena/transport/grade/band scaffolding as the correlator $\hat{\mathbf{G}}_\Lambda$ and introduces no structural change (cf. Corollary 9.16); only the inputs to downstream constructions are unified. Expectation–level objects such as the Relational Levi–Civita connection and effective cones are then read from $\bar{\Sigma}_{\mu\nu}$ in the appropriate physical layer (cf. Definitions 5.122 and 6.7 and Section 7.5).

9.2 Law vs. State, Visibilities, and the Four Quadrants (Pre-Physical)

Definition 9.18 (Graded action of G on correlators)**.** Let G act on channel components by the graded adjoint implemented with the gauge–covariant transport $\mathcal{U}$ of Definition 9.7 (built from the operator–bundle connection; cf. Definitions 6.184 and 6.192). For $g \in G$,

$$\hat{\mathbf{G}}_\Lambda(x,x') \;\longmapsto\; \mathrm{Ad}_g\,\hat{\mathbf{G}}_\Lambda(x,x') \;:=\; g(x)\,\hat{\mathbf{G}}_\Lambda(x,x')\,g(x')^\dagger,$$

with block entries $\hat{G}_\Lambda^{\alpha\beta}$ defined as in Definitions 4.9 and 6.4 and eq. (4.24). This action is compatible with the Fourfold bundle structure and graded kinematics (cf. Sections 4.1.2 and 4.1.7 and Definition 9.8) and preserves the Hermiticity/covariance properties of the correlator (cf. Proposition 9.6).

Definition 9.19 (Correlator amplitude and normalizations)**.** Fix local modal vectors $|\psi_1\rangle_x, |\psi_2\rangle_{x'}$ in the Fourfold fibres (cf. Section 4.6) and define the scalar amplitude and normalizations by

$$\begin{aligned} \mathsf{G}(x,x';\psi_1,\psi_2) &:= \Big\langle \mathring{\mathbf{\Psi}} \Big|\, \hat{G}_\Lambda(\mathfrak{B}_x,\mathfrak{B}_{x'})[\psi_1^*,\psi_2] \,\Big|\, \mathring{\mathbf{\Psi}} \Big\rangle, \\ N(\psi_1,x) &:= \mathsf{G}(x,x;\psi_1,\psi_1)^{1/2}, \\ N(\psi_2,x') &:= \mathsf{G}(x',x';\psi_2,\psi_2)^{1/2}. \end{aligned} \tag{9.3}$$

Here $\hat{G}_\Lambda(\mathfrak{B}_x,\mathfrak{B}_{x'})[\psi_1^*,\psi_2]$ is the bilinear evaluation of the Fourfold correlator with parallel transport $\mathcal{U}(x \leftarrow x';\gamma)$ aligning frames (cf. Definition 4.9, eq. (4.24), and Proposition 9.6). Expectations are taken in the GNS/Holo-State sense (cf. Definitions 1.18 and 1.34), and band–limited locality is enforced by the tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (cf. Definitions 6.280 and 9.10 and eq. (9.2)).

Definition 9.20 (Operator-valued chronogeometry on the band)**.** On the band $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ of Definition 9.10, form the composite operator distances and temporal functionals from the correlator–based triads $d_{\mathrm{corr}}, d_{\mathrm{vac}}, d_{\mathrm{spec}}$ (cf. Definitions 4.338, 4.428 and 4.463) with spectral generator $\hat{D}$ (cf. Definitions 4.341 and 4.386). Assuming spectral discipline (cf. Proposi-

tion 9.13 and Remark 4.425), their SOT–C^2 Hessians at coincidence yield

$$\begin{aligned}\hat{g}_{\mu\nu}(x) &:= \partial_{x^\mu}\partial_{x'^\nu} D^2(x,x')\Big|_{x'=x},\\ \hat{t}_{\mu\nu}(x) &:= \partial_{x^\mu}\partial_{x'^\nu} T^2(x,x')\Big|_{x'=x},\\ \hat{\Sigma}_{\mu\nu}(x) &:= \hat{g}_{\mu\nu}(x) + \hat{t}_{\mu\nu}(x),\end{aligned} \tag{9.4}$$

which are Hermitian, symmetric in μ,ν, and covariant under local frame changes (cf. Definition 9.7 and Proposition 9.14). At the expectation level $\bar{\Sigma}_{\mu\nu} := \langle\hat{\Sigma}_{\mu\nu}\rangle = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ (cf. eq. (5.8) and Definitions 5.17 and 6.7).

Remark 9.21 (Finiteness and band regularity)**.** Under Spectral Smoothness and Finite Entanglement Capacity (cf. Definitions 1.34, 4.392 and 4.428), all triadic distances/times are finite on the band, hence $\hat{g}_{\mu\nu}, \hat{t}_{\mu\nu}$ and $\hat{\Sigma}_{\mu\nu}$ are well–defined and smooth (cf. Propositions 9.13 and 9.14). Consequently, for any $\varepsilon > 0$ there exist effective cutoffs $\Lambda_{\text{eff}}(x,x';\varepsilon)$ consistent with the band construction (cf. Definition 9.10 and eq. (7.130)) and with causal cones determined by $\bar{\Sigma}$ (cf. Definition 5.122).

Definition 9.22 (Chronogeometric quadratic form)**.** For a small displacement $v = v^\mu\partial_\mu|_x$, define on the band (cf. Definition 9.10) the local quadratic form built from the operator–valued chronogeometry (cf. Definition 9.20):

$$\hat{Q}_x[v] \;:=\; v^\mu v^\nu\,\hat{\Sigma}_{\mu\nu}(x), \qquad \bar{Q}_x[v] \;:=\; \langle\hat{Q}_x[v]\rangle \;=\; v^\mu v^\nu\,\bar{\Sigma}_{\mu\nu}(x). \tag{9.5}$$

Here $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ is obtained as the SOT–C^2 Hessian at coincidence of the composite distance/time functionals (cf. eqs. (5.8) and (9.4) and Definition 5.17), and $\bar{\Sigma}_{\mu\nu} := \langle\hat{\Sigma}_{\mu\nu}\rangle$ (cf. Definition 6.7). The tensor $\hat{\Sigma}_{\mu\nu}$ transforms covariantly under local frame changes, hence $\hat{Q}_x[v]$ transforms by endpoint conjugation (cf. Definition 9.7 and Proposition 9.14); by gauge covariance of the correlator and cyclicity of the Born pairing, the expectation $\bar{Q}_x[v]$ is gauge–invariant in gauge–covariant states (cf. Proposition 9.6, Definitions 1.18 and 1.34, and Section 4.19.1).

Definition 9.23 (Pre-physical Σ-law and Σ-state contrasts)**.** Let $\mathcal{I}$ be any gauge–invariant, band–local functional (e.g. Holo–State Born pairing or a regulated band–trace; cf. Definitions 1.18, 1.34, 6.280 and 9.10 and eq. (9.2)). Using the graded adjoint action Ad_g of G on correlator–derived objects (cf. Definitions 9.7 and 9.18 and Proposition 9.6), define, for $g \in G$ and $v = v^\mu\partial_\mu|_x$,

$$\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v) := \Big(\mathcal{I}\Big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big]\Big)^{1/2}, \tag{9.6}$$

$$\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v) := \Big|\mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big] - \mathcal{I}_{g\cdot\Psi}\Big[\hat{Q}_x[v]\Big]\Big|^{1/2}, \tag{9.7}$$

where $\mathcal{I}_\Psi[\cdot] = \langle\Psi|\cdot|\Psi\rangle$ is the pre–physical Holo–State evaluation (cf. Definition 1.18), and $g\cdot\Psi$ denotes the push–forward of the Holo–State by the unitary representation implementing g on the bundle (implicit in Definitions 6.184 and 6.192 and Proposition 9.6). These contrasts are

computed on the band and are BRST–functorial whenever the tag is hygienic (cf. Lemma 9.11 and eq. (7.24)); they quantify, respectively, explicit law asymmetry and state asymmetry at the pre–physical level, prior to projection to $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$ (cf. Sections 6.10 and 7.5).

Lemma 9.24 (Gauge/frame covariance of contrasts)**.** *The quantities $\Delta^{\text{pre},\Sigma}_{\text{law}}$ and $\Delta^{\text{pre},\Sigma}_{\text{state}}$ are independent of local frame choices and respect the graded action of G described in Definition 9.18. In particular, they depend only on the conjugacy class of g at x.*

Proof. Recall that the chronogeometric quadratic form is $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ with $\hat{\Sigma}_{\mu\nu}$ the covariant SOT–C^2 Hessian on the band (cf. Definitions 9.20 and 9.22). Under a local frame change $h : \mathcal{X}_q \to \mathrm{U}(\mathcal{H}_{\text{em}})$ (implemented by the operator–bundle connection/transport; cf. Definitions 6.184, 6.192 and 9.7), the correlator and any tensor derived covariantly from it transform by endpoint conjugation (cf. Proposition 9.6), hence

$$\hat{Q}_x[v] \;\longmapsto\; \mathrm{Ad}_{h(x)}\,\hat{Q}_x[v] := h(x)\,\hat{Q}_x[v]\,h(x)^\dagger. \tag{9.8}$$

Likewise, the graded adjoint action of $g \in G$ on correlator–derived objects transforms as

$$\mathrm{Ad}_{g(x)} \;\longmapsto\; \mathrm{Ad}_{h(x)g(x)h(x)^{-1}}, \qquad \text{and} \qquad \mathrm{Ad}_{h(x)g(x)h(x)^{-1}} \circ \mathrm{Ad}_{h(x)} = \mathrm{Ad}_{h(x)} \circ \mathrm{Ad}_{g(x)}, \tag{9.9}$$

(cf. Definitions 9.7 and 9.18). Band–local, gauge–invariant functionals $\mathcal{I}$ and $\mathcal{I}_\Psi[\cdot] = \langle\Psi|\cdot|\Psi\rangle$ are conjugation invariant by construction (Born cyclicity/unitarity; cf. Definitions 1.18, 1.34 and 9.23 and Section 4.19.1), i.e.

$$\mathcal{I}[\mathrm{Ad}_h\, X] = \mathcal{I}[X], \qquad \mathcal{I}_{h\cdot\Psi}[\mathrm{Ad}_h\, X] = \mathcal{I}_\Psi[X], \tag{9.10}$$

where $h \cdot \Psi$ denotes the pushed-forward Holo–State (unitary representation).

Law contrast. Using (9.8)–(9.10) in the definition of $\Delta^{\text{pre},\Sigma}_{\text{law}}$ (cf. Definition 9.23):

$$\begin{aligned}
\Big(\Delta^{\text{pre},\Sigma}_{\text{law}}(g;x;v)\Big)^2 &= \mathcal{I}\Big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big] \\
&\xrightarrow{h}\; \mathcal{I}\Big[\mathrm{Ad}_{h(x)}\,\hat{Q}_x[v] - \mathrm{Ad}_{h(x)g(x)h(x)^{-1}}\,\mathrm{Ad}_{h(x)}\,\hat{Q}_x[v]\Big] \\
&= \mathcal{I}\Big[\mathrm{Ad}_{h(x)}\Big(\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big)\Big] = \mathcal{I}\Big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big]\,,
\end{aligned}$$

which shows frame independence. The middle line used (9.9). Consequently, $\Delta^{\text{pre},\Sigma}_{\text{law}}$ depends only on the conjugacy class of $g(x)$.

State contrast. Similarly, with $\mathcal{I}_\Psi[\cdot] = \langle\Psi|\cdot|\Psi\rangle$ (cf. Definition 9.23) and the representation property $(hgh^{-1})\cdot(h\cdot\Psi) = h\cdot(g\cdot\Psi)$:

$$\begin{aligned}
\Big(\Delta^{\text{pre},\Sigma}_{\text{state}}(g;x;v)\Big)^2 &= \Big|\mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big] - \mathcal{I}_{g\cdot\Psi}\Big[\hat{Q}_x[v]\Big]\Big| \\
&\xrightarrow{h}\; \Big|\mathcal{I}_{h\cdot\Psi}\Big[\,\mathrm{Ad}_{h(x)}\,\hat{Q}_x[v]\Big] - \mathcal{I}_{(hgh^{-1})\cdot(h\cdot\Psi)}\Big[\,\mathrm{Ad}_{h(x)}\,\hat{Q}_x[v]\Big]\Big| \\
&= \Big|\mathcal{I}_\Psi\Big[\hat{Q}_x[v]\Big] - \mathcal{I}_{g\cdot\Psi}\Big[\hat{Q}_x[v]\Big]\Big|,
\end{aligned}$$

by (9.10). Hence $\Delta^{\text{pre},\Sigma}_{\text{state}}$ is frame independent and depends only on the conjugacy class of $g(x)$.

Both contrasts therefore respect the graded action of G (they are built from the graded adjoint, cf. Definition 9.18) and are invariant under local frame changes dictated by the operator–bundle connection/transport (cf. Definitions 6.184, 6.192 and 9.7). This completes the proof. □

Proposition 9.25 (Reduction to correlator-only distances)**.** *If $\hat{\Sigma}_{\mu\nu}$ is decomposed into triadic parts* $(\mathrm{corr}, \mathrm{vac}, \mathrm{spec})$ *as in the expectation–level decomposition of Definition 5.54 (cf. also eqs. (5.8) and (5.21)), then choosing the band–local, gauge–invariant functional $\mathcal{I}$ channelwise yields*

$$\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}} \rightsquigarrow \left(\Delta^{\mathrm{pre,corr}}_{\mathrm{law}}, \Delta^{\mathrm{pre,vac}}_{\mathrm{law}}, \Delta^{\mathrm{pre,spec}}_{\mathrm{law}}\right), \quad \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}} \rightsquigarrow \left(\Delta^{\mathrm{pre,corr}}_{\mathrm{state}}, \Delta^{\mathrm{pre,vac}}_{\mathrm{state}}, \Delta^{\mathrm{pre,spec}}_{\mathrm{state}}\right),$$

and, in particular, the correlator–only contrasts of the original construction when the other channels are deactivated.

Proof. Triadic split and quadratic forms. By Definition 9.20, the band–local chronogeometry admits the operator–level triadic split $\hat{\Sigma}_{\mu\nu} = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{\Sigma}^{(a)}_{\mu\nu}$, consistent with the expectation–level decomposition $\bar{\Sigma}_{\mu\nu} = \sum_a \bar{\Sigma}^{(a)}_{\mu\nu}$ (cf. Definition 5.54 and eqs. (5.8) and (5.21)). Define the channelwise quadratic forms (cf. Definition 9.22)

$$\hat{Q}^{(a)}_x[v] := v^\mu v^\nu \hat{\Sigma}^{(a)}_{\mu\nu}(x), \qquad \hat{Q}_x[v] = \sum_a \hat{Q}^{(a)}_x[v].$$

Channelwise functionals. Let $\mathcal{I}$ be a gauge–invariant, band–local functional (e.g. Born pairing or regulated band–trace; cf. Definitions 1.18, 1.34, 9.10 and 9.23 and eq. (9.2)). By the $\mathbb{Z}_2 \times \mathbb{Z}_2$ grading and block structure of the Fourfold bundle (cf. Definition 9.8, eq. (4.24), and Section 4.1.7), there exist channel–projected functionals $\mathcal{I}^{(a)}$ that act on the (a)–block and annihilate the others, i.e. $\mathcal{I}^{(a)}[\hat{Q}^{(b)}_x[v]] = 0$ for $b \neq a$ and $\mathcal{I}^{(a)}[\hat{Q}_x[v]] = \mathcal{I}^{(a)}[\hat{Q}^{(a)}_x[v]]$. (Concretely, $\mathcal{I}^{(a)}$ is obtained by inserting the band–local projector onto the (a)–block before taking the expectation/trace; the existence of these projectors follows from the graded algebra and transport covariance, cf. Definition 9.7 and Proposition 9.6.)

Law contrast. Using Definition 9.23 and linearity of $\mathcal{I}^{(a)}$,

$$\begin{aligned}\left(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)\right)^2 &= \mathcal{I}\left[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\right] = \sum_a \mathcal{I}^{(a)}\left[\hat{Q}^{(a)}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}^{(a)}_x[v]\right] \\ &=: \sum_a \left(\Delta^{\mathrm{pre},a}_{\mathrm{law}}(g;x;v)\right)^2,\end{aligned}$$

where the graded adjoint $\mathrm{Ad}_{g(x)}$ respects the channel decomposition (cf. Definition 9.18). Thus evaluating with each $\mathcal{I}^{(a)}$ yields the channelwise law contrasts $\Delta^{\mathrm{pre},a}_{\mathrm{law}}$.

State contrast. Similarly, with $\mathcal{I}_\Psi[\cdot] = \langle\Psi|\cdot|\Psi\rangle$ (cf. Definition 9.23),

$$\begin{aligned}\left(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v)\right)^2 &= \left|\mathcal{I}_\Psi[\hat{Q}_x[v]] - \mathcal{I}_{g\cdot\Psi}[\hat{Q}_x[v]]\right| = \left|\sum_a \left(\mathcal{I}_\Psi[\hat{Q}^{(a)}_x[v]] - \mathcal{I}_{g\cdot\Psi}[\hat{Q}^{(a)}_x[v]]\right)\right| \\ &\rightsquigarrow \left(\Delta^{\mathrm{pre,corr}}_{\mathrm{state}}, \Delta^{\mathrm{pre,vac}}_{\mathrm{state}}, \Delta^{\mathrm{pre,spec}}_{\mathrm{state}}\right),\end{aligned}$$

by evaluating with $\mathcal{I}^{(a)}_\Psi$ (the channel–projected Born pairing). Gauge/frame covariance of these contrasts follows from Lemma 9.24.

Correlator–only reduction. If the vacuum and spectral channels are deactivated (or their projectors are set to zero on the band), one retains only the correlator channel. In that case, $\hat{\Sigma}_{\mu\nu} \to \hat{\Sigma}^{(\mathrm{corr})}_{\mu\nu}$ and $\hat{Q}_x[v] \to \hat{Q}^{(\mathrm{corr})}_x[v]$, and the contrasts reduce to the correlator–only diagnostics built from d_{corr} and its induced metric data (cf. Definition 4.338 and Section 4.10.2). Analogous single–channel reductions hold for the vacuum and spectral channels (cf. Definitions 4.428 and 4.463).

Independence/orthogonality. Functional orthogonality and Fréchet–type independence of the triadic generators validate the channelwise treatment above (cf. Section 4.11.5), ensuring that no cross–terms are introduced by the graded action.

Combining the steps yields the claim. □

Definition 9.26 (Aggregated Σ-contrasts and visibilities)**.** Given a finite probe set $\{v_k\}_{k=1}^m \subset T_x\mathcal{X}_q$, define the aggregated (root–sum–square) pre–physical Σ–contrasts built from the pointwise contrasts of Definition 9.23 and the quadratic form of Definition 9.22:

$$\begin{aligned} \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x) &:= \left(\sum_{k=1}^{m} \left[\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v_k) \right]^2 \right)^{1/2}, \\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x) &:= \left(\sum_{k=1}^{m} \left[\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v_k) \right]^2 \right)^{1/2}. \end{aligned} \tag{9.11}$$

Here each $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v_k)$ and $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v_k)$ is evaluated with $\hat{Q}_x[v_k] = v_k^\mu v_k^\nu \hat{\Sigma}_{\mu\nu}(x)$ as in Definition 9.22, using any band–local, gauge–invariant functional $\mathcal{I}$ (e.g. Holo–State Born pairing or regulated band–trace; cf. Definitions 1.18, 1.34, 6.280 and 9.10 and eq. (9.2)). By frame covariance of $\hat{Q}_x[v]$ and conjugation–invariance of the functionals (cf. Proposition 9.6, Definition 9.7, and Section 4.19.1), and by Lemma 9.24, the aggregated quantities are independent of local frame choices and respect the graded G–action of Definition 9.18. Channelwise decompositions and correlator–only reductions are consistent with Proposition 9.25, Definition 5.54, and eqs. (5.8) and (5.21). Operationally, the associated *pre–physical visibilities* are any such band–local, gauge–invariant functionals of $\hat{Q}_x[v]$ (or $\bar{Q}_x[v] = \langle \hat{Q}_x[v] \rangle$) used to estimate (9.11) (cf. Definitions 9.20 and 9.23).

Lemma 9.27 (Finiteness and stability under band deformations)**.** *Under the hypotheses of Remark 9.21, the maps $v \mapsto \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)$ and $v \mapsto \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v)$ are continuous and bounded; moreover, small changes in the band parameters $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\lambda'_{\mathrm{UV}}, \ell')$ induce $\mathcal{O}(\varepsilon)$ variations controlled by the effective cutoff $\Lambda_{\mathrm{eff}}(x,x';\varepsilon)$ of Remark 9.21.*

Proof. (1) Continuity and boundedness in v. By Definitions 9.20 and 9.22, $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ with $\hat{\Sigma}_{\mu\nu}$ the band–regular, Hermitian SOT–C^2 Hessian (existence/regularity from Propositions 9.13 and 9.14). Let $\|\cdot\|$ denote the operator norm on the band fibre $P_x(\lambda_{\mathrm{UV}})\mathcal{H}_{\mathrm{total}}$. Then

$$\|\hat{Q}_x[v]\| \;\le\; \|\hat{\Sigma}(x)\|\,\|v\|^2, \qquad \|\hat{Q}_x[v] - \hat{Q}_x[w]\| \;\le\; \|\hat{\Sigma}(x)\| \left(\|v\| + \|w\|\right) \|v - w\|,$$

so $v \mapsto \hat{Q}_x[v]$ is continuous and (locally) Lipschitz. For any admissible, gauge–invariant, band–local functional $\mathcal{I}$ (e.g. Born pairing or regulated band–trace; cf. Definitions 1.18, 6.280,

9.10 and 9.23 and eq. (9.2)), boundedness $\big|\mathcal{I}[X]\big| \le C\,\|X\|$ holds with C determined by the state/trace. Therefore

$$\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)\Big)^2 = \mathcal{I}\Big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big] \;\le\; 2C\,\|\hat{\Sigma}(x)\|\,\|v\|^2,$$

and similarly for $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}$, showing boundedness on bounded v–sets and continuity by composition (cf. Definitions 9.18 and 9.23 and Proposition 9.6).

(2) Stability under band deformations $(\lambda_{\mathrm{UV}},\ell)$. Write the band tag as in Definition 9.10 and eq. (9.2), with its parameter dependence encoded by $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ (cf. Definition 6.280 and eq. (7.130)). Under Spectral Smoothness and Finite Entanglement Capacity, Remark 9.21 provides, for each $\varepsilon>0$, an effective cutoff $\Lambda_{\mathrm{eff}}(x,x';\varepsilon)$ such that modes above Λ_{eff} contribute less than ε to all band–local functionals under consideration. For the UV part, the variation of the spectral projector obeys

$$\Big\|P_x(\lambda'_{\mathrm{UV}}) - P_x(\lambda_{\mathrm{UV}})\Big\| \;\le\; C_{\mathrm{UV}}\,\Theta\Big(\Lambda_{\mathrm{eff}} - \min\{\lambda_{\mathrm{UV}},\lambda'_{\mathrm{UV}}\}\Big) \;+\; \mathcal{O}(\varepsilon),$$

with the $\mathcal{O}(\varepsilon)$ term supplied by the cutoff (the precise constant depends on the spectral density near the band edge but the tail is ε–small by construction). For the IR part, strong continuity $\|K^{(\ell')}_{\mathrm{IR}} - K^{(\ell)}_{\mathrm{IR}}\| \to 0$ as $\ell' \to \ell$ follows from the window definition and causal regularity (cf. Definition 6.280), hence

$$\Big\|\mathfrak{B}_{\lambda'_{\mathrm{UV}},\ell'}[\mathfrak{O}] - \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}]\Big\| \;\le\; C_{\mathfrak{O}}\left(\Big\|P(\lambda'_{\mathrm{UV}}) - P(\lambda_{\mathrm{UV}})\Big\| + \Big\|K^{(\ell')}_{\mathrm{IR}} - K^{(\ell)}_{\mathrm{IR}}\Big\|\right) \;+\; \mathcal{O}(\varepsilon),$$

for local $\mathfrak{O}$ and some constant $C_{\mathfrak{O}}$ (from the bounded transport $\mathcal{U}$, cf. Definitions 6.184 and 6.192). Applying this to the ingredients that define D^2, T^2 and their SOT–Hessians yields

$$\Big\|\hat{\Sigma}'_{\mu\nu}(x) - \hat{\Sigma}_{\mu\nu}(x)\Big\| \;=\; \mathcal{O}(\varepsilon),$$

hence $\Big\|\hat{Q}'_x[v] - \hat{Q}_x[v]\Big\| \le \|v\|^2\,\Big\|\hat{\Sigma}' - \hat{\Sigma}\Big\| = \mathcal{O}(\varepsilon)$ uniformly for $\|v\|\le R$. By boundedness of $\mathcal{I}$ and $\mathcal{I}_\Psi$ (cf. Definition 9.23),

$$\Big|\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}\Big)^2{}' - \Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}\Big)^2\Big| \;\le\; C\,\Big\|\hat{Q}'_x[v] - \hat{Q}_x[v]\Big\| \;=\; \mathcal{O}(\varepsilon),$$

and similarly for the state contrast. Taking square roots preserves $\mathcal{O}(\varepsilon)$ control on compact v–sets. This is consistent with the finite–difference stability diagnostics used on the $(\ln\lambda_{\mathrm{UV}}, \ln\ell)$ grid (cf. eqs. (7.394) to (7.396)) and the acceptance rules for plateau certification (cf. Proposition 7.203).

Combining (1) and (2) proves continuity, boundedness, and $\mathcal{O}(\varepsilon)$ stability of the contrasts under small band deformations, with control by $\Lambda_{\mathrm{eff}}(x,x';\varepsilon)$ from Remark 9.21. □

Definition 9.28 (Quadrant predicate (pre-physical, Σ-aware))**.** Fix a tolerance $\varepsilon \ll 1$ and a band $(\lambda_{\mathrm{UV}},\ell)$. Declare at x:

$$\textbf{QI}:\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x)<\varepsilon,\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x)<\varepsilon; \quad \textbf{QII}:\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x)<\varepsilon,\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x)>\varepsilon;$$

$$\textbf{QIII}:\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x)>\varepsilon,\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x)<\varepsilon; \quad \textbf{QIV}:\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x)>\varepsilon,\ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x)>\varepsilon.$$

This mirrors the physical quadrant logic in $H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Definition 6.224 and Remark 6.223).

Proposition 9.29 (Interpretability via triadic attribution)**.** *Writing the expectation–level chronogeometry as a triadic sum* $\bar{\Sigma}_{\mu\nu} = \bar{\Sigma}^{\mathrm{corr}}_{\mu\nu} + \bar{\Sigma}^{\mathrm{vac}}_{\mu\nu} + \bar{\Sigma}^{\mathrm{spec}}_{\mu\nu}$ *(cf. Definition 5.54 and eqs. (5.8) and (5.21)), a quadrant decision based on* Σ*–contrasts can be attributed to channelwise contributions from coherence, vacuum, and spectral shear, respectively; this attribution preserves gauge invariance and band locality.*

Proof. (i) Channelwise decomposition on the band. At the operator level, $\hat{\Sigma}_{\mu\nu} = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{\Sigma}^{(a)}_{\mu\nu}$ by Definition 9.20, consistent with the expectation–level split quoted above (cf. Definition 5.54). For any probe v, the quadratic form $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ of Definition 9.22 splits as $\hat{Q}_x[v] = \sum_a \hat{Q}^{(a)}_x[v]$ with $\hat{Q}^{(a)}_x[v] := v^\mu v^\nu \hat{\Sigma}^{(a)}_{\mu\nu}(x)$.

(ii) Channel projectors and band–local functionals. By the graded bundle structure and block decomposition of the Fourfold algebra (cf. Definition 9.8, eq. (4.24), and Section 4.1.7), there exist band–local channel projectors $\Pi^{(a)}$ that commute with the transport (graded–covariantly) and select each (a)–block (cf. Definition 9.7 and Proposition 9.6). Define channelwise, gauge–invariant band functionals by $\mathcal{I}^{(a)}[X] := \mathcal{I}[\Pi^{(a)} X \Pi^{(a)}]$, where $\mathcal{I}$ is as in Definitions 9.23 and 9.26. Then $\mathcal{I}^{(a)}[\hat{Q}_x[v]] = \mathcal{I}^{(a)}[\hat{Q}^{(a)}_x[v]]$ and $\mathcal{I}^{(a)}[\hat{Q}^{(b)}_x[v]] = 0$ for $b \neq a$.

(iii) Channelwise attribution of the Σ*–contrasts.* From Definition 9.23 and linearity,

$$\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)\Big)^2 = \mathcal{I}\Big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big] = \sum_a \mathcal{I}^{(a)}\Big[\hat{Q}^{(a)}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}^{(a)}_x[v]\Big].$$

The summands define the channelwise law–contributions $\Big(\Delta^{\mathrm{pre},a}_{\mathrm{law}}(g;x;v)\Big)^2$. A completely analogous decomposition holds for the state contrast:

$$\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v)\Big)^2 = \sum_a \Big(\mathcal{I}^{(a)}_\Psi[\hat{Q}^{(a)}_x[v]] - \mathcal{I}^{(a)}_{g\cdot\Psi}[\hat{Q}^{(a)}_x[v]]\Big),$$

with $\mathcal{I}^{(a)}_\Psi$ the channel–projected Born pairing (cf. Definitions 1.18 and 1.34).

(iv) Gauge invariance and band locality. Each term is invariant under local frame changes by the conjugation invariance of $\mathcal{I}, \mathcal{I}_\Psi$ and the covariance of $\hat{Q}^{(a)}_x[v]$ (cf. Proposition 9.6, Definition 9.7, Section 4.19.1, and Lemma 9.24). Band locality follows from the construction of $\mathcal{I}$ and the tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (cf. Definitions 6.280 and 9.10 and eq. (9.2)). Functional orthogonality/independence of the triadic generators (cf. Section 4.11.5) ensures that no spurious cross–terms arise in the attribution. Therefore a quadrant decision based on the Σ–contrasts can be interpreted as a sum of channelwise, gauge–invariant, band–local contributions from coherence, vacuum, and spectral shear. □

Corollary 9.30 (Consistency with the original correlator-distance scheme)**.** *Setting* $\hat{t}_{\mu\nu} \equiv 0$ *and restricting* $\mathcal{I}$ *to the correlator channel reduces Definitions 9.22, 9.23 and 9.26 to the correlator–only distances/contrasts of the initial pre–physical formulation based on* d_{corr} *with normalizations* $N(\cdot)$ *as in Definition 9.19.*

Proof. With $\hat{t}_{\mu\nu} \equiv 0$, one has $\hat{\Sigma}_{\mu\nu} \to \hat{\Sigma}^{(\mathrm{corr})}_{\mu\nu}$ and $\hat{Q}_x[v] \to \hat{Q}^{(\mathrm{corr})}_x[v]$ (cf. Definitions 9.20 and 9.22). Choosing the functional $\mathcal{I}$ to be the correlator–channel restriction $\mathcal{I}^{(\mathrm{corr})}$ constructed in the proof of Proposition 9.29 yields

$$\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)\Big)^2 = \mathcal{I}^{(\mathrm{corr})}\Big[\hat{Q}^{(\mathrm{corr})}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}^{(\mathrm{corr})}_x[v]\Big],$$

and the analogous expression for the state contrast. These are precisely the correlator–only pre–physical law/state contrasts, i.e. the ones obtained from the correlator distance d_{corr} (cf. Definition 4.338) with the fibre normalizations $N(\psi, x)$ defined by Definition 9.19 and the GNS expectation (cf. Definitions 1.18 and 1.34). The aggregated versions Definition 9.26 reduce accordingly. Thus the Σ–formulation is consistent with, and collapses to, the original correlator–only scheme when the temporal and spectral channels are deactivated. □

Operational note. When working at the expectation level, the chronogeometric quadratic form may be evaluated as $\bar{Q}_x[v] = v^\mu v^\nu \bar{\Sigma}_{\mu\nu}(x)$ with $\bar{\Sigma}_{\mu\nu} := \langle \hat{\Sigma}_{\mu\nu} \rangle$ (cf. Definitions 6.7, 9.20 and 9.22). Using the same band–local, gauge–invariant functionals $\mathcal{I}$ as in the operator–level definitions (Born pairing or regulated band–trace; cf. Definitions 1.18, 1.34, 6.280 and 9.10), one obtains expectation–level $\bar{\Delta}$ versions of (9.6)–(9.7). Gauge/frame covariance follows from the conjugation invariance of the functionals together with the transport covariance of $\hat{\Sigma}_{\mu\nu}$ (cf. Proposition 9.6, Definition 9.7, and Lemma 9.24). The band/plateau discipline of Section 9.1—namely BRST hygiene of the tag (cf. Lemma 9.11 and eq. (7.24)), causal IR windowing (cf. Definition 6.280), and spectral smoothness/finitedness (cf. Proposition 9.13 and Remark 9.21)—ensures that these $\bar{\Delta}$ inputs are well–defined and ready for the realization step on the physical cohomology (cf. Sections 6.10 and 9.5). Plateau certification and acceptance (cf. eqs. (7.394) to (7.396) and Proposition 7.203) then license the Σ–realization and evaluation of physical, gauge–parameter–independent spectra/visibilities.

Summary of Section 9.2. The "distances only" inputs were replaced by the unified operator $\hat{\Sigma}_{\mu\nu}$ (cf. Definition 9.20 and eq. (9.4)), from which the chronogeometric quadratic form $\hat{Q}_x[v]$ was built (cf. Definition 9.22). On this basis, the Σ–law and Σ–state contrasts (9.6)–(9.7) were defined using band–local, gauge–invariant functionals, with full gauge/frame covariance under the graded G–action (cf. Definition 9.18 and Lemma 9.24). These contrasts admit aggregated versions for finite probe sets (cf. Definition 9.26) and possess channelwise attributions by the triadic split (cf. Proposition 9.29, Definition 5.54, and eqs. (5.8) and (5.21)). Finiteness and stability on the band are ensured by spectral discipline and effective cutoffs (cf. Remark 9.21, Proposition 9.13, and Lemma 9.27); moreover, the scheme reduces consistently to the correlator–only construction when the temporal/spectral channels are deactivated (cf. Corollary 9.30 and Definitions 4.338 and 9.19). The resulting Σ–contrasts feed the pre–physical quadrant predicate QI–QIV (cf. Definition 9.28), thereby elevating temporal phase–flow and channel mixing to first–class diagnostic status while remaining fully compatible with the Fourfold correlator/transport scaffolding (cf. Definitions 6.4, 9.7, 9.8 and 9.10, eq. (4.24), and Proposition 9.6).

9.3 From Algebraic Breakings to Quanta

Definition 9.31 (Field blocks and generalized field operator)**.** Let $\hat{\mathbf{F}} = (\hat{\mathbf{\Phi}}, \hat{\mathbf{\Theta}})^{\mathsf{T}}$ be the generalized field operator (cf. Ch. 7) and let the unified inter-modal correlator decompose as

$$\hat{\mathbf{G}}_\Lambda = \begin{pmatrix} \hat{G}_{\Phi\Phi} & \hat{G}_{\Phi\Theta} \\ \hat{G}_{\Theta\Phi} & \hat{G}_{\Theta\Theta} \end{pmatrix}, \tag{9.12}$$

with blocks acting on the Gaiamiti (Φ) and Tantrakyma (Θ) sectors, respectively; see Definition 9.5 and Ch. 7's block structure. The graded, gauge-covariant transport is as in Definition 9.7.

Definition 9.32 (Law-symmetric tangent map (graded adjoint))**.** For a generator $X \in \mathfrak{g} = \mathrm{Lie}(G)$, the *law-symmetric tangent* of a correlator component is

$$\delta_X \hat{G}^{\alpha\beta}_\Lambda := \frac{d}{dt}\Big|_{t=0} \mathrm{Ad}_{e^{tX}} \hat{G}^{\alpha\beta}_\Lambda = [X, \hat{G}^{\alpha\beta}_\Lambda]_{\mathrm{gr}}, \qquad \alpha, \beta \in \{0, 1, p, s\}, \tag{9.13}$$

where Ad_g is the graded adjoint action of Definition 9.18.

Definition 9.33 (Σ-weighted inner products on operator modes)**.** Restrict the operator-valued chronogeometry $\hat{\Sigma}_{\mu\nu}$ of Definition 9.20 to the field blocks

$$\hat{\Sigma}^{(\Phi)} := \Pi^\dagger_{\Phi\Phi}\, \hat{\Sigma}\, \Pi_{\Phi\Phi}, \qquad \hat{\Sigma}^{(\Theta)} := \Pi^\dagger_{\Theta\Theta}\, \hat{\Sigma}\, \Pi_{\Theta\Theta},$$

and let $\mathcal{I}$ be any gauge-invariant, band-local functional. For band-tagged operator densities O_1, O_2 (on $\mathcal{H}_{\mathrm{em}}$),

$$\langle\!\langle O_1, O_2 \rangle\!\rangle_{\Sigma,\Phi} := \mathcal{I}\Big[O_1^\dagger, \hat{\Sigma}^{(\Phi)}, O_2\Big], \qquad \langle\!\langle O_1, O_2 \rangle\!\rangle_{\Sigma,\Theta} := \mathcal{I}\Big[O_1^\dagger, \hat{\Sigma}^{(\Theta)}, O_2\Big]. \tag{9.14}$$

These are positive semi-definite and gauge/frame covariant on the band specified in Definition 9.10.

Lemma 9.34 (Positivity and covariance)**.** *Under the spectral discipline of Proposition 9.13, $\langle\!\langle \cdot, \cdot \rangle\!\rangle_{\Sigma,\Phi/\Theta}$ are well-defined, positive semi-definite and transform by conjugation under local frame changes; they are invariant under the Born expectation.*

Definition 9.35 (Pre-physical Apeiron and Kymon mode spaces (Σ-aware))**.** Fix a band $(\lambda_{\mathrm{UV}}, \ell)$. Let $\mathfrak{B}$ be the set of *broken* generators X at x in the sense of Definition 9.23 (i.e., $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(e^{tX}; x) > \varepsilon$ while $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(e^{tX}; x) < \varepsilon$). Define

$$\mathcal{N}^{\mathrm{pre}}_\Phi := \overline{\mathrm{span}}\Big\{\text{left/right singular vectors of } \delta_X \hat{G}_{\Phi\Phi} \;:\; X \in \mathfrak{B}\Big\},$$

$$\mathcal{N}^{\mathrm{pre}}_\Theta := \overline{\mathrm{span}}\Big\{\text{left/right singular vectors of } \delta_X \hat{G}_{\Theta\Theta} \;:\; X \in \mathfrak{B}\Big\}.$$

The graded commutator $[\cdot, \cdot]_{\mathrm{gr}}$ enforces selection rules for admissible channel mixing (Definition 9.8).

Proposition 9.36 (Σ-weighted generalized eigenproblems (principal modes))**.** *For each broken $X \in \mathfrak{B}$, define the Gram operators*

$$C_\Phi := (\delta_X \hat{G}_{\Phi\Phi})^\dagger\, \hat{\Sigma}^{(\Phi)}\, (\delta_X \hat{G}_{\Phi\Phi}), \qquad C_\Theta := (\delta_X \hat{G}_{\Theta\Theta})^\dagger\, \hat{\Sigma}^{(\Theta)}\, (\delta_X \hat{G}_{\Theta\Theta}), \tag{9.15}$$

where $\delta_X(\cdot)$ is the graded tangent defined by the adjoint action (cf. Definitions 9.7 and 9.18) and $\hat{\Sigma}^{(\Phi)}, \hat{\Sigma}^{(\Theta)}$ are the block–restrictions of the band–local chronogeometry $\hat{\Sigma}$ (cf. Definitions 6.4 and 9.20 and eq. (4.24)). Then the block–wise generalized eigenproblems

$$C_\Phi\, u_a = \lambda_a\, \hat{\Sigma}^{(\Phi)} u_a, \qquad C_\Theta\, v_b = \mu_b\, \hat{\Sigma}^{(\Theta)} v_b, \tag{9.16}$$

admit complete $\hat{\Sigma}$–orthonormal systems $\{u_a\} \subset \mathcal{N}^{\mathrm{pre}}_\Phi$ and $\{v_b\} \subset \mathcal{N}^{\mathrm{pre}}_\Theta$ on the band, with non–negative eigenvalues λ_a, μ_b.

Proof. Step 0 (band–local pre–Hilbert modules and Σ–pairings). On the band specified by the tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (cf. Definitions 6.280 and 9.10 and eq. (9.2)), equip the block spaces with the Σ–weighted sesquilinear forms

$$\langle f,g\rangle_{\Sigma^{(\Phi)}} := \mathcal{I}\Big[f^{\dagger}\hat{\Sigma}^{(\Phi)}g\Big], \qquad \langle f,g\rangle_{\Sigma^{(\Theta)}} := \mathcal{I}\Big[f^{\dagger}\hat{\Sigma}^{(\Theta)}g\Big],$$

where $\mathcal{I}$ is any band–local, gauge–invariant functional (Born pairing or regulated band–trace; cf. Definitions 1.18, 1.34 and 9.23). By spectral discipline (cf. Propositions 9.13 and 9.14 and Remark 9.21), $\hat{\Sigma}$ is positive and defines pre–Hilbert norms $\|f\|^2_{\Sigma^{(\Phi)}} := \langle f,f\rangle_{\Sigma^{(\Phi)}}$ and similarly for Θ. Denote the corresponding completions by $\mathcal{N}^{\mathrm{pre}}_{\Phi}$ and $\mathcal{N}^{\mathrm{pre}}_{\Theta}$.

Step 1 (boundedness and positivity of the Gram forms). Let $A_\Phi := \hat{\Sigma}^{(\Phi)\,1/2}(\delta_X\hat{G}_{\Phi\Phi})$ on the band; define A_Θ analogously. Then $C_\Phi = A_\Phi^{\dagger}A_\Phi$ and $C_\Theta = A_\Theta^{\dagger}A_\Theta$ as operators on the respective blocks. For any $u \in \mathcal{N}^{\mathrm{pre}}_{\Phi}$,

$$\langle u, C_\Phi u\rangle_{\Sigma^{(\Phi)}} = \mathcal{I}\Big[u^{\dagger}(\delta_X\hat{G}_{\Phi\Phi})^{\dagger}\hat{\Sigma}^{(\Phi)}(\delta_X\hat{G}_{\Phi\Phi})u\Big] = \Big\|A_\Phi u\Big\|^2_{L^2(\mathcal{I})} \ge 0,$$

hence C_Φ is positive (and likewise C_Θ). Gauge/frame covariance follows from the graded transport and conjugation–invariance of $\mathcal{I}$ (cf. Definition 9.7, Proposition 9.6, and Section 4.19.1); thus the constructions are frame–independent on the band.

Step 2 (compactness on the band). By the UV projection $P_x(\lambda_{\mathrm{UV}})$ and causal IR window $K^{(\ell)}_{\mathrm{IR}}$ entering the tag (cf. Definitions 6.280 and 9.10), and by spectral smoothness/finite capacity (cf. Proposition 9.13 and Remark 9.21), the band–limited kernels of $\delta_X\hat{G}_{\bullet\bullet}$ are square–integrable on $\mathcal{X}_q\times\mathcal{X}_q$ with respect to the relational measure (cf. Definition 6.33), hence $\delta_X\hat{G}_{\bullet\bullet}$ are Hilbert–Schmidt and therefore compact on the band–local modules. Since $\hat{\Sigma}^{(\bullet)\,1/2}$ are bounded and positive on the band (cf. Definition 9.20), the compositions $A_\bullet = \hat{\Sigma}^{(\bullet)\,1/2}(\delta_X\hat{G}_{\bullet\bullet})$ are also compact; therefore $C_\bullet = A_\bullet^{\dagger}A_\bullet$ are positive, self–adjoint, compact operators on $\mathcal{N}^{\mathrm{pre}}_{\bullet}$.

Step 3 (reduction to an ordinary compact eigenproblem). Define the bounded, positive isomorphisms on the supports of $\hat{\Sigma}^{(\bullet)}$,

$$J_\Phi : \mathcal{N}^{\mathrm{pre}}_{\Phi} \to \mathcal{N}^{\mathrm{pre}}_{\Phi}, \quad J_\Phi u := \hat{\Sigma}^{(\Phi)\,1/2}u, \qquad J_\Theta v := \hat{\Sigma}^{(\Theta)\,1/2}v,$$

and the compact, positive operators

$$K_\Phi := J_\Phi^{-1}C_\Phi J_\Phi^{-1} = \hat{\Sigma}^{(\Phi)\,-1/2}(\delta_X\hat{G}_{\Phi\Phi})^{\dagger}\hat{\Sigma}^{(\Phi)}(\delta_X\hat{G}_{\Phi\Phi})\hat{\Sigma}^{(\Phi)\,-1/2} = A_\Phi^{\dagger}A_\Phi,$$

with K_Θ analogously. Then K_Φ and K_Θ act on the ordinary (unweighted) pre–Hilbert structures and are compact, positive, self–adjoint (by Step 2).

Step 4 (spectral theorem and Σ–orthonormal systems). By the spectral theorem for compact, positive, self–adjoint operators, there exist orthonormal bases $\{w_a\}$ and $\{z_b\}$ with

$$K_\Phi w_a = \lambda_a w_a, \qquad K_\Theta z_b = \mu_b z_b, \qquad \lambda_a,\mu_b \ge 0,$$

and w_a, z_b complete in their respective closures. Setting $u_a := J_\Phi^{-1}w_a = \hat{\Sigma}^{(\Phi)\,-1/2}w_a$ and $v_b := J_\Theta^{-1}z_b = \hat{\Sigma}^{(\Theta)\,-1/2}z_b$ yields

$$C_\Phi u_a = \lambda_a\,\hat{\Sigma}^{(\Phi)}u_a, \qquad C_\Theta v_b = \mu_b\,\hat{\Sigma}^{(\Theta)}v_b,$$

i.e. the generalized eigenproblems (9.16). Moreover,

$$\langle u_a, u_{a'}\rangle_{\Sigma^{(\Phi)}} = \langle w_a, w_{a'}\rangle = \delta_{aa'}, \qquad \langle v_b, v_{b'}\rangle_{\Sigma^{(\Theta)}} = \langle z_b, z_{b'}\rangle = \delta_{bb'},$$

so $\{u_a\}$ and $\{v_b\}$ are Σ–orthonormal systems. Completeness follows from the completeness of $\{w_a\}$ and $\{z_b\}$ and the fact that $J_\bullet$ are isomorphisms on the supports of $\hat\Sigma^{(\bullet)}$ (the null–spaces of $\hat\Sigma^{(\bullet)}$ can be quotient–out as usual if present; cf. positivity/semidefiniteness in Definition 9.20 and Proposition 9.14).

Step 5 (gauge/frame compatibility). All constructions are compatible with the graded G–action and local frames: $C_\bullet$ and $\hat\Sigma^{(\bullet)}$ transform by conjugation under transport (cf. Definition 9.7 and Proposition 9.6), while $\mathcal{I}$ is conjugation–invariant (cf. Section 4.19.1). Hence the spectra $\{\lambda_a\}, \{\mu_b\}$ and the Σ–orthonormality relations are frame–independent on the band.

Combining the steps establishes (9.16) with non–negative eigenvalues and complete $\hat\Sigma$–orthonormal systems on the band. □

Definition 9.37 (Apeiron/Kymon creation operators (pre-physical, Σ-normalized))**.** Let $\{u_a\}$, $\{v_b\}$ be principal solutions of (9.16). There exist band-localized operator densities $\hat A_a^\dagger, \hat K_b^\dagger \in \mathcal{B}(\mathcal{H}_{\mathrm{em}})$ such that

$$\hat G_{\Phi\Phi}^{(\lambda_{\mathrm{UV}},\ell)} = \sum_a s_a\, \hat A_a\, \hat A_a^\dagger, \qquad \hat G_{\Theta\Theta}^{(\lambda_{\mathrm{UV}},\ell)} = \sum_b t_b\, \hat K_b\, \hat K_b^\dagger, \tag{9.17}$$

with $s_a, t_b \geq 0$ the band-restricted spectral weights, and the Σ-normalizations

$$\langle\!\langle \hat A_a, \hat A_{a'}\rangle\!\rangle_{\Sigma,\Phi} = \delta_{aa'}, \qquad \langle\!\langle \hat K_b, \hat K_{b'}\rangle\!\rangle_{\Sigma,\Theta} = \delta_{bb'}. \tag{9.18}$$

We call $\hat A_a^\dagger$ *Apeiron* creators (Gaiamiti sector) and $\hat K_b^\dagger$ *Kymon* creators (Tantrakyma sector).

Lemma 9.38 (Phase–vs–amplitude split via Σ)**.** *Let $v \in T_x\mathcal{X}_q$ and $\hat Q_x[v] = v^\mu v^\nu \hat\Sigma_{\mu\nu}(x)$ as in Definition 9.22, with $\hat\Sigma_{\mu\nu} = \hat g_{\mu\nu} + \hat t_{\mu\nu}$ (cf. Definition 9.20). If $\bar g_{\mu\nu}(x)\, v^\mu v^\nu = 0$ while $\bar t_{\mu\nu}(x)\, v^\mu v^\nu > 0$, then the associated principal directions in $\{u_a\}$ (geometry block) obtained from Proposition 9.36 are* pure phase–flow *(Goldstone–like) precursors. If instead $\bar g_{\mu\nu}(x)\, v^\mu v^\nu > 0$ dominates the contraction of $\bar\Sigma_{\mu\nu}$ along v, these principal directions are* amplitude *(Higgs/Gaiaton–like). An analogous statement holds for the matter block $\{v_b\}$.*

Proof. (1) Directional contractions and Σ–weighted Rayleigh quotients. Contract the chrono-geometric tensors along v:

$$\bar g[v] := \bar g_{\mu\nu} v^\mu v^\nu, \qquad \bar t[v] := \bar t_{\mu\nu} v^\mu v^\nu, \qquad \bar\Sigma[v] = \bar g[v] + \bar t[v],$$

and analogously $\hat\Sigma[v]$ on the band (cf. Definitions 9.20 and 9.22). On the geometry block, the generalized eigenproblem of Proposition 9.36 admits the standard Rayleigh characterization with the Σ–inner product:

$$\mathcal{R}_\Phi(u) \;:=\; \frac{\langle u,\, C_\Phi u\rangle_{\Sigma^{(\Phi)}}}{\langle u, u\rangle_{\Sigma^{(\Phi)}}} \;=\; \frac{\mathcal{I}\Big[\,(\delta_X \hat G_{\Phi\Phi} u)^\dagger\, \hat\Sigma^{(\Phi)}\, (\delta_X \hat G_{\Phi\Phi} u)\Big]}{\mathcal{I}\Big[\,u^\dagger\, \hat\Sigma^{(\Phi)} u\Big]},$$

where $\mathcal{I}$ is any band–local, gauge–invariant functional (Born pairing / regulated band–trace; cf. Definitions 1.18, 1.34 and 9.23). Directional probing along v amounts to replacing $\hat{\Sigma}^{(\Phi)}$ by its contraction $\hat{\Sigma}^{(\Phi)}[v] = v^\mu v^\nu \hat{\Sigma}^{(\Phi)}_{\mu\nu}$ in both numerator and denominator (cf. Definition 9.22); the corresponding expectation–level quotient reads

$$\overline{\mathcal{R}}^{[v]}_{\Phi}(u) \;=\; \frac{\mathcal{I}\Big[\,(\delta_X \hat{G}_{\Phi\Phi} u)^\dagger\, \hat{\Sigma}^{(\Phi)}[v]\, (\delta_X \hat{G}_{\Phi\Phi} u)\Big]}{\mathcal{I}\Big[\,u^\dagger\, \hat{\Sigma}^{(\Phi)}[v]\, u\Big]}\,,$$

and its stationary points select the same principal directions $\{u_a\}$ (the weighting changes but the Euler–Lagrange equations coincide with Proposition 9.36 after contraction).

(2) Phase–flow regime ($\bar{g}[v] = 0$, $\bar{t}[v] > 0$). If $\bar{g}[v] = 0$ while $\bar{t}[v] > 0$, then $\bar{\Sigma}[v] = \bar{t}[v]$ and the directional inner product reduces to the temporal piece:

$$\langle u, u\rangle_{\Sigma^{(\Phi)}[v]} = \mathcal{I}\Big[u^\dagger\, \hat{t}^{(\Phi)}[v]\, u\Big], \qquad \hat{t}^{(\Phi)}[v] := v^\mu v^\nu \hat{t}^{(\Phi)}_{\mu\nu}(x).$$

Thus the metric contribution to the directional norm vanishes, and the response measured by $\overline{\mathcal{R}}^{[v]}_{\Phi}$ is purely *phase–flow* (temporal–curvature) in the sense that the geometric distance part registers no cost along v (cf. the chronogeometric split and its interpretation in Section 5.2.5 and Definition 5.122). In the QII setting (law–symmetric, state–asymmetric), such tangential directions coincide with Goldstone–like modes of the geometric vacuum (Section 9.17.2), and after plateau/BRST realization they furnish the spin–2 graviton as the massless Goldstone direction (Section 7.5 with the BRST/Nielsen framework). Hence the principal directions singled out by $\overline{\mathcal{R}}^{[v]}_{\Phi}$ in this regime are *pure phase–flow* precursors.

(3) Amplitude regime ($\bar{g}[v] > 0$ dominates). If $\bar{g}[v] > 0$ dominates the contraction of $\bar{\Sigma}[v] = \bar{g}[v] + \bar{t}[v]$, then the directional norm $\langle u, u\rangle_{\Sigma^{(\Phi)}[v]} = \mathcal{I}[u^\dagger(\hat{g}^{(\Phi)}[v] + \hat{t}^{(\Phi)}[v])u]$ is controlled by the metric part $\hat{g}^{(\Phi)}[v]$. Geometrically this corresponds to *radial* (distance–changing) deformations in the Σ–geometry, i.e. amplitude modes. On the Lagrangian side these are the directions that probe the curvature of the Gaiamiti potential $V(\hat{\mathbf{\Phi}})$ (cf. Definitions 6.172 and 6.174), and upon realization give massive Gaiaton excitations rather than Goldstone transport (cf. interpretation via Section 9.5 and Proposition 9.36).

(4) Matter block. The same argument, with $\hat{\Sigma}^{(\Theta)}$ and C_Θ in Proposition 9.36, yields the analogous classification for principal directions $\{v_b\}$ in the Tantrakyma block, identifying phase–flow versus amplitude behavior with $\bar{g}[v]$ versus $\bar{t}[v]$ dominance under the Σ–weighted quotient (cf. Definitions 6.4 and 6.142).

(5) Covariance and band–regularity. All directional contractions and Rayleigh quotients are band–local, gauge/frame covariant and finite by Propositions 9.6, 9.13 and 9.14 and Definition 9.10, and are stable under small band deformations by Lemma 9.27. Therefore the phase–vs–amplitude classification is well–posed on the band and persists to the realized physical layer after plateau/BRST projection (cf. Sections 6.10 and 9.5).

The stated alternatives follow. □

Proposition 9.39 (Channel mixing and block diagonality)**.** *If $[\hat{\Sigma}^{(\Phi)}, \delta_X \hat{G}_{\Phi\Phi}] = 0$ (respectively, $[\hat{\Sigma}^{(\Theta)}, \delta_X \hat{G}_{\Theta\Theta}] = 0$), the generalized eigenproblem (9.16) decouples into channel–wise eigenmodes (corr/vac/spec). Otherwise, the cross–terms are absorbed by the generalized eigenproblem, and the principal modes carry the correct Σ–weights across mixed channels.*

Proof. Setup and projectors. On the band (cf. Definitions 6.280 and 9.10) the chronogeometry admits the triadic split $\hat{\Sigma}^{(\Phi)} = \hat{\Sigma}^{(\Phi,\mathrm{corr})} + \hat{\Sigma}^{(\Phi,\mathrm{vac})} + \hat{\Sigma}^{(\Phi,\mathrm{spec})}$, consistent with the expectation–level decomposition $\bar{\Sigma}_{\mu\nu} = \bar{\Sigma}^{\mathrm{corr}}_{\mu\nu} + \bar{\Sigma}^{\mathrm{vac}}_{\mu\nu} + \bar{\Sigma}^{\mathrm{spec}}_{\mu\nu}$ (cf. Definitions 5.54 and 9.20 and eqs. (5.8) and (5.21)). By the graded bundle structure and block algebra (cf. Definitions 9.7 and 9.8, eq. (4.24), and Section 4.1.7), there exist band–local channel projectors $\Pi^{(a)}$ ($a \in \{\mathrm{corr}, \mathrm{vac}, \mathrm{spec}\}$) such that

$$\Pi^{(a)}\Pi^{(b)} = \delta_{ab}\Pi^{(a)}, \qquad \sum_a \Pi^{(a)} = \mathbb{I}, \qquad \Pi^{(a)}\hat{\Sigma}^{(\Phi)}\Pi^{(b)} = \delta_{ab}\,\hat{\Sigma}^{(\Phi,a)}.$$

(Construction as in the channel attribution step of Proposition 9.29.)

Decoupled case. Assume $[\hat{\Sigma}^{(\Phi)}, \delta_X\hat{G}_{\Phi\Phi}] = 0$. Then $\delta_X\hat{G}_{\Phi\Phi}$ preserves the spectral decomposition of $\hat{\Sigma}^{(\Phi)}$, hence $[\Pi^{(a)}, \delta_X\hat{G}_{\Phi\Phi}] = 0$ for each a. Let $C_\Phi = (\delta_X\hat{G}_{\Phi\Phi})^\dagger\hat{\Sigma}^{(\Phi)}(\delta_X\hat{G}_{\Phi\Phi})$ (cf. Proposition 9.36). For $a \neq b$,

$$\begin{aligned}\Pi^{(a)}C_\Phi\Pi^{(b)} &= \Pi^{(a)}(\delta_X\hat{G}_{\Phi\Phi})^\dagger\,\underbrace{\hat{\Sigma}^{(\Phi)}\Pi^{(b)}}_{=\Pi^{(b)}\hat{\Sigma}^{(\Phi,b)}}(\delta_X\hat{G}_{\Phi\Phi})\Pi^{(b)}\\ &= (\delta_X\hat{G}_{\Phi\Phi})^\dagger\Pi^{(a)}\Pi^{(b)}\,\hat{\Sigma}^{(\Phi,b)}(\delta_X\hat{G}_{\Phi\Phi})\Pi^{(b)} = 0,\end{aligned}$$

using the commutation with $\Pi^{(a)}$ and orthogonality of the projectors. Thus C_Φ is block–diagonal in the channel decomposition: $C_\Phi = \bigoplus_a C_\Phi^{(a)}$ with $C_\Phi^{(a)} := (\delta_X\hat{G}_{\Phi\Phi})^\dagger\hat{\Sigma}^{(\Phi,a)}(\delta_X\hat{G}_{\Phi\Phi})$ acting on $\Pi^{(a)}\mathcal{N}_\Phi^{\mathrm{pre}}$. The generalized eigenproblem $C_\Phi u = \lambda\,\hat{\Sigma}^{(\Phi)}u$ therefore decouples into

$$C_\Phi^{(a)}\,u^{(a)} = \lambda^{(a)}\,\hat{\Sigma}^{(\Phi,a)}u^{(a)} \qquad (a = \mathrm{corr}, \mathrm{vac}, \mathrm{spec}),$$

i.e. three independent channel–wise problems with Σ–weights *within* each channel. The same argument applies to the Tantrakyma block under $[\hat{\Sigma}^{(\Theta)}, \delta_X\hat{G}_{\Theta\Theta}] = 0$.

Mixed case. If $[\hat{\Sigma}^{(\Phi)}, \delta_X\hat{G}_{\Phi\Phi}] \neq 0$, cross–terms $\Pi^{(a)}C_\Phi\Pi^{(b)}$ with $a \neq b$ need not vanish. However, by Proposition 9.36 (Steps 2–4), the Σ–weighted problem can be reduced to an ordinary compact eigenproblem for

$$K_\Phi := \hat{\Sigma}^{(\Phi)\,-1/2}C_\Phi\hat{\Sigma}^{(\Phi)\,-1/2},$$

which is positive, self–adjoint, and compact on the (unweighted) pre–Hilbert completion; its orthonormal eigenbasis $\{w_a\}$ yields the principal modes $u_a = \hat{\Sigma}^{(\Phi)\,-1/2}w_a$ that are Σ–orthonormal and solve $C_\Phi u_a = \lambda_a\hat{\Sigma}^{(\Phi)}u_a$. In the channel projector basis $\{\Pi^{(a)}\}$, mixing appears as off–diagonal blocks of K_Φ, but the spectral theorem diagonalizes K_Φ globally. Equivalently, the principal modes extremize the Σ–weighted Rayleigh quotient

$$\mathcal{R}_\Phi(u) = \frac{\langle u, C_\Phi u\rangle_{\Sigma^{(\Phi)}}}{\langle u, u\rangle_{\Sigma^{(\Phi)}}} = \frac{\mathcal{I}\Big[(\delta_X\hat{G}_{\Phi\Phi}u)^\dagger\hat{\Sigma}^{(\Phi)}(\delta_X\hat{G}_{\Phi\Phi}u)\Big]}{\mathcal{I}\Big[u^\dagger\hat{\Sigma}^{(\Phi)}u\Big]},$$

(cf. Proposition 9.36), which is basis–independent and automatically accounts for channel mixing via the Σ–weights in numerator and denominator. Channel contributions may still be attributed a posteriori using the functionals $\mathcal{I}^{(a)}$ of Proposition 9.29, but the eigenvectors themselves are generally mixed across channels when the commutator is nonzero.

Covariance and band–regularity. All statements are band–local and gauge/frame covariant by construction (cf. Definitions 9.7 and 9.10 and Proposition 9.6), and the compactness/positivity needed for the spectral reduction follow from spectral discipline (cf. Proposition 9.13 and Remark 9.21) and from the block restrictions of $\hat{\Sigma}$ (cf. Definition 9.20). Thus the generalized eigenproblem absorbs channel mixing and yields Σ–orthonormal principal modes with the correct weights.

The claim follows. □

Corollary 9.40 (Recovery of SVD-based construction)**.** *If $\hat{\Sigma}^{(\Phi)} \propto \mathbb{I}$ (resp. $\hat{\Sigma}^{(\Theta)} \propto \mathbb{I}$) on the band or if only the correlator channel is active, (9.16) reduces to the usual SVD for $\delta_X \hat{G}_{\Phi\Phi}$ (resp. $\delta_X \hat{G}_{\Theta\Theta}$), and (9.17) matches the factorization used in the correlator–only scheme.*

Proof. (1) Reduction of the generalized problem to an ordinary eigenproblem. On the band (cf. Definitions 6.280 and 9.10) define $A_\Phi := \delta_X \hat{G}_{\Phi\Phi}$ and recall $C_\Phi = A_\Phi^\dagger \hat{\Sigma}^{(\Phi)} A_\Phi$ with the generalized eigenproblem $C_\Phi u = \lambda \hat{\Sigma}^{(\Phi)} u$ (cf. Proposition 9.36 and eqs. (9.15) and (9.16)). Let $J_\Phi := \hat{\Sigma}^{(\Phi)\,1/2}$ (well–defined and positive on the band by Definition 9.20 and Propositions 9.13 and 9.14) and set

$$K_\Phi := J_\Phi^{-1} C_\Phi J_\Phi^{-1} = \big(J_\Phi A_\Phi\big)^\dagger \big(J_\Phi A_\Phi\big)$$

on the unweighted pre–Hilbert completion (cf. Proposition 9.36).

Then $K_\Phi w = \lambda w$ with $w := J_\Phi u$ is an *ordinary* compact, positive, self–adjoint eigenproblem (spectral theorem applies; cf. Proposition 9.36).

(2) Case $\hat{\Sigma}^{(\Phi)} = s_\Phi \mathbb{I}$. If $\hat{\Sigma}^{(\Phi)} = s_\Phi \mathbb{I}$ on the band (e.g. within a single active channel with appropriate normalization), then $J_\Phi = \sqrt{s_\Phi}\,\mathbb{I}$ and

$$K_\Phi = s_\Phi\, A_\Phi^\dagger A_\Phi.$$

Hence $K_\Phi w = \lambda w$ is equivalent to $A_\Phi^\dagger A_\Phi w = (\lambda/s_\Phi)\, w$: the eigenvectors $\{w_a\}$ are the *right singular vectors* of $A_\Phi = \delta_X \hat{G}_{\Phi\Phi}$ and $\sigma_a^2 = \lambda_a / s_\Phi$ are the singular values squared. Writing the SVD of A_Φ as $A_\Phi = \sum_a \sigma_a\, |p_a\rangle\langle w_a|$ with $\{p_a\}$ orthonormal (left singular vectors) yields the weighted factorization

$$\delta_X \hat{G}_{\Phi\Phi} = A_\Phi = \sum_a \sigma_a\, |p_a\rangle\langle w_a| = \sum_a \sqrt{\lambda_a}\ \underbrace{|p_a\rangle}_{\text{left modes}}\ \underbrace{\langle u_a|\,\hat{\Sigma}^{(\Phi)}}_{\text{right }\Sigma\text{-dual}}, \qquad u_a := J_\Phi^{-1} w_a = \tfrac{1}{\sqrt{s_\Phi}}\, w_a,$$

which is precisely the Σ–weighted block factorization (9.17) when $\hat{\Sigma}^{(\Phi)} \propto \mathbb{I}$. Gauge/frame covariance and band–locality are inherited from the graded transport and the tag (cf. Definitions 9.7 and 9.10 and Proposition 9.6).

(3) Correlator–only activation. If only the correlator channel is active, channel projectors $\Pi^{(a)}$ (cf. Proposition 9.29) reduce the problem to the correlator block: $\hat{\Sigma}^{(\Phi)} \to \hat{\Sigma}^{(\Phi,\mathrm{corr})}$ and $A_\Phi \to A_\Phi^{(\mathrm{corr})}$, while mixing is absent by construction (cf. Proposition 9.39). With the fibre normalization $N(\psi, x)$ of Definition 9.19, the correlator–channel inner product is the

standard L^2–type pairing, so $\hat{\Sigma}^{(\Phi,\mathrm{corr})} \propto \mathbb{I}$ on the band. Thus Steps (1)–(2) apply verbatim and one recovers the usual SVD of $\delta_X \hat{G}_{\Phi\Phi}$ restricted to the correlator channel, i.e. the original correlator–only construction consistent with Corollary 9.30 and Definition 4.338.

(4) Tantrakyma block. Exactly the same argument applies to the matter block with $A_\Theta := \delta_X \hat{G}_{\Theta\Theta}$ and $\hat{\Sigma}^{(\Theta)}$ (cf. eqs. (4.24), (9.15) and (9.16) and Definition 6.4), yielding the SVD of $\delta_X \hat{G}_{\Theta\Theta}$ when $\hat{\Sigma}^{(\Theta)} \propto \mathbb{I}$ or when only the correlator channel is active.

Therefore, whenever the Σ–weight is proportional to the identity (globally or within the active channel), the generalized eigenproblems (9.16) reduce to ordinary SVDs for $\delta_X \hat{G}_{\Phi\Phi}$ and $\delta_X \hat{G}_{\Theta\Theta}$, and the Σ–weighted block factorization (9.17) coincides with the correlator–only factorization. □

Remark 9.41 (Chrono–Kymon and inter–modal mixing)**.** Within the Tantrakyma (matter) block of the Fourfold correlator (cf. Definition 6.4 and eq. (4.24)), the Σ–tensor restricts to $\hat{\Sigma}^{(\Theta)}$ (cf. Definition 9.20). Isolating its temporal contribution $\hat{t}^{(\Theta)}_{\mu\nu}$—the "torsional" sector obtained from the SOT–C^2 Hessians of temporal functionals (cf. eq. (9.4) and Definition 5.17)—singles out *spin–1 Chrono–Kymon* channels at the pre–physical level. Operationally, probing along $v \in T_x\mathcal{X}_q$ replaces the Σ–weight by its contraction $\hat{\Sigma}^{(\Theta)}[v] = v^\mu v^\nu \hat{\Sigma}^{(\Theta)}_{\mu\nu}(x)$ (cf. Definition 9.22); when $\bar{t}_{\mu\nu} v^\mu v^\nu$ dominates, the principal directions selected by the Σ–weighted Rayleigh quotient are temporal/phase–flow–type in the matter block, i.e. Chrono–Kymon precursors (cf. the phase–vs–amplitude criterion in Lemma 9.38).

Inter–modal entries $\theta^{\alpha\beta}$ inside $\hat{G}_{\Theta\Theta}$ (off–diagonal in the $\{0,1,p,s\}$ grading; cf. Definition 9.8 and Section 4.1.7) control mixing across parasymmetric/holosymmetric channels. Their influence is incorporated *faithfully* by the Σ–weighted generalized eigenproblem

$$(\delta_X \hat{G}_{\Theta\Theta})^\dagger \, \hat{\Sigma}^{(\Theta)} \, (\delta_X \hat{G}_{\Theta\Theta}) \, v_b = \mu_b \, \hat{\Sigma}^{(\Theta)} \, v_b,$$

(cf. Proposition 9.36 and eqs. (9.15) and (9.16)), which is frame– and gauge–covariant by construction (cf. Definition 9.7 and Proposition 9.6) and band–regular (cf. Definition 9.10 and Proposition 9.13). If $[\hat{\Sigma}^{(\Theta)}, \delta_X \hat{G}_{\Theta\Theta}] = 0$, channel projectors $\Pi^{(a)}$ (corr/vac/spec) block–diagonalize the problem and the modes decouple channelwise (cf. Proposition 9.39); otherwise, off–diagonal inter–modal terms are absorbed by the compact, positive operator $K_\Theta = \hat{\Sigma}^{(\Theta)\,-1/2} (\delta_X \hat{G}_{\Theta\Theta})^\dagger \hat{\Sigma}^{(\Theta)} (\delta_X \hat{G}_{\Theta\Theta}) \hat{\Sigma}^{(\Theta)\,-1/2}$, whose spectral theorem furnishes Σ–orthonormal principal modes with the correct temporal weights across mixed channels (cf. Propositions 9.29 and 9.36). In the correlator–only limit or when $\hat{\Sigma}^{(\Theta)} \propto \mathbb{I}$ on the band, one recovers the usual SVD–based construction and block factorization (cf. Corollaries 9.30 and 9.40).

After plateau certification and BRST projection, Chrono–Kymon channels are realized physically only when the Θ–block retarded kernels develop Nielsen–stable, gauge–parameter–independent spin–1 poles with positive residues in $H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Sections 6.10 and 9.5); the inter–modal mixing diagnosed pre–physically then persists as physical mixing consistent with Ward/Slavnov identities on $\mathcal{H}_{\mathrm{phys}}$.

Lemma 9.42 (Stability under band deformations)**.** *Under the continuity bounds of Lemma 9.27, the principal eigenvalues λ_a, μ_b and the Σ–normalizations of the mode operators $\hat{A}_a, \hat{K}_b$ (from the block factorizations) vary continuously with the band parameters $(\lambda_{\mathrm{UV}}, \ell)$. In particular, for $(\lambda_{\mathrm{UV}}, \ell) \mapsto (\lambda'_{\mathrm{UV}}, \ell')$ inside a plateau neighborhood,*

$$|\lambda'_a - \lambda_a| + |\mu'_b - \mu_b| = \mathcal{O}(\varepsilon), \qquad \|\hat{A}'_a - \hat{A}_a\| + \|\hat{K}'_b - \hat{K}_b\| = \mathcal{O}(\varepsilon),$$

with the $\mathcal{O}(\varepsilon)$ control provided by the effective cutoff $\Lambda_{\mathrm{eff}}(x,x';\varepsilon)$ of Remark 9.21; degeneracy splittings are likewise $\mathcal{O}(\varepsilon)$.

Proof. Step 1 (reduce the generalized problems to compact self–adjoint ones). For the geometry block, set $A_\Phi := \delta_X \hat{G}_{\Phi\Phi}$ and $J_\Phi := \hat{\Sigma}^{(\Phi)\,1/2}$ on the band. By Proposition 9.36 and eqs. (9.15) and (9.16), the generalized problem $C_\Phi u = \lambda\, \hat{\Sigma}^{(\Phi)} u$ with $C_\Phi = A_\Phi^\dagger \hat{\Sigma}^{(\Phi)} A_\Phi$ is equivalent to the ordinary compact, positive, self–adjoint eigenproblem

$$K_\Phi w = \lambda\, w, \qquad K_\Phi := J_\Phi^{-1} C_\Phi J_\Phi^{-1} = (J_\Phi A_\Phi)^\dagger (J_\Phi A_\Phi),$$

with $w := J_\Phi u$. Exactly the same reduction holds for the matter block with $K_\Theta := J_\Theta^{-1} C_\Theta J_\Theta^{-1}$, $J_\Theta := \hat{\Sigma}^{(\Theta)\,1/2}$ (cf. Proposition 9.36).

Step 2 (operator–norm continuity under band deformations). By Lemma 9.27, small changes in $(\lambda_{\mathrm{UV}}, \ell)$ induce $\mathcal{O}(\varepsilon)$ variations of the Σ–tensor: $\|\hat{\Sigma}' - \hat{\Sigma}\| = \mathcal{O}(\varepsilon)$ on the band. The band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ depends continuously on $(\lambda_{\mathrm{UV}}, \ell)$ (UV spectral projector and IR window; cf. Definitions 6.280 and 9.10 and eqs. (7.130) and (9.2)), hence the band–limited kernels of $\hat{G}_{\bullet\bullet}$, and therefore of $\delta_X \hat{G}_{\bullet\bullet}$ (graded derivation; cf. Definitions 9.7 and 9.18), vary in operator norm by $\mathcal{O}(\varepsilon)$, controlled by Λ_{eff} (cf. Remark 9.21 and Proposition 9.13). Functional calculus for positive operators gives $\|J'_\Phi - J_\Phi\| = \mathcal{O}(\varepsilon)$ and $\|J'^{-1}_\Phi - J_\Phi^{-1}\| = \mathcal{O}(\varepsilon)$ on the support of $\hat{\Sigma}^{(\Phi)}$ (positivity and band regularity: Definition 9.20 and Proposition 9.14). Consequently,

$$\|K'_\Phi - K_\Phi\| \;\le\; \|(J'_\Phi A'_\Phi)^\dagger (J'_\Phi A'_\Phi) - (J_\Phi A_\Phi)^\dagger (J_\Phi A_\Phi)\| \;=\; \mathcal{O}(\varepsilon),$$

and similarly $\|K'_\Theta - K_\Theta\| = \mathcal{O}(\varepsilon)$.

Step 3 (eigenvalue/eigenspace continuity and splittings). For compact self–adjoint operators, eigenvalues (counting multiplicities) are 1–Lipschitz with respect to operator–norm perturbations: $|\lambda'_a - \lambda_a| \le \|K'_\Phi - K_\Phi\| = \mathcal{O}(\varepsilon)$ and similarly for μ_b (Weyl–Kato continuity; the needed compactness/positivity came from Step 1). If an eigenvalue is degenerate, the spectral projector

$$\mathsf{P}_\Phi(\Gamma) = \frac{1}{2\pi i} \oint_\Gamma (z - K_\Phi)^{-1}\, dz$$

onto the cluster (for a small contour Γ separating it from the rest of the spectrum) varies by $\|\mathsf{P}'_\Phi - \mathsf{P}_\Phi\| \le c\, \|K'_\Phi - K_\Phi\| = \mathcal{O}(\varepsilon)$; thus splittings inside the cluster are $\mathcal{O}(\varepsilon)$. Identical statements hold for K_Θ.

Step 4 (Σ–orthonormal eigenvectors and normalized mode operators). Choose Σ–orthonormal principal vectors by $u_a = J_\Phi^{-1} w_a$ and $v_b = J_\Theta^{-1} z_b$ (cf. Proposition 9.36). Since $J_\bullet$ and the spectral projectors depend continuously on $(\lambda_{\mathrm{UV}}, \ell)$, one may select continuous local frames inside each isolated (or ε–narrow) cluster so that $\|u'_a - u_a\| + \|v'_b - v_b\| = \mathcal{O}(\varepsilon)$. The Σ–normalizations $\langle u_a, u_{a'} \rangle_{\Sigma^{(\Phi)}} = \delta_{aa'}$ and $\langle v_b, v_{b'} \rangle_{\Sigma^{(\Theta)}} = \delta_{bb'}$ are preserved by construction and remain stable because $\|\hat{\Sigma}' - \hat{\Sigma}\| = \mathcal{O}(\varepsilon)$ (cf. Definition 9.20). The creation operators $\hat{A}_a, \hat{K}_b$ entering the block factorizations (Apeiron/Kymon modes) are linear functionals of $A_\bullet$ and the principal vectors (cf. Proposition 9.36 and the Σ–weighted block factorizations eq. (9.17)); hence $\|\hat{A}'_a - \hat{A}_a\| + \|\hat{K}'_b - \hat{K}_b\| = \mathcal{O}(\varepsilon)$.

Combining Steps 1–4 yields the continuity and $\mathcal{O}(\varepsilon)$ stability claims for eigenvalues, eigenvectors, and Σ–normalized mode operators under band deformations controlled by $\Lambda_{\mathrm{eff}}(x,x';\varepsilon)$ (cf. Remark 9.21 and Lemma 9.27). □

Algorithm 1 Σ-aware block-wise mode extraction (pre-physical)

1. Fix band $(\lambda_{\mathrm{UV}}, \ell)$ (Definition 9.10) and build $\hat{\Sigma}_{\mu\nu}$ (Definition 9.20); restrict to $\hat{\Sigma}^{(\Phi)}, \hat{\Sigma}^{(\Theta)}$.
2. Identify broken generators $\mathfrak{B}$ via Σ-contrasts (Definitions 9.23 and 9.28).
3. For each $X \in \mathfrak{B}$, compute $\delta_X \hat{G}_{\Phi\Phi}$, $\delta_X \hat{G}_{\Theta\Theta}$ (Definition 9.32) and solve (9.16).
4. Normalize principal modes by (9.18); assemble $\hat{A}_a^\dagger, \hat{K}_b^\dagger$ and the factorizations (9.17).
5. Record phase/amplitude character using Lemma 9.38; check stability via Lemma 9.42.

Remark 9.43 (Pre-physical status and realization)**.** All constructions above—band tagging, Σ–weighted Gram operators, generalized eigenproblems, principal modes, and their Chrono–Kymon specializations—are posed on the emergent/GNS arena $\mathcal{H}_{\mathrm{em}}$ and are therefore *pre–physical* (cf. Definitions 1.34, 9.10 and 9.20, Proposition 9.36, and Remark 9.41). They provide PSR–level diagnostics and mode bases but do not by themselves assert particle content (cf. Definitions 9.12, 9.23 and 9.26 and Lemma 9.27). Physical poles and residues identifying graviton/Gaiaton/Kymon sectors arise only after the Σ–aware realization step: certify a plateau via the band grid diagnostics and acceptance rule (cf. eqs. (7.394) to (7.396) and Proposition 7.203), then apply the realization map and BRST projection to the cohomology $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Sections 6.10 and 9.5, Lemma 9.11, and eq. (7.24)). Only at this stage are Σ–causal retarded kernels evaluated on H^0 and tested for Nielsen–stable, gauge–parameter–independent poles with positive residues (Ward/Slavnov identities unchanged, now phrased in Σ–compatible form; cf. Proposition 9.6 and Section 7.5). Thus the present eigenmode analysis is a necessary upstream input to the realized spectrum but is *not* yet a statement about particles until the Σ–realized, BRST–physical evaluation is performed.

Summary of Section 9.3. Block–wise mode extraction has been upgraded from a plain SVD to the Σ–weighted generalized eigenproblem (9.16), built from the Gram operators (9.15) and solved in the Σ–pre–Hilbert modules of the geometry and matter blocks (cf. Proposition 9.36). This yields Σ–orthonormal principal systems $\{u_a\} \subset \mathcal{N}_\Phi^{\mathrm{pre}}$ and $\{v_b\} \subset \mathcal{N}_\Theta^{\mathrm{pre}}$ with non–negative spectra, and furnishes *Apeiron* and *Kymon* creators via the Σ–weighted block factorizations (cf. eq. (9.17)). The construction is band–regular and gauge/frame covariant by design: band–locality and causal support come from the tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ and its IR window (cf. Definitions 6.280 and 9.10 and eqs. (7.130) and (9.2)), while covariance is ensured by graded transport and the Hermiticity/covariance of the Fourfold correlator (cf. Definitions 6.4 and 9.7, Proposition 9.6, and eq. (4.24)); finiteness and smoothness on the band follow from spectral discipline (cf. Propositions 9.13 and 9.14 and Remark 9.21).

Crucially, the Σ–weight makes the principal directions intrinsically sensitive to both *amplitude curvature* $\hat{g}$ and *temporal phase–flow* $\hat{t}$ through the chronogeometric quadratic form $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definitions 9.20 and 9.22). The phase–vs–amplitude criterion *along a probe direction* v is encoded by the directional contractions of $\bar{g}$ and $\bar{t}$ and is formalized in Lemma 9.38; in the Tantrakyma block, isolating the temporal torsional

sector identifies spin–1 *Chrono–Kymon* channels and their inter–modal mixing is faithfully captured by the Σ–weighted problem (cf. Remark 9.41). Channel mixing vs. decoupling is governed by the commutator $[\hat{\Sigma}^{(\bullet)}, \delta_X \hat{G}_{\bullet\bullet}]$; exact commutation implies block diagonality and channel–wise eigenproblems, whereas non–commutation is absorbed by the compact, positive operator $K_\bullet = \hat{\Sigma}^{(\bullet)\,-1/2}(\delta_X \hat{G}_{\bullet\bullet})^\dagger \hat{\Sigma}^{(\bullet)}(\delta_X \hat{G}_{\bullet\bullet})\hat{\Sigma}^{(\bullet)\,-1/2}$ with globally diagonalizable spectrum (cf. Propositions 9.36 and 9.39). Channelwise interpretability and attribution to coherence/vacuum/spectral–shear contributions are obtained by the triadic split of Σ and the corresponding projectors/functionals (cf. Proposition 9.29, Definition 5.54, and eqs. (5.8) and (5.21)).

In regimes where $\hat{\Sigma}^{(\bullet)} \propto \mathbb{I}$ on the band—or when only the correlator channel is active—the generalized problem reduces to an ordinary SVD for $\delta_X \hat{G}_{\bullet\bullet}$ and the Σ–weighted factorization matches the correlator–only construction (cf. Corollaries 9.30 and 9.40 and Definitions 4.338 and 9.19). Stability under band deformations is guaranteed: the contrasts are continuous and $\mathcal{O}(\varepsilon)$–stable (Lemma 9.27), which lifts to continuity of principal eigenvalues/eigenspaces and Σ–normalized mode operators with $\mathcal{O}(\varepsilon)$ degeneracy splittings controlled by Λ_{eff} (cf. Lemma 9.42). Finally, all results here are *pre–physical* on $\mathcal{H}_{\text{em}}$ (cf. Remark 9.43); they become BRST–physical diagnostics only after Σ–aware realization—plateau certification and projection to $\mathcal{H}_{\text{phys}} := H^0(\hat{Q}_{\text{BRST}})$—where Ward/Slavnov identities and Nielsen stability are evaluated without altering the downstream cohomological machinery (cf. Sections 6.10, 7.5 and 9.5).

9.4 Pre-physical Symmetry Reduction (PSR)

Definition 9.44 (Law–kernel functionals and band-tagged diagnostics)**.** Let $\mathfrak{L}$ be a graded–covariant *law–kernel functional* acting on the Fourfold correlator $\hat{\mathbf{G}}_\Lambda$ (cf. Definitions 6.4 and 9.5 and eq. (4.24)) and transforming under the graded adjoint as in Definition 9.18. Such functionals may be assembled from band–projected kernels (e.g. operator kernels playing the role of $\mathcal{K}$, $\mathcal{M}^2$ in a given symmetric law) using the gauge–covariant transport $\mathcal{U}$ (cf. Definitions 6.184, 6.192 and 9.7). On a band $(\lambda_{\text{UV}}, \ell)$, define the band–tagged diagnostic by

$$\mathfrak{L}_{\text{pre}} := \mathfrak{B}_{\lambda_{\text{UV}},\ell}\Big[\mathfrak{L}(\hat{\mathbf{G}}_\Lambda)\Big],$$

with $\mathfrak{B}_{\lambda_{\text{UV}},\ell}$ the UV/IR tag (cf. Definitions 6.280 and 9.10 and eqs. (7.130) and (9.2)). Expectations are taken in the Holo–State/GNS sense, $\omega^\Psi(\cdot) = \langle\Psi|\cdot|\Psi\rangle$ (cf. Definitions 1.18 and 1.34). By Hermiticity/covariance of $\hat{\mathbf{G}}_\Lambda$ and endpoint covariance of $\mathcal{U}$ (cf. Proposition 9.6), $\mathfrak{L}$ is graded–adjoint covariant and $\omega^\Psi(\mathfrak{L}_{\text{pre}})$ is gauge–invariant; frame independence follows from the conjugation invariance of the functionals (cf. Sections 4.1.7 and 4.19.1).

Definition 9.45 (Chronogeometric quadratic probe and Σ–contrasts)**.** Let $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ be the operator–valued chronogeometric tensor on the band (cf. Definition 9.20), and for a local probe $v \in T_x\mathcal{X}_q$ set $\hat{Q}_x[v] := v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definition 9.22). Fix a gauge–invariant, band–local functional $\mathcal{I}$ (Holo–State Born pairing or regulated band–trace; cf. Definitions 1.18, 1.34, 6.280 and 9.10). For $g \in G$, define the pre–physical Σ–law and Σ–state contrasts

(cf. Definition 9.23):

$$\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v) := \Big(\mathcal{I}\big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\big]\Big)^{1/2}, \tag{9.19}$$

$$\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v) := \Big|\mathcal{I}_\Psi\big[\hat{Q}_x[v]\big] - \mathcal{I}_{g\cdot\Psi}\big[\hat{Q}_x[v]\big]\Big|^{1/2}. \tag{9.20}$$

By gauge/frame covariance of $\hat{Q}_x[v]$ and conjugation invariance of $\mathcal{I}$ and $\mathcal{I}_\Psi$ (cf. Proposition 9.6, Definition 9.7, and Section 4.19.1), these quantities are frame–independent and respect the graded G–action of Definition 9.18; see Lemma 9.24. Aggregated versions over finite probe sets $\{v_k\}$ are given in Definition 9.26, and stability under band deformations is ensured by Lemma 9.27. Channelwise attributions and correlator–only reductions follow from Proposition 9.29 and Corollary 9.30.

Lemma 9.46 (Band regularity and finiteness)**.** *Under Spectral Smoothness and Finite Entanglement Capacity, the triads and $\hat{\Sigma}$ exist on $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ and render (9.19)–(9.20) finite and continuous in v and in the band knobs $(\lambda_{\mathrm{UV}},\ell)$.*

Proof. Existence and finiteness on the band. The correlator–based triads D^2, T^2 (and their channel refinements $d_{\mathrm{corr}}, d_{\mathrm{vac}}, d_{\mathrm{spec}}$) are defined via the spectral generator with self–regularizing properties (cf. Definitions 4.338, 4.341, 4.386, 4.428 and 4.463). Spectral Smoothness together with the Principle of Finite Entanglement Capacity imply band–level finiteness and smoothness of these functionals and of the operator fields derived from their SOT–C^2 coincident Hessians, namely $\hat{g}_{\mu\nu}, \hat{t}_{\mu\nu}$ and $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ (cf. Propositions 9.13 and 9.14, Definition 9.20, and eq. (9.4)). Band–tagging by the UV projector and causal IR window (cf. Definitions 6.280 and 9.10 and eqs. (7.130) and (9.2)) preserves gauge/transport covariance (cf. Proposition 9.6 and Definition 9.7) and yields a band–regular $\hat{\Sigma}$.

Finiteness of the Σ–contrasts. Fix x and $v \in T_x\mathcal{X}_q$. The quadratic probe is $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definition 9.22). With $\|\cdot\|$ the operator norm on the band fibre,

$$\|\hat{Q}_x[v]\| \;\le\; \|\hat{\Sigma}(x)\|\,\|v\|^2,$$

so $\hat{Q}_x[v]$ is bounded for fixed v. Any admissible band–local, gauge–invariant functional $\mathcal{I}$ (Born pairing or regulated band–trace; cf. Definitions 1.18 and 1.34) satisfies $|\mathcal{I}[X]| \le C\,\|X\|$ for some $C < \infty$. Hence the law contrast and the state contrast in (9.19)–(9.20) are finite.

Continuity in v. For $v, w \in T_x\mathcal{X}_q$,

$$\|\hat{Q}_x[v] - \hat{Q}_x[w]\| = \|v^\mu v^\nu - w^\mu w^\nu\|\,\|\hat{\Sigma}_{\mu\nu}(x)\| \;\le\; \|\hat{\Sigma}(x)\|\,(\|v\| + \|w\|)\,\|v - w\|,$$

so $v \mapsto \hat{Q}_x[v]$ is (locally) Lipschitz. By continuity of $\mathcal{I}$ and of the push–forward $g\cdot\Psi$ (cf. Definition 9.18 and Section 4.19.1), the maps $v \mapsto \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)$ and $v \mapsto \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v)$ are continuous (cf. Definition 9.45).

Continuity in $(\lambda_{\mathrm{UV}},\ell)$. By Remark 9.21, for every $\varepsilon > 0$ there exists an effective cutoff $\Lambda_{\mathrm{eff}}(x,x';\varepsilon)$ such that changing $(\lambda_{\mathrm{UV}},\ell)$ inside the plateau neighborhood alters band–limited kernels by at most $\mathcal{O}(\varepsilon)$ in operator norm. In particular, $\|\hat{\Sigma}' - \hat{\Sigma}\| = \mathcal{O}(\varepsilon)$ and thus

$$\|\hat{Q}'_x[v] - \hat{Q}_x[v]\| \;\le\; \|v\|^2\,\|\hat{\Sigma}' - \hat{\Sigma}\| \;=\; \mathcal{O}(\varepsilon),$$

uniformly on bounded v–sets. Applying the bounded functional $\mathcal{I}$ (and its state–dependent version $\mathcal{I}_\Psi$) yields

$$\left|\left(\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}\right)^2 - \left(\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}\right)^2\right| \le C\,\|\hat{Q}'_x[v] - \hat{Q}_x[v]\| = \mathcal{O}(\varepsilon),$$

and likewise for the state contrast; taking square roots preserves continuity on compact v–domains. This agrees with the contrast–level stability already established in Lemma 9.27.

Combining the steps proves that, under Spectral Smoothness and Finite Entanglement Capacity, the triads and $\hat{\Sigma}$ exist on the band and render (9.19)–(9.20) finite and continuous in both v and $(\lambda_{\mathrm{UV}}, \ell)$. □

Definition 9.47 (Aggregated Σ–order parameters and visibilities)**.** Given probe directions $\{v_k\}_{k=1}^m \subset T_x\mathcal{X}_q$, aggregate the pointwise Σ–contrasts of Definition 9.45 (built from the quadratic probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ of Definition 9.22) by the root–sum–square prescription

$$\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}(g;x) := \left(\sum_{k=1}^m \left[\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}(g;x;v_k)\right]^2\right)^{1/2}, \quad \Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}(g;x) := \left(\sum_{k=1}^m \left[\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}(g;x;v_k)\right]^2\right)^{1/2}. \tag{9.21}$$

This is consistent with the general aggregation pattern of Definition 9.26. By Lemma 9.24, the aggregated quantities remain frame–independent and respect the graded G–action; by Lemmas 9.27 and 9.46, they are finite and continuous in both the probe set and the band parameters $(\lambda_{\mathrm{UV}}, \ell)$.

Define Σ–*visibilities* as complements (choose a normalization $C > 0$):

$$\Lambda_{\mathrm{law}}^{\Sigma} := 1 - \frac{1}{C}\,\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}, \qquad \Lambda_{\mathrm{state}}^{\Sigma} := 1 - \frac{1}{C}\,\Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}. \tag{9.22}$$

A convenient choice is to take C from a local band bound supplied by Lemma 9.46 or from fibre normalizations $N(\psi, x)$ in Definition 9.19, ensuring $0 \le \Lambda_\bullet^\Sigma \le 1$. Interferometric realizations of these visibilities are provided by holosymmetric overlaps in the control–unitary scheme: evaluate the same band–local functionals of $\hat{Q}_x[v_k]$ (or of $\bar{Q}_x[v_k] = \langle \hat{Q}_x[v_k] \rangle$) as Born pairings in the Holo–State/GNS setting (cf. Definitions 1.18, 1.34 and 9.8, Section 4.19.1, and Remark 9.9). Gauge/transport covariance of $\hat{\mathbf{G}}_\Lambda$ and of $\mathcal{U}$ (cf. Proposition 9.6 and Definition 9.7) and band regularity of $\hat{\Sigma}$ (cf. Definitions 6.280 and 9.10 and Proposition 9.13) guarantee that the interferometric visibilities operationalize (9.21)–(9.22) on the band; stability under band deformations then follows from Lemmas 9.27 and 9.42.

Proposition 9.48 (Equivalence with correlator-only diagnostics and triadic attribution)**.** *If* $\bar{\Sigma}_{\mu\nu} = \bar{\Sigma}_{\mu\nu}^{\mathrm{corr}} + \bar{\Sigma}_{\mu\nu}^{\mathrm{vac}} + \bar{\Sigma}_{\mu\nu}^{\mathrm{spec}}$ *(expectation–level triadic split; cf. Definition 5.54 and eqs. (5.8) and (5.21)), then choosing the band–local, gauge–invariant functional* $\mathcal{I}$ *channelwise yields*

$$(\Delta_{\mathrm{law}}^{\mathrm{pre},\Sigma}, \Delta_{\mathrm{state}}^{\mathrm{pre},\Sigma}) \rightsquigarrow \left(\Delta_{\mathrm{law}}^{\mathrm{pre,corr}}, \Delta_{\mathrm{law}}^{\mathrm{pre,vac}}, \Delta_{\mathrm{law}}^{\mathrm{pre,spec}}\right), \left(\Delta_{\mathrm{state}}^{\mathrm{pre,corr}}, \Delta_{\mathrm{state}}^{\mathrm{pre,vac}}, \Delta_{\mathrm{state}}^{\mathrm{pre,spec}}\right),$$

and, in particular, the correlator–distance scheme upon deactivating the other channels.

Proof. (i) Operator–level triadic split and quadratic forms. On the band, the chronogeometry admits the operator–level split $\hat{\Sigma}_{\mu\nu} = \hat{\Sigma}^{(\mathrm{corr})}_{\mu\nu} + \hat{\Sigma}^{(\mathrm{vac})}_{\mu\nu} + \hat{\Sigma}^{(\mathrm{spec})}_{\mu\nu}$ consistent with the expectation–level decomposition (cf. Definitions 5.54 and 9.20). For a probe $v \in T_x\mathcal{X}_q$, the Σ–quadratic form $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definition 9.22) decomposes as

$$\hat{Q}_x[v] = \sum_{a\in\{\mathrm{corr,vac,spec}\}} \hat{Q}^{(a)}_x[v], \qquad \hat{Q}^{(a)}_x[v] := v^\mu v^\nu \hat{\Sigma}^{(a)}_{\mu\nu}(x).$$

(ii) Channel projectors and channelwise functionals. By the Fourfold grading and its block algebra (cf. Definition 9.8, eq. (4.24), and Section 4.1.7), there exist band–local projectors $\Pi^{(a)}$ selecting the triadic channels and commuting with graded transport (cf. Definition 9.7 and Proposition 9.6). Define channelwise functionals from any admissible band–local, gauge–invariant $\mathcal{I}$ (Born pairing / regulated band–trace; cf. Definitions 1.18, 1.34, 6.280 and 9.10) by

$$\mathcal{I}^{(a)}[X] := \mathcal{I}\Big[\Pi^{(a)} X \Pi^{(a)}\Big].$$

Then $\mathcal{I}^{(a)}[\hat{Q}_x[v]] = \mathcal{I}^{(a)}[\hat{Q}^{(a)}_x[v]]$ and $\mathcal{I}^{(a)}[\hat{Q}^{(b)}_x[v]] = 0$ for $b \neq a$.

(iii) Law contrast. Using the definition of the pre–physical Σ–law contrast (9.19) (cf. Definition 9.45) and linearity,

$$\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x;v)\Big)^2 = \mathcal{I}\Big[\hat{Q}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}_x[v]\Big] = \sum_a \mathcal{I}^{(a)}\Big[\hat{Q}^{(a)}_x[v] - \mathrm{Ad}_{g(x)}\,\hat{Q}^{(a)}_x[v]\Big].$$

ummands define the channelwise law contributions $\Big(\Delta^{\mathrm{pre},a}_{\mathrm{law}}(g;x;v)\Big)^2$. Frame independence and graded G–covariance follow from Lemma 9.24.

(iv) State contrast. Similarly, with $\mathcal{I}_\Psi[\cdot] = \langle\Psi|\cdot|\Psi\rangle$ (cf. Definition 9.45),

$$\Big(\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x;v)\Big)^2 = \Big|\mathcal{I}_\Psi[\hat{Q}_x[v]] - \mathcal{I}_{g\cdot\Psi}[\hat{Q}_x[v]]\Big| = \sum_a \Big(\mathcal{I}^{(a)}_\Psi[\hat{Q}^{(a)}_x[v]] - \mathcal{I}^{(a)}_{g\cdot\Psi}[\hat{Q}^{(a)}_x[v]]\Big),$$

which yields the channelwise state contributions $\Delta^{\mathrm{pre},a}_{\mathrm{state}}$. Aggregation over $\{v_k\}$ is compatible with these splits (cf. Definitions 9.26 and 9.47).

(v) Correlator–only reduction and attribution. If the vacuum and spectral channels are deactivated (or their projectors set to zero on the band), only $a = \mathrm{corr}$ remains. Then $\hat{\Sigma} \to \hat{\Sigma}^{(\mathrm{corr})}$, $\hat{Q}_x[v] \to \hat{Q}^{(\mathrm{corr})}_x[v]$, and the contrasts reduce to the correlator–only diagnostics built from d_{corr} with fibre normalizations $N(\cdot)$ (cf. Definitions 4.338 and 9.19 and Corollaries 9.30 and 9.40). Functional independence/orthogonality of the triadic generators ensures that no spurious cross–terms contaminate the channelwise attributions (cf. Section 4.11.5); stability and finiteness are guaranteed by Lemmas 9.27 and 9.46.

Combining (iii)–(v) proves the claimed channelwise attribution and the correlator–only equivalence. □

Definition 9.49 (Quadrant predicate (pre-physical, Σ-aware))**.** Fix a tolerance $\varepsilon \ll 1$ and a band $(\lambda_{\mathrm{UV}}, \ell)$ (cf. Definitions 6.280 and 9.10 and eq. (7.130)). Using the pre–physical Σ–contrasts of Definition 9.45 (or their aggregated versions in Definition 9.47), declare at x:

$$\textbf{QI}: \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x) < \varepsilon, \ \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x) < \varepsilon; \qquad \textbf{QII}: \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x) < \varepsilon, \ \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x) > \varepsilon;$$

$$\textbf{QIII}: \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x) > \varepsilon, \ \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x) < \varepsilon; \qquad \textbf{QIV}: \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x) > \varepsilon, \ \ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}}(g;x) > \varepsilon.$$

By construction, these predicates are frame–independent and respect the graded G–action (cf. Lemma 9.24); finiteness and continuity with respect to v and $(\lambda_{\mathrm{UV}}, \ell)$ follow from Lemmas 9.27 and 9.46. The choice of ε may be tied to local plateau diagnostics and acceptance (cf. eqs. (7.394) to (7.396) and Proposition 7.203). This pre–physical rule mirrors the physical quadrant decision on $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ after Σ–aware realization (cf. Sections 6.10 and 9.5), where law–channel safety and gauge–parameter independence are ensured by the BRST/Nielsen framework and Ward/Slavnov identities evaluated on plateaus (cf. Section 7.5).

Band-limited BRST complex and graded bracket. On the band/IR–tagged multiplet

$$\mathfrak{X}^{(\lambda_{\mathrm{UV}},\ell)} := \Big(\delta\hat{\mathbf{\Phi}}_{\lambda_{\mathrm{UV}},\ell},\, \delta\hat{\mathbf{\Theta}}_{\lambda_{\mathrm{UV}},\ell},\, c_{\lambda_{\mathrm{UV}},\ell},\, \bar{c}_{\lambda_{\mathrm{UV}},\ell},\, b_{\lambda_{\mathrm{UV}},\ell}\Big)^{\mathsf{T}},$$

ghost numbers are assigned by $\mathrm{gh}(\delta\hat{\mathbf{\Phi}}) = \mathrm{gh}(\delta\hat{\mathbf{\Theta}}) = \mathrm{gh}(b) = 0$, $\mathrm{gh}(c) = +1$, $\mathrm{gh}(\bar{c}) = -1$, and the BRST differential $\zeta(\,\cdot\,) := \{\hat{Q}_{\mathrm{BRST}}, \cdot\}$ raises ghost number by $+1$. By construction, the scale tags commute with the BRST charge and channel projectors, so the band functor $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ preserves the BRST complex and its ghost grading (cf. Section 7.2.1 and Definition 7.11). We use the graded commutator $[A,B]_{\pm} := AB - (-1)^{|A||B|}BA$; nilpotency and (Krein-)Hermiticity of $\hat{Q}_{\mathrm{BRST}}$ hold on a common invariant domain stable under the tags, $\hat{Q}^2_{\mathrm{BRST}} = 0$, $\hat{Q}^{\dagger}_{\mathrm{BRST}} = \hat{Q}_{\mathrm{BRST}}$.

Definition 9.50 (Graded bracket and BRST closure)**.** On a $\mathbb{Z}_2$–graded algebra, the graded (super)–bracket of homogeneous A, B with parities $|A|, |B| \in \{0,1\}$ is

$$[A,B]_{\pm} \ := \ AB \ - \ (-1)^{|A|\,|B|}\, BA.$$

An operator (or instrument) $\mathcal{O}$ is *BRST–closed* if $[\hat{Q}_{\mathrm{BRST}}, \mathcal{O}]_{\pm} = 0$, where $\hat{Q}_{\mathrm{BRST}}$ is the odd BRST charge ($|\hat{Q}_{\mathrm{BRST}}| = 1$). If $|\mathcal{O}| = 0$ (even), then $[\hat{Q}_{\mathrm{BRST}}, \mathcal{O}]_{\pm} = [\hat{Q}_{\mathrm{BRST}}, \mathcal{O}]$; if $|\mathcal{O}| = 1$ (odd), the condition reads $\{\hat{Q}_{\mathrm{BRST}}, \mathcal{O}\} = 0$.

Definition 9.51 (Band tag and its parity)**.** Let $P_x(\lambda_{\mathrm{UV}})$ denote the UV projector (ghost number 0) and $K^{(\ell)}_{\mathrm{IR}}$ the causal IR window (ghost number 0). The *band tag* $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\cdot]$ is the linear instrument obtained by composing these even inputs with the observable argument using only parity–preserving operations (algebraic composition, adjunction, and integration). Consequently, $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is *even*:

$$\big|\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\big| = 0.$$

Proposition 9.52 (BRST-closure and naturality of the band tag)**.** *If $P_x(\lambda_{\mathrm{UV}})$ and $K^{(\ell)}_{\mathrm{IR}}$ are BRST–closed and even, i.e.*

$$[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})]_{\pm} = 0, \qquad [\hat{Q}_{\mathrm{BRST}}, K^{(\ell)}_{\mathrm{IR}}]_{\pm} = 0,$$

then:

(i) Closure

$\big[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\big]_{\pm} = 0$ *as an operator identity; in particular* $|\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}| = 0$ *so the bracket is an ordinary commutator here.*

(ii) Naturality

For every (homogeneous) operator $\hat{O}$*,*

$$\big[\hat{Q}_{\mathrm{BRST}},\, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{O}]\,\big]_{\pm} \;=\; \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[\,[\hat{Q}_{\mathrm{BRST}}, \hat{O}]_{\pm}\,\Big].$$

Proof. Recall from Definition 9.50 that $\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(\,\cdot\,) := [\hat{Q}_{\mathrm{BRST}},\, \cdot\,]_{\pm}$ is an *odd graded derivation*: for homogeneous A, B,

$$\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(AB) = \mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(A)\, B + (-1)^{|A|} A\, \mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(B). \tag{9.23}$$

By Definition 9.51, $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is even and is built from the *even, BRST–closed* $P_x(\lambda_{\mathrm{UV}})$ and $K_{\mathrm{IR}}^{(\ell)}$ using only parity–preserving operations (composition, adjunction, linear smearing/integration by even kernels).

Step 1 (UV sandwich). Let $\mathcal{P}_\lambda(\hat{O}) := P(\lambda_{\mathrm{UV}})\, \hat{O}\, P(\lambda_{\mathrm{UV}})$. Since $[\hat{Q}_{\mathrm{BRST}}, P(\lambda_{\mathrm{UV}})]_{\pm} = 0$ and $|P| = 0$, (9.23) yields

$$\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}\Big(\mathcal{P}_\lambda(\hat{O})\Big) = P\, \mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(\hat{O})\, P = \mathcal{P}_\lambda\Big(\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(\hat{O})\Big).$$

Step 2 (IR smearing). Write the IR window as an even kernel $K_{\mathrm{IR}}^{(\ell)}$ implementing an even linear superoperator $\mathcal{K}_\ell$ by smearing/convolution, schematically $\mathcal{K}_\ell(X) = \int K_{\mathrm{IR}}^{(\ell)} \diamond X$, with a parity–preserving bilinear pairing $\diamond$. Since $[\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_{\pm} = 0$ and $|K_{\mathrm{IR}}^{(\ell)}| = 0$, linearity and (9.23) give

$$\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}\Big(\mathcal{K}_\ell(X)\Big) = \int K_{\mathrm{IR}}^{(\ell)} \diamond \mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(X) = \mathcal{K}_\ell\Big(\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(X)\Big).$$

Step 3 (Band tag). By construction $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = \mathcal{K}_\ell \circ \mathcal{P}_\lambda$. Combining Steps 1–2,

$$\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}\Big(\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}(\hat{O})\Big) = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big(\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}(\hat{O})\Big),$$

which is the stated naturality. Taking $\hat{O}$ as a basis of operators implies $\mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}} \circ \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} \circ \mathrm{ad}_{\hat{Q}_{\mathrm{BRST}}}$ as superoperators, hence $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]_{\pm} = 0$. □

Corollary 9.53 (Even case (commutator form))**.** *Under the hypotheses of Proposition 9.52,*

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0, \qquad [\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{O}]] = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big[[\hat{Q}_{\mathrm{BRST}}, \hat{O}]\Big].$$

Proof. Let $\mathrm{ad}_{\hat{Q}}(\cdot) := [\hat{Q}_{\mathrm{BRST}}, \cdot]_{\pm}$ denote the graded derivation (cf. Definition 9.50), and recall from Definition 9.51 that the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is *even*, $|\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}| = 0$. By Proposition 9.52 (closure and naturality in graded form) we have, for every homogeneous $\hat{O}$,

$$\mathrm{ad}_{\hat{Q}}\Big(\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{O}]\Big) = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big(\mathrm{ad}_{\hat{Q}}(\hat{O})\Big) \quad \text{and} \quad \mathrm{ad}_{\hat{Q}}(\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}) = 0, \tag{9.24}$$

as operator identities on a common invariant domain stable under $\hat{Q}_{\mathrm{BRST}}$ and the tag (cf. Section 7.2.1 and Definition 7.11).

Outer (left) bracket becomes an ordinary commutator. Because $|\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}| = 0$ and $|\hat{Q}_{\mathrm{BRST}}| = 1$,

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]_{\pm} = \hat{Q}_{\mathrm{BRST}}\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell} - (-1)^{1\cdot 0}\,\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\hat{Q}_{\mathrm{BRST}} = [\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}],$$

so the first statement in (9.24) yields

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}] = 0.$$

Inner bracket reduces for even (ghost–number zero) observables. On the BRST complex used for diagnostics and EOM in Chapters 7–8, the physical/observable sector and the band–tagged PSR functionals live at ghost number 0 (even parity). Thus for every such $\hat{O}$ we have $|\hat{O}| = 0$, and hence

$$[\hat{Q}_{\mathrm{BRST}}, \hat{O}]_{\pm} = \hat{Q}_{\mathrm{BRST}}\hat{O} - (-1)^{1\cdot 0}\hat{O}\hat{Q}_{\mathrm{BRST}} = \hat{Q}_{\mathrm{BRST}}\hat{O} - \hat{O}\hat{Q}_{\mathrm{BRST}} = [\hat{Q}_{\mathrm{BRST}}, \hat{O}].$$

Using this in the naturality identity of (9.24) gives

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\hat{O}]] = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big([\hat{Q}_{\mathrm{BRST}}, \hat{O}]\Big),$$

where the outer bracket is also an ordinary commutator by the first part.

Domain statement. All equalities hold on the common invariant core for $\hat{Q}_{\mathrm{BRST}}$ specified in Section 7.2.1 and preserved by $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ (see Definition 7.11); by linearity and closability (Chapter 7), they extend to the natural operator domains encountered in the band–tagged constructions of Definition 6.272. This proves the two identities of the corollary. □

Lemma 9.54 (BRST hygiene of band-tagged diagnostics)**.** *If the UV projector $P_x(\lambda_{\mathrm{UV}})$ and the IR window $K_{\mathrm{IR}}^{(\ell)}$ are BRST–closed (ghost number 0), then the band tag $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\cdot]$ descends to the physical sector and physical readouts are gauge–parameter independent. Hence the PSR diagnostics* are *valid inputs to the realization in $H^0(\hat{Q}_{\mathrm{BRST}})$.*

Proof. (i) BRST–compatibility of the band tag. By definition (cf. Definitions 6.280 and 9.10 and eq. (9.2)) and the "tag hygiene" hypothesis $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda_{\mathrm{UV}})]_{\pm} = [\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_{\pm} = 0$ (cf. eq. (7.24)), the band tag superoperator satisfies

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}]_{\pm} = 0,$$

as established in Lemma 9.11. Equivalently, for any local operator $\mathfrak{O}$ of ghost number 0,

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}]]_{\pm} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}\Big([\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}]_{\pm}\Big),$$

i.e. $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ is a chain map for the BRST complex (cf. Definition 9.12).

(ii) Descent to cohomology and the physical projector. Let $\mathsf{P}_{\mathrm{phys}}$ denote the projection onto $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10). If $\mathfrak{O}$ is ghost–number 0 and $\mathfrak{O} \sim \mathfrak{O} + [\,\hat{Q}_{\mathrm{BRST}}, Y]_{\pm}$ in cohomology for some local operator Y of ghost number -1, then by the chain–map property,

$$\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}] \;\sim\; \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}] + [\,\hat{Q}_{\mathrm{BRST}},\, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[Y]\,]_{\pm},$$

so the cohomology class of $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}]$ is well–defined. Hence physical readouts (matrix elements with $\mathsf{P}_{\mathrm{phys}}$ inserted) depend only on the class

$$\big\langle \mathsf{P}_{\mathrm{phys}}\, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}]\, \mathsf{P}_{\mathrm{phys}} \big\rangle,$$

and therefore $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}$ descends to H^0.

(iii) Gauge–parameter independence (Nielsen/Slavnov identities). Variations of the gauge–fixing parameter(s) modify the gauge–fixed generator by a BRST–exact insertion; physical expectations of BRST–closed observables are invariant (Nielsen identities, Ward/Slavnov framework; cf. Section 7.5). Since $\mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\cdot]$ is BRST–compatible and (by construction) ghost–number preserving, for any BRST–closed preimage $\mathfrak{O}$ one has

$$\frac{\partial}{\partial \xi}\big\langle \mathsf{P}_{\mathrm{phys}}\, \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{O}]\, \mathsf{P}_{\mathrm{phys}} \big\rangle \;=\; \big\langle \mathsf{P}_{\mathrm{phys}}\, [\hat{Q}_{\mathrm{BRST}}, \dots]_{\pm}\, \mathsf{P}_{\mathrm{phys}} \big\rangle \;=\; 0,$$

so physical readouts are gauge–parameter independent on plateaus (cf. Section 9.5).

(iv) Application to PSR diagnostics. The law–kernel diagnostic $\mathfrak{L}_{\mathrm{pre}} = \mathfrak{B}_{\lambda_{\mathrm{UV}},\ell}[\mathfrak{L}(\hat{\mathbf{G}}_\Lambda)]$ (cf. Definition 9.44) and the Σ–contrasts built from $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definitions 9.20, 9.22 and 9.45) are band–local, gauge–covariant constructs (transport by $\mathcal{U}$; cf. Definition 9.7 and Proposition 9.6). By Step (i), their band–tagged versions are BRST–compatible; by Steps (ii)–(iii) they define elements in H^0 whose physical readouts are gauge–parameter independent. Thus the PSR diagnostics are valid inputs to the Σ–aware realization map and subsequent evaluation on $\mathcal{H}_{\mathrm{phys}}$ (cf. Section 9.5).

Combining (i)–(iv) proves the claim. □

Proposition 9.55 (Operational visibilities and overlaps)**.** *Prepare two chronogeometric histories with unitary propagators $\hat{U}_0, \hat{U}_1$ generated by band–smeared $\hat{\Sigma}_{\mu\nu}$,*

$$\hat{U}_j \;:=\; \exp\!\Big(-i \int_{\mathcal{X}_q} f^{\mu\nu}_{(j)}(x)\, \hat{\Sigma}_{\mu\nu}(x)\, \mathrm{d}\mu_x \Big), \qquad j = 0, 1,$$

where $f^{\mu\nu}_{(j)}$ are band–supported smearing kernels (cf. Definitions 6.280, 9.10 and 9.20 and eq. (9.2)). In the control–unitary interferometric scheme (holosymmetric overlap), the detection probability at output c for a phase bias φ is

$$p_c(\mathbf{0} \mid \varphi) \;=\; \tfrac{1}{2}\Big(1 + \mathrm{Re}\,\big[e^{-i\varphi}\, \langle \Psi_{\mathrm{RR}} | \hat{U}_1^\dagger \hat{U}_0 | \Psi_{\mathrm{RR}} \rangle\big]\Big), \tag{9.25}$$

with $|\Psi_{\mathrm{RR}}\rangle$ a Holo–State readout vector (cf. Definitions 1.18 and 1.34 and Section 4.19.1). The fringe visibility $V := \big|\langle \Psi_{\mathrm{RR}} | \hat{U}_1^\dagger \hat{U}_0 | \Psi_{\mathrm{RR}} \rangle\big|$ is band–local, gauge/frame covariant (cf. Proposition 9.6 and Definition 9.7) and coincides—up to a normalization constant $C > 0$—with the Σ–visibility Λ^Σ defined in Definition 9.47, i.e.

$$V \;\equiv\; \Lambda^\Sigma \;:=\; 1 - \frac{1}{C}\,\Delta^{\mathrm{pre},\Sigma}, \qquad \Delta^{\mathrm{pre},\Sigma} \in \Big\{ \Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}},\; \Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}} \Big\}$$

(cf. eqs. (9.21) and (9.22)), after calibrating C with the same band and probe set. Phase damping with dephasing factor $\eta \in [0, 1]$ on the control arm multiplies the visibility: $V \mapsto \eta\, V$.

Proof. (i) Band–local, covariant histories. By construction the generators $\int f^{\mu\nu}_{(j)}\hat{\Sigma}_{\mu\nu}$ are band–smeared, hence bounded on the band fibre and covariant under graded transport (cf. Definitions 9.7 and 9.20 and Propositions 9.13 and 9.14). Therefore $\hat{U}_j$ are well–defined unitary operators on $\mathcal{H}_{\mathrm{em}}$ that transform by endpoint conjugation, and their matrix elements in gauge–covariant Holo–States are gauge–invariant (cf. Proposition 9.6 and Section 4.19.1).

(ii) Control–unitary interferometry and overlap formula. In the standard control–unitary scheme (holosymmetric overlaps; cf. Definition 9.47 and Section 4.19.1), the control qubit routes the system through $\hat{U}_0$ or $\hat{U}_1$ and recombines with phase bias φ. Tracing the control in the $\{|c\rangle\}$ basis yields (9.25), with complex fringe amplitude $A := \langle\Psi_{\mathrm{RR}}|\hat{U}_1^\dagger\hat{U}_0|\Psi_{\mathrm{RR}}\rangle$ and operational visibility $V = |A|$.

(iii) Identification with Σ–visibilities via BCH/Duhamel and cumulants. Write $\hat{U}_0 = \exp\!\big(-i\hat{H}_0\big)$, $\hat{U}_1 = \exp\!\big(-i\hat{H}_1\big)$ with $\hat{H}_j = \int f^{\mu\nu}_{(j)}\hat{\Sigma}_{\mu\nu}$, and set $\delta\hat{H} := \hat{H}_0 - \hat{H}_1 = \int \delta f^{\mu\nu}\hat{\Sigma}_{\mu\nu}$ where $\delta f^{\mu\nu} := f^{\mu\nu}_{(0)} - f^{\mu\nu}_{(1)}$ has the same band support. The Baker–Campbell–Hausdorff/Duhamel control on the band gives

$$e^{i\hat{H}_1}e^{-i\hat{H}_0} = \exp\!\Big(-i\,\delta\hat{H} \;+\; \tfrac{1}{2}[\hat{H}_1,-\hat{H}_0] \;+\; \mathcal{O}(\|\delta\hat{H}\|^2)\Big) = \exp\!\big(-i\,\delta\hat{H} \;+\; \hat{R}\big),$$

where $\hat{R}$ is anti–Hermitian and $\|\hat{R}\| = \mathcal{O}(\|\delta\hat{H}\|^2)$ (boundedness from band–smoothing; cf. Definitions 6.280 and 9.10). Hence

$$A = \Big\langle e^{-i\,\delta\hat{H}+\hat{R}}\Big\rangle_{\Psi_{\mathrm{RR}}} = \Big\langle e^{-i\,\delta\hat{H}}\Big\rangle_{\Psi_{\mathrm{RR}}} + \underbrace{\langle\hat{R}\rangle_{\Psi_{\mathrm{RR}}}}_{\text{purely imaginary at } \mathcal{O}(\|\delta\hat{H}\|^2)} + \mathcal{O}(\|\delta\hat{H}\|^3).$$

Expanding (or using the cumulant expansion) for the single operator $\delta\hat{H}$ gives

$$\begin{aligned}\Big\langle e^{-i\,\delta\hat{H}}\Big\rangle_{\Psi_{\mathrm{RR}}} &= 1 - i\langle\delta\hat{H}\rangle_{\Psi_{\mathrm{RR}}} - \tfrac{1}{2}\langle\delta\hat{H}^2\rangle_{\Psi_{\mathrm{RR}}} + \mathcal{O}(\|\delta\hat{H}\|^3)\\ &= \exp\!\Big(-i\,\langle\delta\hat{H}\rangle_{\Psi_{\mathrm{RR}}} - \tfrac{1}{2}\,\mathrm{Var}_{\Psi_{\mathrm{RR}}}(\delta\hat{H}) + \mathcal{O}(\|\delta\hat{H}\|^3)\Big),\end{aligned}$$

with $\mathrm{Var}_{\Psi_{\mathrm{RR}}}(\delta\hat{H}) := \langle\delta\hat{H}^2\rangle_{\Psi_{\mathrm{RR}}} - \langle\delta\hat{H}\rangle^2_{\Psi_{\mathrm{RR}}}$. Choosing the interferometer phase as $\varphi = \langle\delta\hat{H}\rangle_{\Psi_{\mathrm{RR}}} + \mathcal{O}(\|\delta\hat{H}\|^2)$ removes the linear phase. Since $\langle\hat{R}\rangle_{\Psi_{\mathrm{RR}}}$ is imaginary at order $\|\delta\hat{H}\|^2$, it alters only the *phase* at that order; the *magnitude* $V = |A|$ is therefore

$$V = 1 - \tfrac{1}{2}\,\mathrm{Var}_{\Psi_{\mathrm{RR}}}(\delta\hat{H}) + \mathcal{O}(\|\delta\hat{H}\|^3).$$

Now decompose $\delta\hat{H}$ along the quadratic probes: $\delta\hat{H} = \sum_k w_k\,\hat{Q}_x[v_k]$, with band–local weights w_k encoding the smearing and probes (cf. Definitions 9.22 and 9.47). Using the same gauge–invariant, band–local functional $\mathcal{I}$ as in Definition 9.45, calibrate a constant $C > 0$ (fixed by $\{v_k\}$ and $\{w_k\}$) so that $\mathrm{Var}_{\Psi_{\mathrm{RR}}}(\delta\hat{H}) = \frac{1}{C}\Big(\Delta^{\mathrm{pre},\Sigma}\Big)^2$. Therefore

$$V \;=\; 1 - \frac{1}{2C}\Big(\Delta^{\mathrm{pre},\Sigma}\Big)^2 + \mathcal{O}\big(\Delta^3\big), \qquad \Lambda^{\Sigma} := 1 - \frac{1}{C}\,\Delta^{\mathrm{pre},\Sigma}$$

(cf. eqs. (9.21) and (9.22)), and after the (plateau–fixed) calibration, V coincides with Λ^{Σ} up to the stated normalization and higher–order terms (cf. Proposition 7.203 and Lemmas 9.27 and 9.46).

(iv) Phase damping. A dephasing channel on the control with factor $\eta \in [0,1]$ multiplies the off–diagonal coherence of the control state by η; since the fringe term in (9.25) is proportional to this coherence, the visibility scales as $V \mapsto \eta V$ (standard interferometric damping; cf. Section 4.19.1). Band–locality and covariance are unaffected, as the dephasing acts only on the control degree of freedom.

Finally, BRST hygiene of the band–tagged diagnostics ensures these interferometric readouts are valid inputs to realization in H^0 (cf. Lemma 9.54 and Section 9.5). This proves the claim. □

Supporting sources for steps (ii)–(iii): the control–unitary overlap formula is stated in Proposition 5.36 (law–layer visibility as a relational overlap). For BCH/Duhamel control and product formulas, see [457, 116, 91]. The interferometric identification and phase choice are standard in quantum information [287] and connect to fidelity/overlap functionals [357]. For a QIV–layered Duhamel/BCH statement at plateau points, see Proposition 7.616.

Corollary 9.56 (Plateau consistency of the law channel)**.** *On certified plateaus $\mathfrak{P}$, law–channel visibilities satisfy $\left|\Lambda^{\Sigma}_{\mathrm{law}} - 1\right) = \mathcal{O}(\varepsilon_{\mathrm{plat}})$ (Nielsen–safe), hence pre–physical QII decisions (law–symmetric, state–asymmetric) are stable under Σ–aware upgrade to the physical sector.*

Proof. (i) Plateau control and band stability. By the grid diagnostics and acceptance rule for a certified plateau (cf. eqs. (7.394) to (7.396) and Proposition 7.203), all band–local observables vary by at most $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ under $(\lambda_{\mathrm{UV}}, \ell)$–moves within $\mathfrak{P}$. In particular, the Σ–law contrast of Definition 9.45 (and its aggregated version Definition 9.47) obeys

$$\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}(g;x) \;=\; \mathcal{O}(\varepsilon_{\mathrm{plat}}),$$

with continuity furnished by Lemmas 9.27 and 9.46.

(ii) From contrasts to visibilities. By Definition 9.47, $\Lambda^{\Sigma}_{\mathrm{law}} = 1 - \frac{1}{C}\,\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}}$ for a fixed normalization $C > 0$ calibrated on the same band/probe set. Hence,

$$\left|\Lambda^{\Sigma}_{\mathrm{law}} - 1\right| = \frac{1}{C}\,\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}} = \mathcal{O}(\varepsilon_{\mathrm{plat}}).$$

Operationally, the control–unitary interferometric visibility V of Proposition 9.55 coincides with $\Lambda^{\Sigma}_{\mathrm{law}}$ up to this fixed C, so the same plateau bound holds for V.

(iii) Nielsen safety and descent to H^0. The band tag is BRST–compatible (cf. Lemmas 9.11 and 9.54 and eq. (7.24)), so the law–channel readouts descend to $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ with gauge–parameter independence ensured by the Nielsen/Ward–Slavnov identities on plateaus (cf. Sections 6.10, 7.5 and 9.5). Therefore the near–unity bound for $\Lambda^{\Sigma}_{\mathrm{law}}$ persists after realization, i.e. it is Nielsen–safe.

(iv) Stability of the QII decision. The pre–physical quadrant predicate (Definition 9.49) declares QII when $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law}} < \varepsilon$ and $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{state}} > \varepsilon$. By (i)–(iii), upgrading to the physical layer alters the law–channel by at most $\mathcal{O}(\varepsilon_{\mathrm{plat}})$ and does not introduce gauge–parameter drift; by continuity and the plateau acceptance slack (cf. Proposition 7.203), this does not cross the law–threshold. State–channel continuity & band stability (Lemmas 9.27, 9.42 and 9.46) prevent threshold crossing provided the empirical margin exceeds $\mathcal{O}(\varepsilon_{\mathrm{plat}})$. Hence QII decisions are stable under upgrade. □

Remark 9.57 (Why Σ strengthens PSR)**.** The Σ–diagnostics probe both *amplitude curvature* $\hat{g}$ and *phase–flow curvature* $\hat{t}$ within a single operator $\hat{\Sigma} = \hat{g} + \hat{t}$ (cf. Definition 9.20 and eq. (9.4)) via the quadratic probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definition 9.22). Thus the pre–physical contrasts (cf. Definitions 9.45 and 9.47) are intrinsically sensitive to temporal/Nielsen–type effects and to channel mixing handled by the Σ–weighted eigenmode extraction (cf. Propositions 9.36 and 9.39 and Remark 9.41). At the expectation level, $\bar{\Sigma}_{\mu\nu} = \bar{g}_{\mu\nu} + \bar{t}_{\mu\nu}$ fixes the causal cones governing hyperbolicity and response (the Σ–causal viewpoint), sharpening linear–response kernels and Ward/Slavnov checks without altering the BRST/cohomological downstream machinery (cf. Sections 7.5 and 9.5). This unified treatment is strictly stronger than "distances–only'' diagnostics: it preserves all correlator–only conclusions in the appropriate limit (cf. Corollaries 9.30 and 9.40) while adding principled sensitivity to temporal phase–flow and inter–modal couplings (cf. Lemma 9.38 and Proposition 9.29).

Practical decision rule. Compute the pre–physical Σ–contrasts $\Delta^{\mathrm{pre},\Sigma}_{\mathrm{law/state}}$ using the quadratic probe $\hat{Q}_x[v] = v^\mu v^\nu \hat{\Sigma}_{\mu\nu}(x)$ (cf. Definitions 9.20 and 9.22) and the band–local, gauge–invariant functionals $\mathcal{I}$ of Definition 9.45. When multiple probes $\{v_k\}$ are used, aggregate them by the root–sum–square prescription in Definition 9.47, i.e. (9.21), and optionally report the complementary visibilities (9.22). Assign the quadrant label QI–QIV via the Σ–aware predicate of Definition 9.49, and record channelwise (corr/vac/spec) attributions using the triadic split and channel–projected functionals of Proposition 9.48. Finiteness and continuity of all diagnostics are guaranteed on the band by Lemmas 9.27 and 9.46; gauge/frame covariance follows from the graded transport and Fourfold Hermiticity/covariance (cf. Definition 9.7 and Proposition 9.6). On certified plateaus (grid diagnostics and acceptance: eqs. (7.394) to (7.396) and Proposition 7.203), the law channel is Nielsen–flat and descends to $H^0(\hat{Q}_{\mathrm{BRST}})$ by BRST hygiene of the tag (cf. Lemma 9.54); hence the near–unity bound of Corollary 9.56 ensures that law–symmetric (QII) decisions are stable under Σ–aware realization.

Summary of Section 9.4. We defined Σ–based PSR order parameters using band–tagged, graded–covariant operators that integrate amplitude curvature $\hat{g}$ and temporal phase–flow $\hat{t}$ into the single chronogeometric tensor $\hat{\Sigma} = \hat{g} + \hat{t}$ (cf. Definition 9.20 and eq. (9.4)). (i) These order parameters are *finite and robust* on the band: the quadratic probes and their contrasts are well–defined, continuous in probes and tag knobs, and stable under small band deformations (cf. Definitions 9.45 and 9.47 and Lemmas 9.27 and 9.46); covariance is ensured by Definition 9.7 and Proposition 9.6. (ii) They *reduce to the correlator–only scheme* with explicit triadic attribution: choosing $\mathcal{I}$ channelwise yields correlator/vacuum/spectral contributions and collapses to the original correlator distances when the other channels are deactivated (cf. Proposition 9.48 and Corollaries 9.30 and 9.40). (iii) They *feed a QI–QIV predicate* identical in logic to the physical sector's: the pre–physical quadrant rule Definition 9.49 mirrors the BRST–physical decision after Σ–aware realization (cf. Sections 6.10 and 9.5), with the law channel Nielsen–safe on plateaus by Lemma 9.54 and Corollary 9.56. Altogether, the Σ–diagnostics supply band–regular, gauge–covariant, and triad–interpretable inputs that prepare clean, BRST–consistent realization in $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$.

9.5 Realization to the BRST-physical Sector and Spectrum

Definition 9.58 (Certified plateau and Σ-regularity)**.** A *certified plateau* $\mathfrak{P}$ is a nonempty set of band choices $\{(\lambda,\ell)\}$ (cf. Definitions 6.280 and 9.10 and eqs. (7.130) and (9.2)) with the following properties:

(i) Σ-regularity.
The operator Hessians at coincidence exist and are stable on the band, yielding $\hat{g}_{\mu\nu}, \hat{t}_{\mu\nu}$ and $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ (cf. Definition 9.20 and eq. (9.4)). Finiteness and smoothness on the band follow from Spectral Smoothness and Finite Entanglement Capacity (cf. Propositions 9.13 and 9.14 and Remark 9.21).

(ii) Causality/hyperbolicity.
The expectation $\bar{\Sigma}$ admits a Lorentzian projection and defines causal cones that control response (cf. Definitions 6.7 and 9.22 and Remark 9.15).

(iii) Nielsen-flatness.
Physical observables' poles or residues are insensitive to gauge-parameter or fermion scans on $\mathfrak{P}$, i.e. law-channel visibilities are near unity and gauge-parameter independent (cf. Corollary 9.56, Lemma 9.54, Section 7.5, and Proposition 9.55).

(iv) BRST viability.
$Q_{\mathrm{BRST}}^2 = 0$ and $[Q_{\mathrm{BRST}}, \hat{H}] = 0$ on the relevant domains so that projection to $\mathcal{H}_{\mathrm{phys}} = H^0(\hat{Q}_{\mathrm{BRST}})$ is well-defined and consistent with the band tag (cf. Section 6.10, Lemma 9.11, and Remark 9.17).

Plateau certification is effected by the local grid diagnostics and acceptance rule (cf. eqs. (7.394) to (7.396) and Proposition 7.203).

Lemma 9.59 (BRST hygiene of the band map)**.** *If* $[\hat{Q}_{\mathrm{BRST}}, P_x(\lambda)]_\pm = [\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_\pm = 0$ *(cf. Lemma 9.11), then* $[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}]_\pm = 0$*. In particular, band–tagging commutes with BRST cohomology, so BRST–exact signals are removed by the physical projector* $\mathsf{P}_{\mathrm{phys}}$*.*

Proof. Recall the band map (cf. Definitions 6.280 and 9.10 and eq. (9.2))

$$\mathfrak{B}_{\lambda,\ell}[\mathfrak{O}](x) := \int_{\mathcal{X}_q} K_{\mathrm{IR}}^{(\ell)}(x,y)\, P_y(\lambda)\, \mathfrak{O}(y)\, P_y(\lambda)\, \mathrm{d}\mu_y,$$

with all kernels/transport chosen gauge–covariantly (cf. Definition 9.7 and Proposition 9.6). Using the graded Leibniz rule for commutators and the hypotheses $[\hat{Q}_{\mathrm{BRST}}, P(\lambda)]_\pm = 0$, $[\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_\pm = 0$ (tag hygiene; cf. Lemma 9.11), one obtains for any local operator $\mathfrak{O}$ of ghost number 0:

$$\begin{aligned}
[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}[\mathfrak{O}]]_\pm &= \int \Big([\hat{Q}_{\mathrm{BRST}}, K_{\mathrm{IR}}^{(\ell)}]_\pm\, P\, \mathfrak{O}\, P + K_{\mathrm{IR}}^{(\ell)} [\hat{Q}_{\mathrm{BRST}}, P]_\pm\, \mathfrak{O}\, P \\
&\qquad \pm K_{\mathrm{IR}}^{(\ell)} P\, [\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}]_\pm\, P \pm K_{\mathrm{IR}}^{(\ell)} P\, \mathfrak{O}\, [\hat{Q}_{\mathrm{BRST}}, P]_\pm \Big)\, \mathrm{d}\mu \\
&= \int K_{\mathrm{IR}}^{(\ell)}(x,y)\, P_y(\lambda)\, [\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}(y)]_\pm\, P_y(\lambda)\, \mathrm{d}\mu_y \\
&= \mathfrak{B}_{\lambda,\ell}\Big([\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}]_\pm \Big),
\end{aligned}$$

i.e. $\mathfrak{B}_{\lambda,\ell}$ is a chain map for the BRST complex:

$$[\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}]_{\pm} = 0.$$

Thus $\mathfrak{B}_{\lambda,\ell}$ descends to cohomology: if $\mathfrak{O} \sim \mathfrak{O} + [\,\hat{Q}_{\mathrm{BRST}}, Y]_{\pm}$ for some ghost–number -1 operator Y, then

$$\mathfrak{B}_{\lambda,\ell}[\mathfrak{O}] \;\sim\; \mathfrak{B}_{\lambda,\ell}[\mathfrak{O}] + [\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}[Y]]_{\pm},$$

so the class $[\mathfrak{B}_{\lambda,\ell}[\mathfrak{O}]] \in H^0(\hat{Q}_{\mathrm{BRST}})$ is well–defined (cf. Definition 9.12 and Lemma 9.54).

Finally, with $\mathsf{P}_{\mathrm{phys}}$ the projector onto $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10), one has $\mathsf{P}_{\mathrm{phys}}\hat{Q}_{\mathrm{BRST}} = 0 = \hat{Q}_{\mathrm{BRST}}\mathsf{P}_{\mathrm{phys}}$ on the relevant domains. Hence for any ghost–number -1 operator Y,

$$\mathsf{P}_{\mathrm{phys}}\,\mathfrak{B}_{\lambda,\ell}\Big([\,\hat{Q}_{\mathrm{BRST}}, Y]_{\pm}\Big)\,\mathsf{P}_{\mathrm{phys}} = \mathsf{P}_{\mathrm{phys}}[\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}[Y]]_{\pm}\mathsf{P}_{\mathrm{phys}} = 0,$$

so BRST–exact signals are removed by the physical projection. This establishes the claim. □

Definition 9.60 (Σ–realization map)**.** Given any band–tagged pre–physical operator $\hat{X}$, define its Σ–*realization* by

$$\mathcal{U}_{\Sigma}[\hat{X}] \;:=\; \lim_{(\lambda,\ell)\in\mathfrak{P}} \mathsf{P}_{\mathrm{phys}}\,\mathfrak{B}_{\lambda,\ell}[\hat{X}]\,\mathsf{P}_{\mathrm{phys}}, \qquad \text{with } \mathfrak{P} \text{ as in Definition 9.58.} \tag{9.26}$$

Here $\mathfrak{B}_{\lambda,\ell}$ is the gauge–covariant band map built from the UV projector and causal IR window (cf. Definitions 6.280 and 9.10 and eqs. (7.130) and (9.2)), and $\mathsf{P}_{\mathrm{phys}}$ projects onto $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10). BRST hygiene of the tag implies that $\mathfrak{B}_{\lambda,\ell}$ is a chain map, $[\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}]_{\pm} = 0$ (cf. Lemmas 9.11 and 9.59), so (9.26) is well–defined on BRST cohomology and BRST–exact contributions are removed by $\mathsf{P}_{\mathrm{phys}}$. Existence of the limit along the plateau net follows from plateau certification and stability—Σ–regularity and causality/hyperbolicity on $\mathfrak{P}$ together with continuity bounds in the band knobs (cf. Definition 9.58, Lemmas 9.27, 9.42 and 9.46, and Corollary 9.56). Gauge/frame covariance of $\mathcal{U}_{\Sigma}[\hat{X}]$ is inherited from the graded transport and the Hermiticity/covariance of the Fourfold correlator (cf. Definition 9.7 and Proposition 9.6).

Applying (9.26) to the chronogeometric operator field $\hat{\Sigma}_{\mu\nu} = \hat{g}_{\mu\nu} + \hat{t}_{\mu\nu}$ defined by SOT–C^2 Hessians on the band (cf. Definition 9.20 and eq. (9.4)) yields the *physical chronogeometry*

$$\bar{\Sigma}_{\mu\nu}(x) \;:=\; \big\langle \mathcal{U}_{\Sigma}[\hat{\Sigma}_{\mu\nu}(x)] \big\rangle \;=\; \bar{g}_{\mu\nu}(x) + \bar{t}_{\mu\nu}(x), \tag{9.27}$$

with the expectation taken in the physical GNS/Born sense (cf. Definitions 1.18 and 1.34). The resulting $\bar{\Sigma}$ admits the relational/Lorentzian projection and governs Σ–causal response on $\mathcal{H}_{\mathrm{phys}}$ (cf. Definition 6.7, Remark 9.15, and Section 9.5).

Proposition 9.61 (Gauge–parameter independence of $\bar{\Sigma}$ (Σ–Nielsen identity))**.** *Under the conditions of Definition 9.58, one has* $\partial_{\xi,\alpha_{\mathrm{gf}}}\bar{\Sigma}_{\mu\nu}(x) = 0$*. Hence all* $\bar{\Sigma}$*–dependent visibilities and response kernels are gauge–parameter independent on the plateau.*

Proof. Step 0 (realized chronogeometry on a certified plateau). By definition,

$$\bar{\Sigma}_{\mu\nu}(x) = \Big\langle \mathcal{U}_\Sigma\big[\hat{\Sigma}_{\mu\nu}(x)\big] \Big\rangle = \lim_{(\lambda,\ell)\in\mathfrak{P}} \Big\langle \mathsf{P}_{\mathrm{phys}}\, \mathfrak{B}_{\lambda,\ell}\big[\hat{\Sigma}_{\mu\nu}(x)\big]\, \mathsf{P}_{\mathrm{phys}} \Big\rangle,$$

with $\mathcal{U}_\Sigma$ in Definition 9.60, $\mathfrak{P}$ certified by Definition 9.58, and $\hat{\Sigma}_{\mu\nu}$ defined band–locally by SOT–C^2 Hessians (cf. Definition 9.20 and eq. (9.4)). Plateau regularity and band stability (Definition 9.58 and Lemmas 9.27, 9.42 and 9.46) justify interchanging the limit and the gauge–parameter derivatives.

Step 1 (BRST chain–map property of the band tag). Tag hygiene (Lemma 9.11) implies for any ghost–number–0 operator $\mathfrak{O}$:

$$[\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}[\mathfrak{O}]\,]_\pm = \mathfrak{B}_{\lambda,\ell}\Big([\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{O}\,]_\pm\Big),$$

i.e. $[\,\hat{Q}_{\mathrm{BRST}}, \mathfrak{B}_{\lambda,\ell}\,]_\pm = 0$ (cf. Lemma 9.59). Thus $\mathfrak{B}_{\lambda,\ell}$ descends to cohomology and BRST–exact contributions are annihilated by $\mathsf{P}_{\mathrm{phys}}$ (cf. Section 6.10).

Step 2 (Nielsen/Slavnov identity at the operator level). On a certified plateau, BRST viability holds ($Q^2_{\mathrm{BRST}} = 0$ and well–defined domains; cf. Definition 9.58). A change of a gauge–fixing parameter $\theta \in \{\xi, \alpha_{\mathrm{gf}}\}$ deforms the gauge–fixed generator through a BRST–exact variation of the gauge–fixing fermion (standard Nielsen identity; cf. Section 7.5). Equivalently, there exists the band–local Nielsen insertion functional $\mathcal{W}_\theta(\cdot)$ (cf. Definition 9.64) such that for any gauge–covariant, ghost–number–0 observable $\mathfrak{O}$,

$$\partial_\theta\, \mathfrak{O} \;=\; [\,\hat{Q}_{\mathrm{BRST}},\, \mathcal{W}_\theta(\mathfrak{O})\,]_\pm.$$

Applying the band map and using Step 1,

$$\partial_\theta\, \mathfrak{B}_{\lambda,\ell}[\mathfrak{O}] = \mathfrak{B}_{\lambda,\ell}\Big(\partial_\theta \mathfrak{O}\Big) = \mathfrak{B}_{\lambda,\ell}\Big([\,\hat{Q}_{\mathrm{BRST}}, \mathcal{W}_\theta(\mathfrak{O})\,]_\pm\Big) = \Big[\,\hat{Q}_{\mathrm{BRST}},\, \mathfrak{B}_{\lambda,\ell}[\mathcal{W}_\theta(\mathfrak{O})]\,\Big]_\pm.$$

Step 3 (projection to H^0 and gauge–parameter independence). With $\mathsf{P}_{\mathrm{phys}}$ the projector onto $\mathcal{H}_{\mathrm{phys}} := H^0(\hat{Q}_{\mathrm{BRST}})$ (cf. Section 6.10), one has $\mathsf{P}_{\mathrm{phys}}\hat{Q}_{\mathrm{BRST}} = 0 = \hat{Q}_{\mathrm{BRST}}\mathsf{P}_{\mathrm{phys}}$. Therefore for $\mathfrak{O} = \hat{\Sigma}_{\mu\nu}(x)$,

$$\partial_\theta \Big\langle \mathsf{P}_{\mathrm{phys}}\, \mathfrak{B}_{\lambda,\ell}[\hat{\Sigma}_{\mu\nu}(x)]\, \mathsf{P}_{\mathrm{phys}} \Big\rangle = \Big\langle \mathsf{P}_{\mathrm{phys}} \Big[\,\hat{Q}_{\mathrm{BRST}},\; \mathfrak{B}_{\lambda,\ell}[\mathcal{W}_\theta(\hat{\Sigma}_{\mu\nu}(x))]\,\Big]_\pm \mathsf{P}_{\mathrm{phys}} \Big\rangle = 0.$$

Passing to the plateau limit (Step 0) yields $\partial_\theta\, \bar{\Sigma}_{\mu\nu}(x) = 0$, proving the Σ–Nielsen identity for all $\theta \in \{\xi, \alpha_{\mathrm{gf}}\}$.

Step 4 (visibilities and response kernels). Any band–regular functional or kernel that depends on the gauge parameters only through $\bar{\Sigma}$ inherits the same independence: if F is smooth in its tensor argument, then

$$\partial_\theta\, F\Big(\bar{\Sigma}\Big) = \frac{\partial F}{\partial \bar{\Sigma}_{\rho\sigma}}\, \partial_\theta \bar{\Sigma}_{\rho\sigma} = 0.$$

In particular, $\bar{\Sigma}$–based visibilities (operational overlaps/response built from Proposition 9.55 evaluated after realization) and Σ–causal response kernels on H^0 are gauge–parameter independent on $\mathfrak{P}$ (cf. Corollary 9.56 and Section 9.5). □

Definition 9.62 (Relational Levi–Civita and Σ–causality)**.** Let $\bar{\Sigma}_{\mu\nu}$ be the realized chronogeometric tensor obtained from the Σ–realization map (cf. Definition 9.60 and eq. (9.27)) on a certified plateau (cf. Definition 9.58). Denote by $\nabla^{(\mathrm{rel})}$ the torsion–free, $\bar{\Sigma}$–compatible connection (the *Relational Levi–Civita*; cf. Definition 6.7), and by $\bar{g}^{\mathrm{Lor}}$ the Lorentzian projection of the realized metric part $\bar{g}$ (cf. Definition 9.20, eq. (9.4), and Remark 9.15). For any physical quadratic operator $\mathcal{K}_\Psi(\bar{\Sigma})$ (law–kernel built on the physical sector; cf. Definition 9.44 and Section 9.5), the Σ*–causal retarded kernel* is the unique Green function $G^{\mathrm{R}}(x, x')$ supported in the future cone defined by $\bar{\Sigma}$ and satisfying

$$\mathcal{K}_\Psi(\bar{\Sigma})\, G^{\mathrm{R}} = \delta$$

with retarded boundary conditions fixed by $\nabla^{(\mathrm{rel})}$ (cf. Definition 9.22 and Remark 9.15). Gauge–parameter independence of G^{R} on plateaus follows from the Σ–Nielsen identity (cf. Proposition 9.61) and BRST hygiene (cf. Lemma 9.59).
